Due to HSA's predilection for visceral anatomic sites in concert with its metastatic nature, radiation is rarely used. It has been noted anecdotally that significant decreases in bulky disease has followed externally located HSA treated with palliative radiation, but the impact on prolongation of survival has not yet been published.

185 CHAPTER • 185 Bone and Joint Tumors

Julius M. Liptak

Nicole Ehrhart

185.1 PRIMARY APPENDICULAR TUMORS

185.1.1 Canine Osteosarcoma

The four primary bone tumors are osteosarcoma (OSA), chondrosarcoma (CSA), fibrosarcoma (FSA), and hemangiosarcoma (HSA).[1] Liposarcoma, rhabdomyosarcoma, plasma cell tumors (solitary plasmacytoma and multiple myeloma), and lymphoma are also reported to involve bone; however, these tumors more typically involve bone as a secondary process.[1] OSA is the most common primary bone tumor accounting for greater than 85% of all appendicular bone tumors.[1] OSA occurs in the axial skeleton and may occur in extraskeletal tissues, including visceral organs, skin, and mammary glands.

OSA is a tumor of unknown cause. Repetitive injury to the physis has been proposed due to the high incidence of OSA in the metaphyseal region of large breed dogs with late-closing physes, however, recent evidence fails to support this theory.[1,2] Other potential causes include viral transmission and a genetic predisposition.[1,3] OSA has been reported in association with previous fractures, particularly in the femoral diaphysis, and other bone diseases, such as infarcts and bone cysts.[3] Radiation-induced OSA has also been documented and may be associated with protocols involving radiation doses greater than 3.5 Gy per fraction.[1]

185.1.1.1 Signalment

Appendicular OSA is usually a disease of large to giant breeds of dogs.[1] OSA also affects smaller breeds but they are 20 times less likely to develop OSA.[4] Breed predispositions have been reported; however, size, and particularly height, are more important risk factors than breed.[1,5] Neutered dogs, regardless of sex, have a two-fold risk of developing OSA compared with sexually intact dogs.[5] The age distribution at diagnosis is bimodal, with most dogs between 7 and 9 years of age and a smaller population between 1 and 2 years of age.[1,5]

185.1.1.2 Diagnosis

Lameness and localized limb swelling are the most common signs.[1] Pain and lameness are caused by microfractures, disruption of the periosteum with tumor extension, and pathologic fracture.[1] Appendicular OSA occurs in the metaphyseal region of long bones. The thoracic limb is involved 1.7 times more frequently than pelvic limb.[1,6] The distal radius (23.1% of OSA cases) and proximal humerus (18.5%) are the two most common sites for OSA.[1,6] In the hind limb, OSA occurs in the tibia and femur with equal frequency. The femur is the most common site in dogs weighing less than 15 kg.[4]

An orthopedic examination is necessary to localize the source of lameness and differentiate metaphyseal pain from other common orthopedic diseases in large breed dogs, such as osteoarthritis, cranial cruciate ligament rupture, and hip dysplasia. Physical examination and a minimum data base, consisting of hematology, serum biochemistry, and urinalysis, is important to evaluate general health status and ability to tolerate surgery and chemotherapy. Three basic types of OSA exist: (1) endosteal, (2) periosteal, and (3) parosteal.[1,7] Periosteal and parosteal OSA are uncommon and originate from the periosteal surface or, less commonly, the endosteum and medullary canal.[1,7] Endosteal OSA is far more common.[1] Regional radiographs are recommended to establish a tentative diagnosis and differentiate primary bone tumors from other orthopedic diseases. The radiographic appearance of endosteal OSA can range from lytic to blastic and is usually a mixture of both patterns.[1,7] Other characteristic radiographic signs of primary bone tumors include cortical lysis, periosteal proliferation, palisading new bone formation perpendicular to the axis of cortical bone (sunburst effect), periosteal lifting due to subperiosteal hemorrhage (Codman's triangle), loss of the fine trabecular pattern in metaphyseal bone, and pathologic fracture with metaphyseal collapse.[1,7] Appendicular FSA and CSA have a similar radiographic appearance to OSA and cannot be differentiated radiographically. However, classic signalment and radiographic findings are often sufficient for the diagnosis of a primary bone tumor.[1,7]

Differential diagnoses for primary bone tumors include fungal osteomyelitis, especially *Coccidioides immitis* and *Blastomyces dermatitidis*.[1,7] A thorough history is necessary to determine whether the dog lives or has traveled through an area endemic for fungal disease. Dogs with fungal osteomyelitis often have systemic illness and polyostotic bone disease.[1,7] Conversely, dogs with primary bone tumors rarely have systemic illness and bone involvement is usually confined to a single site.[1,7] Bacterial osteomyelitis, atypical bone cysts, and metastatic neoplasia are other potential differential diagnoses.

Bone biopsy can be performed to confirm the diagnosis using closed or open techniques.[8–11] Fine needle aspiration, with or without ultrasound guidance, is a useful, minimally invasive technique to diagnose sarcoma and differentiate primary bone tumors from metastatic disease and fungal osteomyelitis.[8,9] Closed needle-core biopsy, using either a Jamshidi needle or Michele trephine, is invasive and requires general anesthesia.[1] Biopsies should be planned and performed meticulously, preferably by the primary surgeon, so the biopsy does not compromise surgical options.[1] The biopsy should be performed to ensure that the biopsy tract can be excised en bloc with the tumor and unaffected tissues are not contaminated during the biopsy procedure or by postbiopsy hematoma formation.[1] Large core samples can be obtained with a Michele trephine, resulting in a diagnostic accuracy rate of 94%, but the larger bone defect also increases the risk of pathologic fracture.[1,10] Bone biopsies procured with a Jamshidi needle have an accuracy rate of 82%, and the smaller gauge needle decreases the risk of complications and creates a significantly smaller biopsy tract.[11] Two to four biopsies should be collected from the center and periphery of the lesion through a single stab incision in the skin. The risk of pathologic fracture increases if the biopsy needle penetrates both the near and far cortices.[1] Multiple biopsies are preferred to increase diagnostic accuracy because small biopsy samples can be misdiagnosed due to the heterogeneous nature of OSA.[1] Central bone biopsies are recommended because the peripheral aspects of bone tumors often contain reactive bone.[1] After definitive surgery the entire tumor should be submitted for histology to confirm the diagnosis.

Appendicular OSA is a highly aggressive tumor. More than 90% of dogs have micrometastatic disease; however, less than 15% of dogs have clinically detectable metastasis at the time of initial diagnosis[1] Metastasis occurs primarily through hematogenous routes, particularly to the lungs and other bone, although metastasis to the regional lymph node is reported in up to 37% of dogs with OSA.[1,6,9,12] Palpation of regional lymph nodes, thoracic radiographs, and nuclear scintigraphy are essential tools for thorough staging of dogs with a suspected primary bone tumor. The presence of detectable metastatic disease significantly influences the management options for dogs with OSA.[1,13–15] High-detail three-view inspiratory thoracic radiographs, including right and left lateral and ventrodorsal or dorsoventral projections, are required for the diagnosis of pulmonary metastases.[1,7] Lesions of 6 mm diameter or greater can be detected with good-quality radiographs.[1] Computed tomography (CT) provides greater sensitivity to detect lesions less than 6 mm in diameter, but advanced imaging may be cost prohibitive for some clients and has been associated with false-positive diagnoses of metastatic lesions.[1,13] Whole-body bone scintigraphy, using radiolabeled technetium pertechnetate, is highly sensitive for the detection of concurrent skeletal abnormalities, including both primary and metastatic tumors, but is not specific for the diagnosis of neoplasia.[1,14,15] In a recent study a second asymptomatic bone lesion, consistent with metastatic disease, was identified in 7.8% of 399 dogs with OSA.[15] If a suspicious lesion is identified, fine-detail radiographs should be performed of that region. Bone biopsy may be performed for confirmation if radiographic results are equivocal. Alternatively, survey radiographs of the skeleton, consisting of lateral radiographs of long bones and ventrodorsal radiographs of the pelvis, can be used to screen for bone metastases if nuclear scintigraphy is unavailable.[16] When present, metastatic skeletal disease is a negative prognostic indicator. This becomes extremely important for dogs in which limb amputation is planned, because occult skeletal metastases may become clinically symptomatic after surgery, rendering the dog nonambulatory.

185.1.1.3 Palliative Management

Management options for dogs with appendicular OSA are broadly classified into two distinct pathways: (1) palliative-intent or (2) curative-intent. Palliation is indicated for dogs with metastatic disease or when owners do not want to pursue more aggressive treatment options. Palliative therapy is geared toward management of pain and lameness associated with the primary bone tumor but does not improve survival time. Analgesia is the cornerstone for the palliative management of dogs with primary bone tumors (Table 185-1).[17] Nonsteroidal anti-inflammatory drugs (NSAIDS) may initially be sufficient to manage pain and improve quality of life. Cyclooxygenase-1-sparing NSAIDS are preferred as adverse effects are reduced.[17] More potent analgesic drugs, or combinations of drugs, are often required for effective pain relief.[17] These include codeine acetaminophen, partial mu agonists or agonist-antagonists, sustained-release oral morphine, fentanyl patches, and adjunctive drugs, such as N-methyl-D-aspartate (NMDA) antagonists and tricyclic antidepressants.[17] Multiple drug combinations are most efficacious for refractory pain because different aspects of the pain pathway are targeted and result in an additive or synergistic analgesic effect. The median survival time (MST) for dogs with appendicular OSA treated with analgesic drugs alone has not been reported, although anecdotal evidence suggests that 1 to 3 months is a reasonable expectation.

Radiation therapy is effective for palliation of dogs with primary bone tumors. A number of different protocols have been described, most commonly 4 to 10 Gy administered on a 0-7–21 day or monthly protocol.[18–22] These protocols are relatively inexpensive and do not require prolonged hospitalization. Radiation reduces local inflammation, minimizes pain, slows progression of metastatic lesions, and improves

quality of life in dogs with primary and metastatic lesions.[18–23] A 50% to 92% response rate has been reported with the median onset of response 11 to 14 days after initiation of radiation therapy and median duration of response lasting 73 to 130 days.[18–22] The duration of response is significantly improved when less than 50% of bone length is affected by tumor. Proximal humeral OSA has been reported to have the best response.[21,22] Higher cumulative doses, higher intensity of treatment, and the addition of chemotherapy to palliative radiation protocols have been reported to improve response rate and duration of response.[20–22] Palliative radiation therapy is not associated with acute effects and does not negatively influence quality of life.[18–22] The MST for dogs with appendicular OSA treated with palliative radiation is 122 to 313 days.[18–22] Radiopharmaceuticals, such as samarium, have been used for the palliation of primary and metastatic bone lesions but are expensive and, at this time, are not widely available in veterinary medicine.[24,25]

762

763

Table • 185-1 Oral and Transdermal Analgesic Drugs Used for the Palliation of Dogs with Appendicular Osteosarcoma

ANALGESIC DRUG	DOSE	INTERVAL	COMMENTS
NSAIDS			
Carprofen	2.2 mg/kg	12 hr	Idiosyncratic hepatic failure, gastric ulceration, renal failure, lethargy
Deroxicab	1–2 mg/kg	24 hr	Gastric ulceration, renal failure
Etodolac	10–15 mg/kg	24 hr	Gastric ulceration, renal failure
Meloxicam	0.05–0.1 mg/kg	24 hr	Gastric ulceration, renal failure
Ketoprofen	0.5–1.0 mg/kg	24 hr	Gastric ulceration, renal failure, platelet aggregation inhibition
Piroxicam	0.3 mg/kg	48 hr	Gastric ulceration, renal failure
Partial Agonists			
Butorphanol	0.55 mg/kg	1–2 hr	Controlled substance, short duration of activity, ceiling effect of analgesia, sedation, respiratory depression
Opioids Morphine	0.5–1.0 mg/kg	8–12 hr	Controlled substance, sedation, euphoria, bradycardia, vomiting, urine retention, constipation
Fentanyl patch	50 µg/hr (10–20 kg)	72 hr	Controlled substance; variable serum concentration due application site, skin blood flow and
	75 µg/hr (20–30 kg) to	72 hr	temperature, and hydration; correct disposal required because residual dose lethal to humans
	100 µg/hr (>30 kg)	72 hr	
Miscellaneous			
Codeine-acetaminophen	0.5–2.0 mg/kg	6–8 hr	Controlled substance, anemia
Amantadine	3 mg/kg	24 hr	NMDA antagonist
Prednisone	0.5–1.0 mg/kg	12–24 hr	Anti-inflammatory, synergistic activity with opiates, contraindicated with NSAIDs
Amitriptyline	1–2 mg/kg	12–24 hr	Tricyclic antidepressant, alters serotonin and norepinephrine activity

185.1.1.4

Limb Amputation

Limb amputation can be used as palliative therapy and as part of the curative-intent treatment in dogs with primary bone tumors.[1,26,27] Amputation is an effective means of pain control, particularly in dogs with pathologic fracture and lameness unresponsive to analgesic drugs or radiation therapy. Osteoarthritis, neurologic disease, obesity, and large body size have been cited as relative contraindications.[1,26,27] Experience has shown that osteoarthritis, weight, and body size are rarely problematic. The majority of dogs

with OSA are middle-to older-aged, large breed dogs with moderate pre-existing osteoarthritis. They rarely have difficulties after amputation.[27] Dogs with neurologic disease or *severe* clinical osteoarthritis are exceptions, and palliative management or limb-sparing techniques should be considered in these dogs. When thoracic limb amputation is performed, the scapula should be removed. Tumor control, particularly for dogs with proximal humeral OSA, and cosmetic appearance is improved.[1] In the pelvic limb, coxofemoral disarticulation should be performed for dogs with OSA distal to the proximal femur, whereas dogs with proximal femoral OSA should be treated with either en bloc acetabulectomy or subtotal hemipelvectomy to achieve adequate tumor control and minimize the risk of local recurrence. Most dogs are able to ambulate unassisted within 12 to 24 hours after limb amputation. Amputees should be encouraged to ambulate at home by the owners after discharge to speed recovery. Studies have shown that most dogs fully adapt to amputation by 4 weeks after surgery. If the dog was significantly lame from the tumor prior to surgery, full recovery often occurs more quickly than 4 weeks once the painful limb is removed. In addition, a positive attitude by the owners shortens the time to adaptation after amputation.[27] Body weight and thoracic or pelvic limb amputation do not have a significant influence on the time to adaptation after amputation; however, early in the postoperative period, dogs with thoracic limb amputation have greater difficulty in balancing.[27] Behavioral changes, such as increased anxiety and loss of dominance, have also been observed but are relatively uncommon.[27] Complications associated with limb amputation are rare. Intraoperative complications may include hemorrhage, air embolism, and inadvertent thoracotomy (front-limb amputations). Possible postoperative complications include infection and stump recurrence. The survival time of dogs treated with amputation alone is significantly better than with the use of analgesic drugs or palliative radiation therapy.[9] The MST for dogs with OSA treated with limb amputation alone is 103 to 175 days with a 6-month survival rate of 47% to 52%, 12-month survival rate of 11% to 21%, and 24-month survival rate of 0% to 4%.[12,28–31]

763

764

185.1.1.5 Limb-Sparing Surgery

Limb-sparing techniques are becoming more common, despite the success of limb amputation in dogs with primary bone tumors.[1,26,32–42] In fact, the most common reason for performing limb sparing in dogs with OSA is owner reluctance to proceed with amputation. Medical indications for limb sparing include previous amputation of another limb, severe concurrent osteoarthritis, or neurologic disease.[1,26]

Limb-sparing surgery is most successful for dogs with primary bone tumors in the distal radius and ulna.[26,32–34] Limb-sparing surgery for other anatomic locations is often associated with a high complication rate and poor postoperative limb function.[35,36] Candidates for limb-sparing surgery include dogs with tumors confined to the bone, minimal extension into adjacent soft tissue, and involvement of less than 50% of the bone length.[1,26] The extent of bone involvement is most accurately determined using CT scans.[43] Bone involvement is overestimated by radiographs, nuclear scintigraphy, and magnetic resonance imaging (MRI).[43–45] The use of imaging techniques that overestimate the degree of bone involvement may be acceptable because adequate surgical margins and complete resection of the bone tumor may be more readily achieved.[44] Pathologic fractures are a relative contraindication due to soft tissue contamination via hemorrhage and hematoma, although the risk of local tumor recurrence can be reduced by preoperative chemotherapy or radiation therapy.[26]

A number of surgical techniques have been reported to preserve limb function.[1,26,32–42] Marginal resection of the soft tissue component of the bone tumor is common to all techniques. After resection, the osseous defect is traditionally filled with a massive cortical allograft (Figure 185-1), although other options include vascularized ulna grafts, endoprostheses, and segmental bone transport osteogenesis.[1,26,32–42] Arthrodesis of the adjacent joint is often required due to the metaphyseal and periarticular location of appendicular OSA.[1,26] Pancarpal arthrodesis is well tolerated in dogs, but arthrodesis of the shoulder, stifle, and tarsal joints results in poor limb function. Rarely, joint preservation is possible with ulnar or diaphyseal OSA. The limb is placed in a lightly padded bandage postoperatively with dressing changes every 3 to 5 days for 2 to 3 weeks.[1,26] Weight-bearing and range-of-motion exercises can be started immediately postoperatively but should be restricted to leashed walks for the first 4 weeks.[1,26] Exercise is important in preventing flexure contracture of the digits and minimizing swelling of the foot and digits, both of which can occur as a result of resection of the digital extensor muscles and tendons and vascular structures during surgery. Good to excellent limb use is achieved in over 80% of dogs.[1,2,6,32,33]

The most commonly reported complications with limb-sparing surgery are implant failure, local tumor recurrence, and infection.[1,26,32,33,37–39] Implant failure occurs in approximately 10% of cases.[1,26,32,33,37] The injection of methylmethacrylate into the medullary canal of the allograft increases screw pullout strength and reduces the incidence of screw loosening, implant failure, and allograft fracture.[37]

Local tumor recurrence is caused by incomplete resection or, more commonly, residual neoplastic cells in the soft tissue adjacent to the tumor capsule after marginal resection of the primary bone tumor.[1,26] Local recurrence has been reported in up to 28% of cases[33]; however, this rate can be reduced to less than 10% with locally released chemotherapy agents, such as cisplatin from open-cell polylactic acid biodegradable implants, appropriate case selection, and experience.[1,26,38] Local recurrence either has no effect[2] or a negative influence on survival time depending upon the study cited.[35] Local recurrence can be managed with a second limb-sparing surgery, amputation, or palliative radiation therapy.[26]

Figure 185-1 Lateral radiographic projection of limb-sparing surgery of the distal radius using a cortical allograft.

Infection is the most significant postoperative complication encountered with limb-sparing surgery.* The cause of infection is unknown, although the extensive soft tissue resection with vascular compromise to a poorly perfused site, poor soft tissue coverage, implantation of orthopedic implants and nonvascularized and possibly immunogenic cortical bone, and administration of local and systemic chemotherapy are thought to contribute.[26]

Infection occurs in over 40% of limb spare cases where reconstruction is performed with an allograft.[32,33,37,39] Several different bacterial organisms have been cultured with mono-and polymicrobial infections occurring in approximately 50% of cases each.[39] Initially, infections are treated with appropriate antibiotics based on culture and sensitivity results, isotonic saline lavages, and wet-to-dry bandages.[1,39] If the infection is unresponsive or recurrent, antibiotic-impregnated methylmethacrylate beads can be surgically implanted adjacent to the infected bone.[39] Limb amputation may be used as a salvage procedure in dogs with uncontrollable infection.[1,37,39]

185.1.1.6 Radiation Therapy

Radiation therapy is most commonly used for palliation but can be used for control of the primary bone tumor in dogs where surgical options are either not indicated or refused.[46,47] Full-course external beam radiation therapy has been investigated.[46,47] The fractionation and radiosensitization protocols have varied, with total doses ranging between 24 to 54 Gy.[46,47] Complications include moist desquamation, alopecia, depigmentation, bone marrow suppression, and pathologic fracture.[46,47] The MST for dogs with OSA treated with curative-intent radiation therapy and adjuvant chemotherapy (AC) is 7 months.[46,47]

185.1.1.7 Chemotherapy

Definitive management of dogs with appendicular OSA requires treatment of both the local bone tumor and micrometastatic disease. The efficacy of chemotherapy in other types of primary bone tumors is less clear. Surgery, unless combined with chemotherapy, is considered a palliative measure.[28–31,48–54] Conversely, chemotherapy without surgery does not provide a survival benefit over other palliative techniques.[55,56] In most institutions and oncology practices, chemotherapy is initiated at the time of suture removal. Current chemotherapy protocols include the use of cisplatin, carboplatin, and doxorubicin, either as a single agent or in combination (Table 185-2).[1,28–31,48–54] Studies have not shown large differences in survival times between the different protocols using single or multiple agents. Practically speaking, protocol selection is often dependent on drug cost, adverse effects, and intensity of treatment. If cisplatin is used, saline diuresis is necessary to minimize the risk of nephrotoxicity (Table 185-3).[1] Nephrotoxicity can also be reduced by using carboplatin instead of cisplatin or concurrently administering amifostine, which is used to prevent cisplatin-induced nephrotoxicity in humans.[1,42,53,54] Doxorubicin has been associated with myocardial toxicity, particularly with cumulative doses greater than 180 mg/m^2. Hence, an echocardiogram is recommended prior to starting chemotherapy, especially in high-risk breeds.[1]

After administration of chemotherapy, especially after the first chemotherapy dose, dogs should be discharged with antibiotics and antiemetics for palliation of gastrointestinal (GI) disease and nausea if needed at home. Hematology should be performed at the time of nadir, generally 7 to 10 days postchemotherapy, and again immediately prior to subsequent doses of chemotherapy to assess the presence and degree of myelosuppression. Chemotherapy administration should be delayed or the dose decreased if the neutrophil count is less than 2000/μL or platelet count is less than 100,000/μL.[1] The MST for dogs treated with surgery and chemotherapy is 235 to 366 days, with a 33% to 65% 12-month survival rate and 16% to 28% 24-month survival rate.[28–31,48–54]

Table • 185-2 Chemotherapy Protocols Used in the Management of Dogs with Appendicular Osteosarcoma[*†]

AGENT OR AGENTS	DOSE	INTERVAL	NUMBER	COMMENTS
Cisplatin	70 mg/m^2	3 weeks	5	Vomiting during administration, nephrotoxicity, gastrointestinal (GI) toxicity, mild myelosuppression; nadir at 10 days; MST 262–413 days
Carboplatin	300 mg/m^2	3 weeks	4	Myelosuppression, GI toxicity; nadir at 11–14 days; MST 321–366 days
Doxorubicin	30 mg/m^2	2–3 weeks	5	Anaphylaxis during administration, GI toxicity, myocardial toxicity, myelosuppression, nadir at 10 days; MST 366 days
Cisplatin	50 mg/m^2	3 weeks	4	Cisplatin administered on day 1 and doxorubicin on day 2; MST 300–540 days
Doxorubicin	15 mg/m^2			
Carboplatin	300 mg/m^2	3 weeks	6	Carboplatin and doxorubicin administered alternately every 3 weeks for 3 doses each, for a total of 6 doses; MST 388 days
Doxorubicin	30 mg/m^2

† Liptak JM et al: Survival analysis of dogs with appendicular osteosarcoma treated with limb-sparing surgery and adjuvant carboplatin or carboplatin and doxorubicin, *Pers Comm, Proc Vet Cancer Soc Conf* 21:39, 2001.

The role of immunotherapy in the treatment of dogs with OSA is undefined. A significant improvement in disease-free interval (DFI) and survival time has been reported in dogs treated with a nonspecific immunostimulant, muramyl tripeptide phosphatidylethanolamine.[57,58] Increased immune stimulation is also suspected in the prolonged survival times in dogs with infected limb-sparing surgery and four dogs with spontaneous regression of OSA lesions.[53,59]

185.1.1.8 Digit Osteosarcoma

OSA arising in bones distal to the carpus or tarsus are rare.[1,6] Treatment recommendations include limb salvage (i.e., amputation of the affected digit and metacarpal or metatarsal bones) followed by chemotherapy.[1,60] Similar to humans, the prognosis for dogs with OSA distal to the carpus or tarsus is better

than other appendicular sites, with a MST of 466 days.[60] However, the biologic behavior is still aggressive with most dogs euthanatized due to metastatic disease.[60]

185.1.1.9 Metastasis

Metastatic disease is the most common cause of death or euthanasia in dogs with appendicular OSA after definitive treatment.[1] Pulmonary and skeletal sites are most frequently involved, although other metastatic sites include subcutaneous tissue, mediastinum, myocardium, diaphragm, kidneys, spleen, small intestine, spinal cord and brain, and lymph nodes.[1,9,12]

Interestingly, metastatic disease rarely occurs in dogs undergoing palliative, nonsurgical treatment but is the major cause of death in dogs treated with surgery alone, despite the minimal difference in survival time. A recent study, using a mouse OSA model, showed that primary tumor resection enhanced systemic angiogenesis resulting in progression of distant metastatic lesions.[61] The distribution of metastatic lesions depends on the type of treatment. Pulmonary metastases are more common when only the local tumor is ablated, whereas skeletal metastases are more prevalent when chemotherapy is added to the treatment regimen. Pulmonary metastasis accounts for 61% of all metastatic lesions in dogs treated with amputation alone and 26% when treated with amputation and cisplatin.[12,50] In comparison, skeletal metastases develop in 47% of dogs after surgery and postoperative cisplatin.[50]

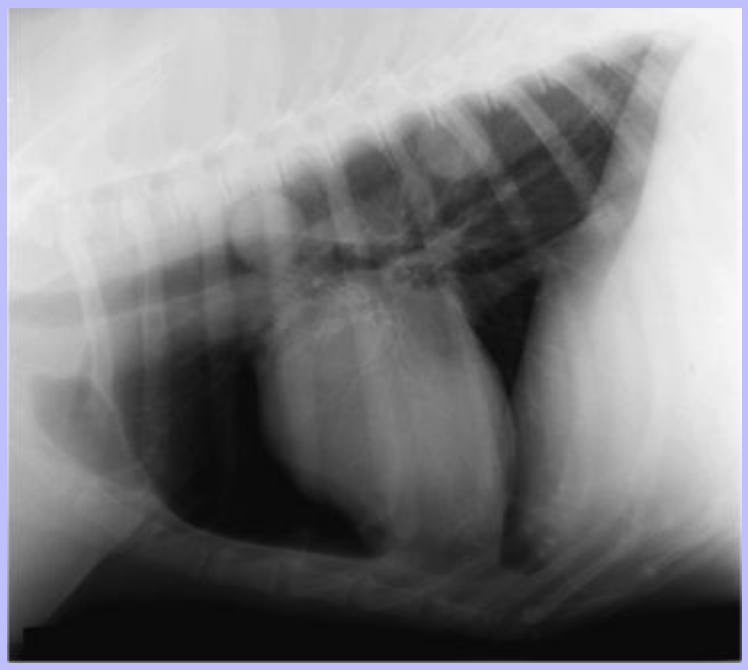
Table • 185-3 Saline Diuresis Protocols Used to Minimize Cisplatin-Associated Nephrotoxicity*

PROTOCOL	PHASE I	PHASE II	PHASE III
6 hr	Saline, 18.3 mL/kg/hr, 4 hr	Cisplatin for 20 min	Saline, 18.3 mL/kg/hr, 2 hr
24 hr	Saline, 3.75 mL/kg/hr, 16 hr	Cisplatin for 16 hr	Saline, 3.75 mL/kg/hr, 6 hr

* Adapted from Dernell WS et al: Tumors of the skeletal system. *In* Withrow SJ, MacEwen EG, editors: *Small animal clinical oncology*, ed 3, Philadelphia, 2001, WB Saunders.

Generalized malaise is the most common sign in dogs with pulmonary metastasis. Respiratory signs are usually a late development (Figure 185-2). Occasionally, hypertrophic osteopathy may be the first indication of pulmonary metastasis. Chemotherapy, using platinum and antibiotic agents, is ineffective in prolonging survival time in dogs with measurable pulmonary metastasis.[62] Surgical resection of metastatic lesions, by either subpleural resection or partial lung lobectomy, can significantly improve survival time in select cases (Figure 185-3).[63] Candidates for pulmonary metastasectomy include dogs that develop pulmonary metastasis greater than 300 days after initial diagnosis of appendicular OSA, have no more than three radiographically evident metastatic lesions, and have lesions that do not double in size or no new lesions that develop in a 4-week period.[63] The MST for dogs with metastasis to the lungs is 61 days when treated with chemotherapy and 176 days after metastasectomy.[62,63]

Figure 185-2 Lateral radiographic projection of a dog 8 months after limb-sparing surgery for a distal radial osteosarcoma (OSA). Two metastatic lesions are seen in the dorsal lung fields.



Management options for dogs with skeletal metastasis include pain control with analgesic drugs, bisphosphonates, and palliative radiation therapy. Bisphosphonates block osteoclast activity, thereby minimizing the risk of pathologic fracture.[6465] Limb-sparing surgery and curative-intent radiation therapy have been used to treat metastatic skeletal lesions for select cases but are not routinely recommended.

185.1.1.10 Prognostic Factors

In dogs with appendicular OSA, a number of factors have been identified as being prognostic. OSA can be histologically subclassified into osteoblastic, chondroblastic, fibroblastic, telangiectatic, and undifferentiated OSA; however, histologic subtype has not been shown to be prognostic in dogs or humans.[1] Poor prognostic factors in dogs with OSA include age less than 7 years and older than 10 years, body weight greater than 40 kg, large tumor volume, proximal humeral location, increased preoperative total and bone-specific serum alkaline phosphatase (ALP) activities and failure to normalize within 40 days of surgical removal of the tumor, high tumor grade, and presence of metastatic disease.[*] Dogs with proximal humeral OSA have a significantly shorter DFI and MST than other appendicular OSA sites; however, this may be a function of tumor volume rather than site.[48] The MST for dogs with normal and elevated total serum ALP is 12.5 and 5.5 months, respectively.[66] The MST for dogs with normal and elevated bone-specific serum ALP is 16.6 and 9.5 months.[66] For both bone-specific and total serum ALP, each increase of 100 IU/L increases the risk of death due to OSA by 25%.[66,67]

185.1.2 Other Canine Appendicular Tumors

185.1.2.1 Chondrosarcoma

CSA is the second most common primary bone tumor in dogs.[1] Appendicular CSA accounts for 9% to 17% of all canine CSA cases.[68–71] The cause is unknown, although CSA has been reported to arise from osteochondroma or sites of previous trauma.

Golden retrievers, German shepherds, and boxers are over-represented, and the median age at presentation is 6 to 8.7 years.[68–71] Clinical findings are similar to dogs with appendicular OSA, and biopsy is required to

differentiate tumor types. The femur is most commonly involved, and CSA may have a more lytic radiographic appearance than OSA.[70,71] Limb amputation and limb salvage procedures can be used to manage the local tumor. Metastatic disease is reported in up to 21% of dogs with CSA but usually occurs late in the course of disease.[68–71] Chemotherapy does not provide a survival benefit in humans with CSA, and a similar situation probably exists in dogs.[72]

Fluoroquinolones may have a role in the management of dogs with CSA because these antibiotics are toxic to chondrocytes and, in in vitro studies, inhibit chondrocytic proliferation and induce chondrocyte apoptosis.[73] The MST for dogs with untreated CSA is 46 days compared with 540 days for dogs treated with limb amputation alone.[71] Prognostic criteria in dogs include tumor location and histologic grade, although these are not well defined.[70,74]

185.1.2.2 Fibrosarcoma

FSA is the third most common skeletal neoplasm in dogs and occurs more commonly in axial than appendicular sites.[69] Two distinct appendicular FSAs exist: (1) central and (2) parosteal.[75] A palpable mass is often present in dogs with parosteal but not central FSA. Parosteal FSA may represent a tumor of soft tissue origin with secondary invasion into bone.[69,75] The radiographic features of appendicular FSA are similar to OSA, although lytic lesions and pathologic fracture are reported in up to 50% of dogs with FSA.[75] Amputation and limb salvage are the main surgical treatment options. The role of AC is unknown. Appendicular FSA metastasizes late in the course of disease, often to sites other than the lungs, such as myocardium, pericardium, skin, and other bones.[75] Survival times are difficult to interpret because more than 50% of fibroblastic OSAs are misdiagnosed as FSA.[1,75] The 12-month survival rate for dogs with appendicular FSA treated with limb amputation alone is 66%.[75]

185.1.2.3 Hemangiosarcoma

HSA is rare and accounts for 3.6% of all primary bone tumors. German shepherd, Great Dane, and boxer dogs are over-represented, with a mean age at presentation of 6.2 to 8.2 years. This is a younger age at presentation than what is reported with most other primary bone tumors.[69] A relatively equal distribution exists between appendicular and axial sites, with 43% of cases occurring in the appendicular skeleton.[69,76] The proximal humerus is the most common appendicular site.[76] Skeletal HSA has a different biologic behavior than other primary bone tumors. The majority of appendicular HSAs have a lytic radiographic appearance. Cortical and periosteal changes may be minimal.[69,76] Polyostotic disease, soft tissue extension, and pathologic fractures are common.[69,76] In dogs with appendicular HSA, abdominal ultrasonography and echocardiography are recommended (in addition to the other standard staging tests), because 82% of dogs are reported with extraosseous disease or metastasis.[76] The value of local and systemic treatment is uncertain because the majority of dogs develop metastatic disease before 6 months and the 12-month survival rate is less than 10%.[69,76] However, limb amputation and doxorubicin-based chemotherapy protocols may be indicated for dogs with nonmetastatic monostotic appendicular HSA.[77] Palliative radiation therapy may be used in dogs with polyostotic disease.

185.1.2.4 Multiple Cartilaginous Exostoses

Multiple cartilaginous exostosis (MCE) is a developmental disease of immature dogs.[78–86] A hereditary predisposition is suspected. The true pathogenesis of MCE in dogs is unknown. Bony lesions in metaphyseal areas near endochondral ossification sites characterize MCE. The lesions can be single (osteochondroma) or multiple.[78–80] They originate at the metaphysis but move away from the physis with progressive longitudinal bone growth.[1] MCEs usually stop growing when dogs reach skeletal maturity. Continued growth beyond skeletal maturity is suggestive of malignant transformation, although continued non-neoplastic growth has been reported.[78–80] Malignant transformation to OSA or CSA of single osteochondromas has been reported.[80–85] A persistent cartilage cap on the apical margins of the MCE has been present in the majority of dogs with malignant transformation and, in humans, where up to 25% of MCE become neoplastic, the potential for malignant transformation can be predicted from the thickness of the apical cap on MRI.[85,86]

The incidence of MCE is difficult to determine because many dogs are clinically asymptomatic. When they occur, clinical signs are caused by interference or compression of adjacent structures, such as the spinal cord, peripheral nerves, or high motion tendons.[78–80] Regional radiographs will reveal a bony mass on the surface of the affected bone.[78–80] The radiographic appearance is consistent with a benign, nonaggressive proliferative process and minimal cortical disruption. Bilaterally symmetrical lesions may be present. The medullary cancellous bone is radiographically and histologically contiguous with the parent bone.[78–80] Epiphyseal bone is nearly never involved.[1,78–80] Vertebral and rib MCE lesions are typically spherical, with a sessile or pedunculated base. Long bone MCE lesions have a more irregular surface.[78–80] The radiographic features of malignantly transformed MCE include an indistinct, poorly mineralized mass with a thickened cartilage cap.[78–85]

Treatment options for MCE vary with age, location, and severity of symptoms. For appendicular lesions, conservative management with analgesic drugs is appropriate until skeletal maturity. Local excision is indicated if the dog is unresponsive to medical management.[1] The entire lesion, including the cartilage cap, should be submitted to ensure accurate histologic interpretation. Neutering is recommended in dogs with MCE due to its possible heritable nature.[1]

The prognosis for dogs with monosteal or bilaterally symmetrical appendicular MCE is good. However, the prognosis for MCE may be guarded when multiple lesions are present. In one review, 38% of dogs were euthanized before 12 months of age due to progressive clinical signs. Malignant transformation of MCE, particularly solitary lesions, was reported in 83% of 6 dogs older than 6 years.[79,80]

185.1.3 Cats

185.1.3.1 Osteosarcoma

Primary bone tumors are uncommon in cats.[87–90] Unlike dogs, 10% to 33% of primary bone tumors in cats are benign.[88] OSA is the most common tumor, accounting for 70% to 80% of all feline bone tumors, whereas FSA, CSA, HSA, and rhabdomyosarcoma have also been reported.[87–89,92] The mean age at diagnosis of

appendicular OSA is 10.2 years, and males are over-represented with a male-to-female ratio of 1.7:1.[88] A number of differences are seen in the presentation and biologic behavior of OSA in cats versus dogs. In feline OSA, bones of the pelvic limb are involved 1.6 times more frequently than the thoracic limb.[88] The proximal humerus is the most common site, closely followed by the distal femur and proximal tibia.[87–91] The radiographic features of primary bone tumors in cats are similar to dogs, although lytic and juxtacortical lesions are more common.[87,88,90,91] Metastasis is uncommon and is diagnosed in less than 10% of cats with OSA.[87–91] Metastatic sites include lungs, brain, liver, kidneys, and spleen. Due to the infrequency of metastatic disease, limb amputation without chemotherapy is recommended for the treatment of cats with appendicular OSA. The MST after limb amputation alone is reported to be 11.8 to 49.2 months.[87,88,90,91]

185.1.3.2 Other Feline Appendicular Tumors

FSA and CSA have a similar biologic behavior to OSA (Figure 185-4). Limb amputation may be curative although metastatic disease has been reported for both tumor types.[87,88]

185.2 PRIMARY AXIAL TUMORS

185.2.1 Canine Osteosarcoma

OSA of the axial skeleton accounts for 25% of all OSA and 59% of OSA in dogs weighing less than 15 kg.[4,93] However, medium to large breed dogs are commonly affected.[93,95] Boxers may be over-represented, and a female predisposition is reported for all axial sites except the ribs and vertebrae.[93,94] The most common sites of axial OSA, in order of frequency, are mandible (27% of axial OSA), maxilla (16% to 22%), vertebrae (7% to 15%), scapula (13%), skull (11% to 12%), ribs (10% to 11%), nasal and paranasal sinuses (9%), and pelvis (4% to 5%).[93,94] OSA of the hard palate and patella have also been reported.[96,97]

Figure 185-4 Juxtacortical chondrosarcoma (CSA) of the proximal humerus of a cat.

Advanced imaging, particularly CT scans, are useful for staging and surgical planning of tumors of the axial skeleton. Surgical resection is recommended although radiation therapy can also be used for control of the local tumor.[93–95] Local recurrence is reported in up to 80% of dogs, and the metastatic rate varies between 11% to 46%.[93–95] Local recurrence, rather than metastasis, is the most common cause of death and chemotherapy has not been shown to improve metastatic rate or survival time.[93–95,98–103]

Overall, the MST for dogs with axial OSA is 120 to 154 days, with a 12-and 24-month survival rates of 26.3% and 18.4%, respectively.[93–95] Prognostic factors include anatomic site, body size, breed, and surgical margins.[94,95,98–103] Smaller breed dogs have a significantly better survival than large breed dogs.[94] The MST of golden retrievers with axial OSA is 100 days, compared with 182 days in pure bred dogs and 264 days in mixed-breed dogs.[95] Mandibular OSA has a better prognosis than OSA of the ribs, scapulae, and skull.[94] The MST after palliative and curative-intent radiation therapy of axial OSA in large breed dogs is 79 and 265 days, respectively.[95] Incomplete surgical resection significantly increases the risk of local recurrence and metastasis.[98–103]

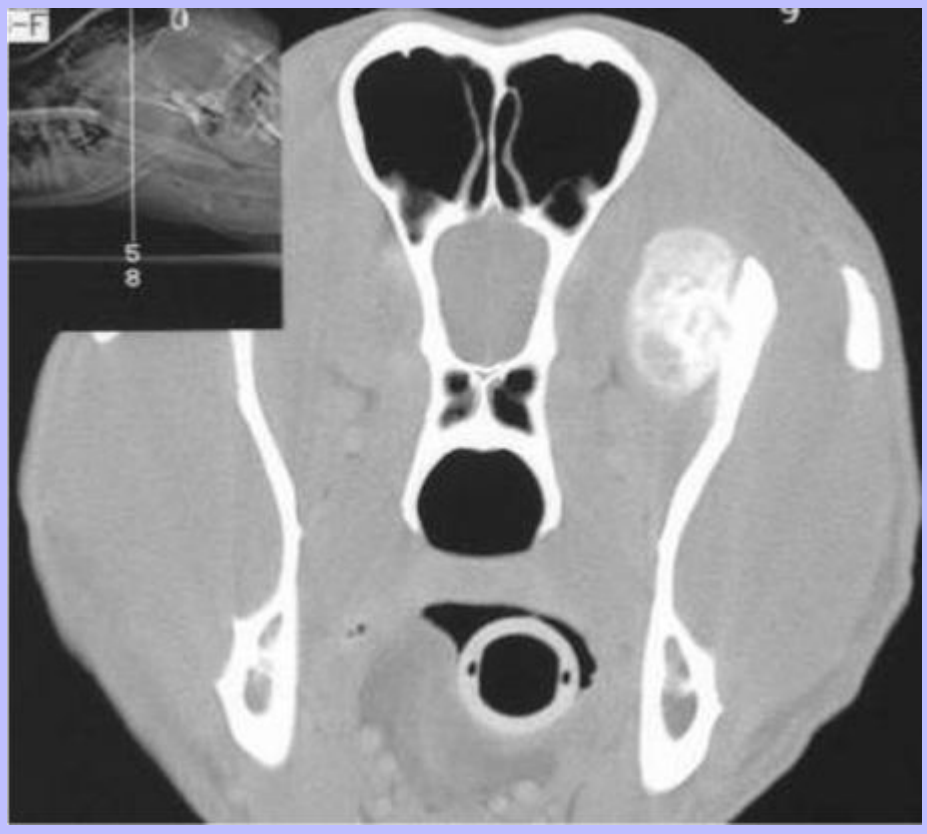
185.2.2 Skull Tumors

OSA of the skull can involve the calvarium, nasal and paranasal sinuses, maxilla, and mandible. Calvarial OSA accounts for 11% to 12% of axial OSA.[93,94] Signs include a visible external mass and neurologic signs due to extradural compression of the brain. Direct invasion of the brain is rare.[1] Surgical resection is recommended after CT imaging. Intra-and postoperative complications include cerebral edema, brain herniation, pneumo-meningocoele, aspiration pneumonia, and death.

Axial OSA may also involve the maxilla and mandible; however, it is less common than the other tumors affecting these bones. The most common canine oral tumors are malignant melanoma, squamous cell carcinoma, FSA, OSA, and the benign epulides.[98–102] In the majority of these tumors, except for OSA, mandibular and maxillary bone is secondarily involved by tumor invasion.[98–102] Signs include a visible mass, halitosis, ptyalism, exophthalmos, and jaw pain; eating difficulties and dyspnea are also reported.[98–102] Regional radiographs are sufficient for local staging of most mandibular tumors, although CT imaging is recommended for tumors of the vertical mandibular ramus (Figure 185-5) and maxilla. Surgical resection (i.e., mandibulectomy, maxillectomy) provides the best opportunity for local tumor control. Postoperative cosmesis is usually excellent.[98–102]

The most common cause of death in dogs with axial OSA is local tumor recurrence rather than metastasis. Metastasis is reported in up to 30% of skull OSA. The MST for mandibular OSA treated with mandibulectomy is 7 to 18 months with a 12-month survival rate of up to 71%.[98–100] Histologic grade and score are predictive of survival in dogs with mandibular OSA.[100] In contrast, the MST for maxillary OSA treated with maxillectomy is 4.5 to 10 months, with a 12-month survival rate of 17% to 27%.[101,102] Aggressive surgical excision, with complete histologic resection, results in a significant improvement in local recurrence and survival rates, with a reported MST greater than 1503 days.[103] Postoperative radiation therapy and chemotherapy have not been shown to provide a survival benefit, even in dogs with incomplete tumor resection.[95,103]

Figure 185-5 Sagittal computerized tomographic (CT) image of a grade III multilobular osteochondrosarcoma (MLO) of the vertical ramus of the mandible. Complete resection was performed with a caudal mandibulectomy and the dog is alive and disease free 308 days postoperatively.



185.2.3 Scapular Tumors

Scapular OSA is relatively uncommon and accounts for up to 13% of all axial OSA.[69,93–95] CSA, FSA, and HSA have also been reported to involve the scapula.[70,104–106] Lameness is the most common clinical sign. Radiographic changes are consistent with appendicular OSA, with a mixed pattern of lytic and productive changes most common.[104] However, due to positioning difficulties and superimposition of the body wall, the extent of disease may be difficult to determine. CT imaging is helpful to determine the location and extent of scapular involvement. Surgical resection (partial scapulectomy) is recommended with good to excellent limb function after subtotal scapulectomy of up to 90% of the scapula.[104,105] Because a high metastatic rate has been reported in dogs with scapular OSA, postoperative chemotherapy is recommended.[93,94]

185.2.4 Pelvic Tumors

OSA of the pelvic bones accounts for 4% to 6% of axial OSA.[69,93,94] Pelvic FSA, CSA, and OSA occur at relatively equal frequencies.[68,70,71,107] Boxer dogs may be predisposed to pelvic CSA.[68] Lameness is common, although tenesmus, due to compression of the rectum, and neurologic deficits, as a result of peripheral nerve compression, have also been observed. Radiographic abnormalities are similar to appendicular OSA (Figure 185-6). CT imaging is helpful for local staging and surgical planning. Surgical resection, with either subtotal or total hemipelvectomy, is the recommended treatment for dogs with pelvic tumors.[107] If necessary, the lateral third of the sacrum, lateral to the dorsal sacral foramina, can be resected en bloc with the affected pelvis. Limb salvage is possible if the weight-bearing axis can be preserved by internal hemipelvectomy. Chemotherapy is recommended for dogs with pelvic OSA because their biologic behavior is similar to appendicular OSA with a high metastatic rate.[107] However, the metastatic rate of pelvic FSA and CSA is low and chemotherapy is probably not required.[107]

185.2.5 Rib Tumors

Rib tumors are uncommon and reported tumor types include OSA, CSA, FSA, HSA, multilobular osteochondrosarcoma (MLO), and mast cell tumor.[1,93–95,108,109] OSA is the most common rib tumor accounting for 73% of rib tumors and 11% of axial OSA.[93,94,108,109] No breed or sex predispositions have been reported, but rib tumors tend to occur in younger, large breed dogs with a mean age of 4.5 to 6 years.[93–95,108,109]

Rib tumors usually occur in the distal third of the rib adjacent to the costochondral junction.[108,109] A palpable firm and fixed mass is the most common clinical sign, although pain and dyspnea are also reported. Radiographic changes include lysis, sclerosis, or a mixture of lytic and blastic patterns, with displacement of adjacent ribs and intrathoracic structures, such as the heart and lungs, and medial displacement of the parietal pleura resulting in an extrapleural sign (Figure 185-7).[108,109] Intrathoracic extension and invasion of adjacent pericardium and lung lobes are relatively common. Pulmonary metastasis is common, particularly with telangiectatic OSA, and up to 45% of dogs with rib OSA have metastatic disease at diagnosis.[108,109] Metastasis was detected in 100% of dogs with rib OSA, 53% to 57% with CSA, 67% with HSA, and 100% of dogs with rib FSA at the time of death.[108,109] Due to the similar biologic behavior of rib and appendicular OSA, rib OSA should be treated with rib resection and postoperative chemotherapy. The role of chemotherapy in other tumor types is undefined but warrants consideration due to the high metastatic rate.

Tumor type and surgical margins are prognostic. The MST after rib resection alone for OSA and CSA is 90 and 1080 days, respectively.[108,109] Completeness of surgical margins is an important prognostic indicator. Dogs with incomplete excision are 5.6 times more likely to develop local recurrence and possibly metastatic disease.[109] In dogs with rib OSA, postoperative treatment with chemotherapy extends the MST to 240 days.[109]

185.2.6 Vertebral Tumors

OSA is the most common extradural tumor of the nervous system and accounts for up to 16% of axial OSA.[93,94,110,111] Other vertebral tumors include CSA, FSA, HSA, MCE, lymphoma, liposarcoma, giant cell

tumor, plasma cell tumors, either as solitary plasmacytoma or multiple myeloma, and metastatic carcinomas and sarcomas.[110,111] A breed predisposition has not been reported, although German shepherd dogs, Labrador retrievers, and standard poodles were over-represented in one study.[110] Large breeds are commonly affected. Only 5% of dogs with vertebral tumors weighed less than 20 kg.[110,111] Primary vertebral tumors tend to occur in a younger subset of dogs than metastatic tumors of the vertebrae. The median age for dogs with primary vertebral tumors is 6 to 8 years and 8 to 9 years for secondary tumors.[111] A thorough physical examination should be performed to identify possible occult primary tumors. Carcinomas of the mammary and thyroid glands, bladder, and prostate, and visceral HSA are known to metastasize to the vertebrae. Thoracic and lumbar vertebrae are most commonly involved.[110]

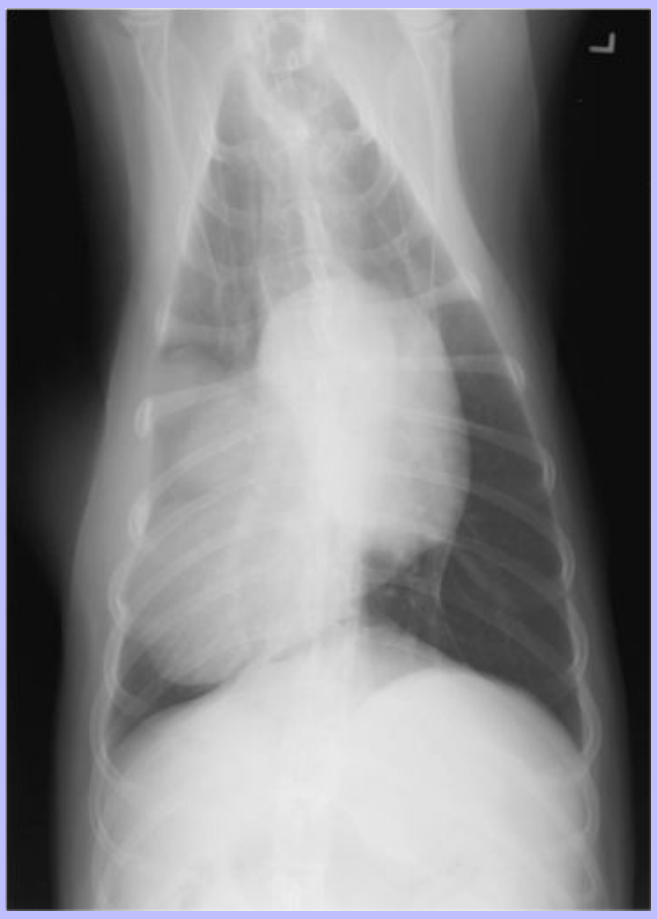
769
770

Figure 185-6 Ventrodorsal radiograph of a grade I chondrosarcoma (CSA) of the right ilium. The reader should note the large tumor volume and compression rather than invasion of the transverse processes of the sixth and seventh lumbar vertebra. Hemipelvectomy was performed, and the dog is alive and disease free 516 days postoperatively.

Pain and neurologic deficits are the two most common signs in dogs with vertebral tumors.[110,111] Neurologic deficits are caused by compression of nerve roots or the spinal cord.[110,111] Neurologic signs are typically slowly progressive, but pathologic fracture will cause an acute deterioration in neurologic function. A neurologic scoring system has been devised and is prognostic for outcome and survival.[111]

A spectrum of radiographic changes is observed in dogs with vertebral tumors. These changes can be difficult to detect due to inconsistent vertebral shape and superimposition of overlying ribs and soft tissue.[110] Cortical lysis with vertebral body collapse is a characteristic finding in primary vertebral tumors but a late event in metastatic tumors.[110,111] Skip and multiple tumors are reported in up to 25% of dogs with vertebral OSA and can be difficult to differentiate from metastatic tumors.[110] Osteochondromas and MCE are well-circumscribed benign lesions that frequently involve the dorsal spinal elements, such as the dorsal lamina and spinous process, rather than the vertebral body.[78,79] Other imaging techniques include myelography, CT and MRI, and nuclear scintigraphy.

Figure 185-7 Ventrodorsal radiograph of an osteosarcoma (OSA) of the seventh rib is displacing the heart and caudal lung lobes to the left side.



Nuclear scintigraphy can be beneficial in identifying the location of single and multiple lesions but cannot differentiate multifocal OSA from multiple metastatic lesions. Furthermore, most plasma cell tumors are photophenic due to marked osteo-lysis and minimal new bone production. Myelographic changes include collapse of the subarachnoid space and unilateral or asymmetric displacement of the spinal cord.[110] Advanced imaging provides the most accurate information for evaluating the degree of vertebral involvement but differentiating intra-and extradural involvement can be difficult.[112]

Surgical resection, with vertebrectomy, is rarely feasible, although dorsal decompression can provide meaningful palliation in dogs with localized dorsal tumors.[111,113] Radiation therapy, either with palliative-or curative-intent, can be beneficial in dogs with vertebral tumors.[111] The role of chemotherapy is unknown, even in dogs with vertebral OSA, because most dogs are euthanatized due to the local tumor rather than metastatic disease.[111]

770

771

Overall, the MST for dogs with malignant vertebral tumors is 135 days.[111] Survival time is not significantly influenced by preoperative neurologic score, tumor type (OSA or FSA), primary or metastatic disease, anatomic location (cervical, thoracic, or lumbar), chemotherapy, or radiation therapy.[111] Although not significant, neurologic score can provide useful information as dogs with a preoperative score of 1 had a survival time of 330 days compared with 120 days if the neurologic score was greater than 1.[111] Furthermore, dogs with a posttreatment neurologic score of 1 or 2 were 12 times more likely to survive than dogs with posttreatment score of 3 or 4.[111] Curative-intent radiation therapy provides a significant improvement in survival time when compared with palliative radiation, with survival times of 150 and 15 days, respectively.[111]

185.2.7 Nasal and Paranasal Tumors

Adenocarcinoma is the most common tumor of the nasal and paranasal sinuses.[114–116] Sarcomas, such as CSA and OSA, are uncommon.[68–71,93–95,114–116] Dolichocephalic breeds are predisposed, particularly if living in an urban environment with exposure to smoke. Nasal and paranasal tumors, regardless of tumor type, are characterized by local invasiveness and a low metastatic rate, although up to 50% of dogs have metastasis to the regional lymph nodes and lungs at necropsy.[114–116] Unilateral epistaxis is the most common sign. Other less frequent signs include sneezing, dyspnea, stertorous respiration, facial deformity, and seizures.[114–116] Advanced imaging is recommended for local staging and determination of the caudal extent of the tumor in relation to the cribriform plate. Unlike tumors of other axial and appendicular sites, nasal and paranasal tumors are usually not amenable to surgical resection. Full-course fractionated radiation therapy is the recommended treatment resulting in a MST of 424 to 580 days.[114–116] An improved survival time is seen when radiation is combined with radiation sensitizers, such as local or systemic cisplatin.[114]

185.2.8 Other Canine Axial Tumors

185.2.8.1 Multilobular Osteochondrosarcoma

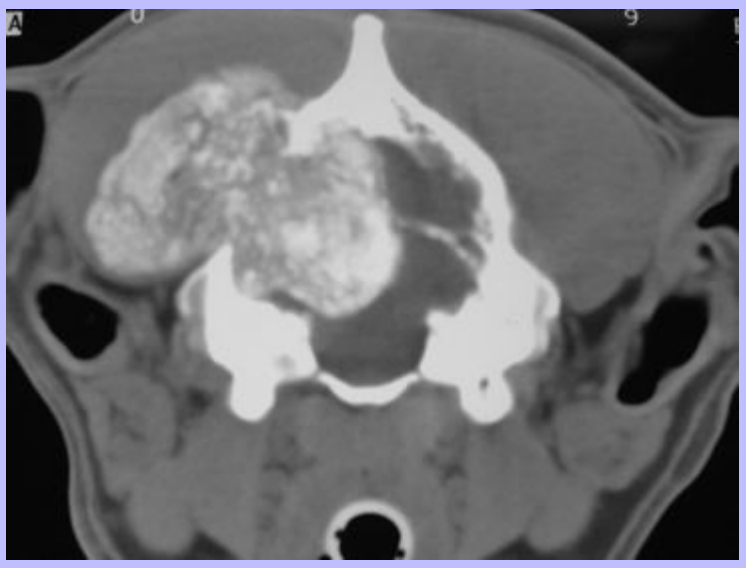
MLO is an uncommon tumor arising from the periosteum of bones formed by intramembranous ossification.[117,118] The skull is most commonly involved, including the calvarium, orbit, zygomatic arch,

mandible, and maxilla.[117,118] Other sites include the pelvis, ribs, and hard palate. Cats have also been reported with MLO.

MLO is usually a disease of middle-aged, large breed dogs.[117,118] No known sex or breed predisposition exists. Clinical signs are dependent on tumor location and include a palpable firm and fixed mass, neurologic signs with calvarial MLO, pain on opening of the jaw with mandibular and zygomatic arch MLO, exophthalmos with orbit MLO, and dyspnea with MLO of the tympanic bulla.[117,118] The imaging changes associated with MLO are characteristic with the tumor described as having a popcorn appearance with well-defined borders and a lobulated pattern on both radiographs and CT scans.[117–120] Advanced imaging is indicated for surgical planning of calvarial MLO because the extent of intracranial involvement can be extensive (Figure 185-8).[119,120]

Treatment options include surgical resection and radiation therapy.[117,118] Cranioplasty, using either allografts or bone cement, has been described after calvarial resection but is probably unnecessary. Neurologic recovery, particularly with marked intracranial involvement, can be prolonged, although the majority of dogs will return to normal function within 2 weeks. MLOs have a slow growth rate, and this would usually result in a relative resistance and poor response to radiation therapy. Although not well investigated, good responses have been reported using external beam radiation therapy and radiopharmaceuticals.[118]

Figure 185-8 A sagittal computerized tomographic (CT) image of a grade I multilobular osteochondrosarcoma (MLO). The reader should note the characteristic popcorn appearance of the mass and significant intracranial involvement.



A histologic grading scheme for MLO is prognostic for local recurrence and metastasis.[117] Other prognostic factors include site and completeness of surgical resection.[117,118] The overall rate of local recurrence is 47%

to 58%, with a median DFI of 426 to 797 days, although this rate varies with histologic grade.[117,118] The local recurrence rate for grade I MLO is 30%, grade II is 47%, and grade III is 78%.[117,118] Furthermore, an aggressive surgical approach is recommended because incomplete resection significantly increases the risk of local recurrence. The median DFI after incomplete resection is 330 days, but median DFI was not reached and greater than 1332 days with completely resected MLO.[117,118]

Metastasis is reported in up to 58% of dogs with MLO. The lungs are the most common metastatic site, accounting for 90% of cases, although other sites include brain, pancreas, kidneys, mediastinum, and ribs.[117,118] Surgical margins and histologic grade are prognostic for the development of metastatic disease.[118] Metastasis is diagnosed in 25% of dogs after complete resection and 75% of dogs with incompletely resected MLO.[118] The metastatic rate for grade I MLO is 30%, grade II MLO is 60%, and grade III MLO is 78%.[118] The MST after diagnosis of recurrent or metastatic disease is 239 days, and many dogs with pulmonary metastasis from MLO are good candidates for pulmonary metastasectomy.[117,118]

The MST for untreated MLO is 24 days compared with 669 to 797 days for surgically resected MLO.[117,118] Tumor site is prognostic with mandibular MLO having a significantly better MST than other sites, with 1487 days for mandibular MLO and 528 days for nonmandibular MLO.[118] The MST for grade I MLO is greater than 897 days, whereas the MST for grade II and III MLO is 520 and 405 days, respectively.[118]

185.2.8.2 Osteoma

Osteomas account for 6% of all primary bone tumors in cats and dogs.[1,69,87] Osteomas are formed by intramembranous bone and occur in the axial skeleton, particularly the skull. A palpable, nonpainful mass is usually present and appears as well-circumscribed dense bony projections on regional radiographs. Osteomas have similar histologic features to reactive bone. Surgical resection is recommended for problematic or uncosmetic lesions.[1]

185.2.9 Cats

185.2.9.1 Osteosarcoma

771 772

OSA is the most common tumor of the feline axial skeleton.[87,91] FSA and CSA are also reported to involve the axial skeleton.[87,88] The mean age at presentation for cats with axial OSA is 10.4 years, which is significantly older than cats with appendicular OSA.[91] The skull and pelvis are frequently affected, although other sites include ribs, vertebrae, and scapulae.[87–91] The presenting signs, radiographic features, and treatment recommendations are similar to malignant canine axial tumors. Periosteal new bone formation and juxtacortical tumors are more common in cats with axial OSA.[87,90] Complete surgical resection is complicated by tumor location, resulting in incomplete resection and poor tumor control. The MST for cats with axial OSA is 5.5 to 6.1 months, with most euthanized due to local recurrence rather than metastatic disease.[90,91]

185.2.9.2 Feline Multiple Cartilaginous Exostosis

In contrast to dogs, feline MCE develop after skeletal maturity, appendicular skeletal involvement is rare, and the majority have a viral or familial cause.[88] The mean age at diagnosis is 3.2 years.[88] A sex or breed predisposition is unlikely, although Siamese were over-represented in early reports.[1] The vast majority of cats with MCE are positive for feline leukemia virus (FeLV).[1,88] In these cats the disease is rapidly progressive with firm, painful swelling of axial sites such as the scapula, vertebrae, and ribs. Radiographically, feline MCEs appear as sessile or pedunculated masses arising from the surface of affected bones with bony lysis and loss of smooth bony contour.[1,88] Surgical resection is indicated for painful lesions, although complete resection is difficult, because the cartilage caps tends to infiltrate adjacent tissue and local recurrence is common.[1,88] Malignant transformation and metastasis are also possible.[88]

185.3 METASTATIC BONE TUMORS

Metastatic bone tumors are infrequently diagnosed in cats and dogs. Metastasis usually occurs via the hematogenous route. In dogs, urogenital carcinomas, particularly bladder and prostate, are the most common primary tumors to metastasize to bone.[4,121] Skeletal metastasis is also reported in dogs with OSA, mammary carcinoma, thyroid carcinoma, pulmonary carcinoma, nasal carcinoma, apocrine gland anal sac adenocarcinoma, and renal tumors.[1,4,121–124] Metastatic lesions represent 24% of all bone tumors in dogs weighing less than 15 kg and only 5% in large breed dogs.[1,4,123] The most common metastatic sites are the axial and proximal appendicular skeleton with less than 11% of dogs having metastatic lesions distal to the elbow or stifle.[121] In contrast, acrometastasis involving one or more digits is the most common presentation for cats with metastatic pulmonary carcinoma.[122–125]

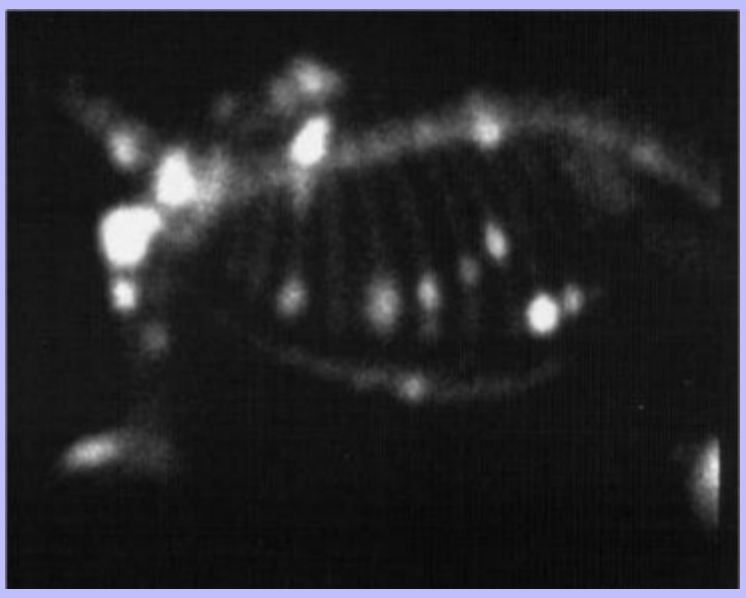
Nuclear scintigraphy is recommended for the identification of multiple bone lesions (Figure 185-9). Treatment options for skeletal metastasis include surgery, radiation therapy, and pharmaceutical agents.[64] Surgical curettage and stabilization of metastatic lesions is uncommonly performed in veterinary medicine but may provide a meaningful response in select cases. Radiation therapy is indicated for management of pain and inflammation.[22]

185.4 PRIMARY JOINT TUMORS

185.4.1 Dogs

Joint tumors are usually primary and malignant.[126–130] Previously, synovial cell sarcoma was considered the most common tumor of the canine joint.[126,127] However, recent evidence suggests that other soft tissue sarcomas of periarticular tissue are more prevalent and immunohistochemistry (IHC) is required to differentiate these tumor types.[128,129] Other reported joint tumors include histiocytic sarcoma and malignant fibrous histiocytoma, synovial myxoma and myxosarcoma, OSA, FSA, CSA, HSA, liposarcoma, rhabdomyosarcoma, and undifferentiated sarcoma.[1,128,129]

Figure 185-9 Nuclear scintigraphy of a dog with prostatic transitional cell carcinoma. The reader should note the numerous metastatic lesions in the proximal radius, proximal humerus, cervical and thoracic vertebrae, ribs, and sternum.



Synovial cell sarcomas are malignant tumors arising from mesenchymal cells within tenosynovial tissue of joints, bursa, and tendon sheaths.[126] The stifle, elbow, shoulder, carpal, tarsal, and hip joints are most commonly involved, in decreasing order.[1,126] The mean age at presentation is 6 to 8 years, and a sex and breed predisposition has been reported.[126–130] Males are over-represented and flat-coated retrievers are predisposed.[26–130] Metastasis to the regional lymph nodes and lungs is reported in up to 32% of dogs at diagnosis and in 41% to 54% of dogs during the course of disease.[126–130]

185.4.1.1 Diagnosis

Typically, dogs have lameness, joint pain, and synovial effusion. Dogs with suspected joint tumors should be staged with palpation of regional lymph nodes and regional and three-view thoracic radiographs. Regional radiographs will often reveal a soft tissue opacity adjacent to the affected joint. Mineralization of the soft tissue mass is occasionally seen in humans but rarely in dogs. Bone involvement is observed in 11% to 100% of cases and can either be smooth and well delineated, due to pressure necrosis from the expansile mass, or permeative to punctate lysis as a result of bony invasion.[126–130]

Biopsy is required for a definitive diagnosis. Analysis of synovial fluid is usually consistent with chronic, low-grade inflammation, and neoplastic cells are rarely identified. Large core biopsies, using either a Jamshidi needle or open wedge, are sufficient to establish a diagnosis and histologic grade.

Synovial cell sarcomas have two distinct populations of cells: (1) epithelioid and (2) spindle.[1,126] Based on these cells, synovial cell sarcomas are subclassified as either monophasic, with one cell type, or biphasic, with both cell types.[126] However, this histologic appearance is not adequate to differentiate synovial cell sarcoma from other types of soft tissue sarcoma. Recently, IHC stains have been used to differentiate joint tumors with synovial cell sarcomas staining positive with cytokeratin antibody AE1/AE3, histiocytic sarcomas staining positive with CD18 antibody, and malignant fibrous histiocytomas staining positive with smooth muscle actin.[129]

772

773

185.4.1.2 Treatment

Limb amputation is the recommended treatment for dogs with a histologically confirmed joint tumor.[126–130] Local recurrence is common after conservative excision and has also been reported with relative frequency in the stump of the amputation site.[126] The role of radiation therapy and chemotherapy is unknown. Chemotherapy does not improve survival time in humans with synovial cell sarcoma.[131] However, doxorubicin-based chemotherapy protocols are recommended for high-grade synovial cell sarcoma due to their high metastatic potential.

185.4.1.3 Prognosis

Several prognostic factors have been identified in dogs with synovial cell sarcoma, including clinical stage, treatment, histologic grade, and IHC staining.[126–130] Synovial cell sarcoma is locally staged as well-defined with no evidence of invasion into regional structures (T_1), invading soft tissue (T_2), and invading bone and joints (T_3).[126] Local staging is not prognostic; however, dogs with metastatic disease, to either regional lymph nodes (N) or lungs (M), have a MST less than 6 months. Aggressive surgical treatment is important in prolonging both DFI and survival time. Local tumor control is poor after conservative local excision with a median DFI of 4.5 months compared with 30 months after limb amputation.[126,130] Furthermore, survival time is significantly improved with more aggressive local treatment regimens: 93 days with no treatment, 455 days with conservative resection, and 840 days with limb amputation.[130] Histologic grade is also prognostic because the MST for dogs with grade I synovial cell sarcoma is greater than 48 months, grade II is 36 months, and grade III only 7 months.[126]

185.4.2 Cats

Synovial cell sarcoma is rarely diagnosed in cats. As a result, the disease has not been investigated in detail, and management and prognostic criteria have not been established. Seven cases have been reported in the veterinary literature, three with benign and four with malignant disease.[132,133] Based on these reports, synovial cell tumors in cats may have a more benign behavior than dogs. However, two cats have recently been diagnosed with metastatic synovial cell sarcoma at Colorado State University. Regional lymph node metastases were present at diagnosis in both cases, and one cat was diagnosed with pulmonary metastasis 12 months postoperatively. Limb amputation is recommended for the local management of synovial cell sarcomas because, similar to dogs, local recurrence has been reported after conservative excision.[132,133] The role of chemotherapy in malignant or metastatic synovial cell sarcomas is unknown.

186 CHAPTER • 186 Mast Cell Disease

Kenita S. Rogers

186.1 OVERVIEW OF CANINE AND FELINE MAST CELL DISEASE

Differences in the incidence, clinical forms, and biologic behavior associated with canine and feline mast cell disease are remarkable enough that separate discussions are required. Briefly, the incidence of cutaneous mast cell disease is higher in the dog and constitutes the most important form in this species; primary noncutaneous forms are uncommon. The biologic behavior of mast cell disease in the dog is also more variable and unpredictable, with a greater risk of systemic spread. Like dogs, cats can develop cutaneous mast cell disease, but primary visceral mastocytosis appears to be an equally important disease process. A primary gastrointestinal (GI) form is infrequently reported in the cat.

186.2 INCIDENCE OF CANINE MAST CELL DISEASE

Mast cell tumors (MCTs) remain one of the most important and frequent neoplasms affecting the canine dermis and subcutis, having been reported to account for 7% to 21% of all canine skin tumors and 11% to 27% of all cutaneous malignancies.[1,2] Mast cell disease can occur in any breed, but those that appear to be at increased risk are most of the brachycephalic breeds and Golden retrievers. Although boxers are at increased risk for developing MCTs, they often develop a well-differentiated form of the disease, which has a more favorable prognosis. Other breeds with an apparent predisposition in some reports include Bassett hounds, Labrador retrievers, Bernese mountain dogs, Chinese Shar Peis, Scottish terriers, pointers, beagles, and German shorthaired pointers. The average age of dogs that develop MCTs is 8.5 to 9.5 years, but they can develop at any age, with no apparent gender predisposition. Development of multiple tumors is a common clinical observation, occurring in approximately 10% to 15% of cases.

186.3 BIOLOGY OF MAST CELLS

Mast cells are a heterogenous cell population that originate in the bone marrow from a CD34+ pluripotential hematopoietic stem cell that is promoted to mast cell differentiation by a hemopoietin called stem cell factor or c-*kit* ligand.[3] Undoubtedly, the development of MCTs involves many factors including genetic propensity, but alteration of c-*kit* receptor expression for stem cell factor in a proportion of canine MCTs suggests that loss of normal regulation may be an important factor in tumor development.[4] Cytoplasmic receptors for estrogen and progesterone have been identified in canine MCTs, but their importance in the pathogenesis of disease is unclear. Committed mast cell precursors move from marrow to blood to tissues where maturation occurs. Besides the skin, the GI tract and lungs are rich in normal mast cells, but development of tumors at these sites is rare.

Normal mast cells play an important role in mediating inflammatory responses. Mast cell activation stimulates release of a variety of substances from the variably sized intracytoplasmic granules, including vasoactive amines (histamine, seratonin), enzymes (acid hydrolases, cathepsin G, phospholipase A, chymase, tryptase, carboxypeptidase) and proteoglycans (heparin, chondroitin sulfate).[3] Mast cells can also synthesize and release lipid mediators and cytokines. The ability to release these active substances and mediators explains many of the clinical manifestations of these tumors. Mast cell functions include promoting hypersensitivity reactions, modulating immune responses by stimulating T cells, defending the host against tissue parasites, and promoting

acute and chronic inflammatory responses by stimulating leukocyte migration, endothelial-leukocyte adhesion, angiogenesis, fibrin deposition, and fibroblast proliferation.[3]

Local release of biologically active substances from the granules can lead to recruitment of other cytokines and inflammatory cells. Unique local clinical signs that are related to these cellular products can range from nonpainful swelling to pruritus, ulceration, erythema, bruising, or prolonged hemorrhage. Poor wound healing may be attributed to proteolytic enzymes and vasoactive amines, but mouse studies suggest that histamine binds to H_1 and H_2 receptors on macrophages, resulting in release of a fibroblastic suppressor factor that decreases normal fibroplasia and results in delayed wound healing.[2] MCTs may cyclically wax and wane in size; manipulation on examination may also lead to degranulation and subsequent swelling or wheal formation. Systemic effects can also occur as part of a paraneoplastic syndrome because plasma histamine concentrations in dogs with MCTs are significantly greater than normal.[5] Increased concentrations of circulating histamine can be associated with gastric hyperacidity and GI ulceration, because binding of histamine to H_2 receptors of gastric mucosal parietal cells stimulates gastric acid secretion and hyperacidity. Histamine also increases GI motility and capillary permeability, promoting intravascular thrombosis and subsequent mucosal ulceration. With marked systemic histamine release, potential also exists for arrhythmias, systemic hypotension, and shock due to H_1 and H_2 receptor binding on blood vessels, cardiac muscle, and smooth muscle.[1]

186.3.1 Biologic Behavior of Canine Mast Cell Tumors

Cutaneous MCTs are likely to arise from tissue mast cells in the dermis. The clinical course of mast cell disease is somewhat unpredictable, but all tumors are considered potentially malignant due to their ability to metastasize. The typical metastatic pattern for MCTs is to the reticuloendothelial system. The first and most common site of metastasis is the regional lymph node, followed by the spleen, liver, and bone marrow.

One of the unique features of MCT behavior is the concurrent development of multiple dermal or subcutaneous tumors. When it occurs, the tumors may seem to erupt simultaneously or develop over months to years. It is unknown if each of the masses is a new individual tumor or whether each tumor represents metastatic spread. The best way to describe the typical biologic course of MCTs is “predictably unpredictable.” MCTs may have a very slow nonprogressive clinical course, they may be present for long periods prior to disseminating, or they may be locally invasive with systemic spread early in the disease course.

Histologically, canine MCTs have been graded 1 through 3, with the grade of the tumor having substantial impact on overall prognosis. Some confusion has existed because of two distinct grading systems. The Patnaik scale is more popular because it uses the more conventional nomenclature of Grade 1 representing the most well-differentiated tumors that are confined to the dermis, Grade 2 representing more pleomorphic tumors that extend into lower dermis and subcutaneous tissues, and Grade 3 representing pleomorphic tumors that replace subcutaneous and deep tissues.[6,7]

186.3.1.1 Clinical Presentation

Tremendous variation exists in the clinical appearance of MCTs. They may be soft and fluctuant or firm, discrete or diffuse, small or large, solitary or multiple, haired or hairless, and dermal or subcutaneous. A good rule of thumb is that MCTs can look like anything! They remain one of the most important reasons that any dermal or subcutaneous mass should be evaluated cytologically, because they can mimic lipomas and other nonneoplastic lesions. At least one half of these tumors have been reported on the trunk and perineum,

but the extremities, head, and neck remain common sites. Although most commonly located within the dermis, some tumors, particularly those that are rapidly growing, extend into the underlying subcutaneous tissues and muscle. Disseminated mastocytosis without an associated cutaneous MCT is reported infrequently in dogs.[8,9] Equally uncommon are reports of MCTs of GI origin.[10] Rare reports exist of MCTs arising from a variety of sites, including the oral cavity, nasal cavity, larynx, and conjunctiva.

Dogs with MCTs often have a solitary nonpainful mass, but more profound local clinical signs that should raise clinical suspicion of a MCT include swelling that may wax and wane (particularly after manipulation of the mass), pruritus, erythema, ulceration, or bruising. Systemic signs of GI ulceration, abdominal discomfort, vomiting, melena, hypotension, or coagulation abnormalities are less common but remain clinically important. If GI ulceration and hemorrhage is persistent, anemia will develop that is progressively less regenerative as external iron loss occurs.

186.3.1.2 Diagnosis and Staging

Early diagnosis of mast cell disease is important because a number of precautions may be taken if the diagnosis is known preoperatively, most notably premedication with H_1 and H_2 receptor blockers and more extensive planning for wide surgical margins. Most MCTs are easily diagnosed with fine needle aspiration due to distinctive cytologic characteristics. It has been suggested that manual quick stains, such as Diff Quick, may stain mast cell granules poorly.[3] Because the lack of adequate staining may be associated with dissolution of the mast cell granules by these largely aqueous stains if fixation is inadequate, particular care should be taken to adequately fix the slides when using these in-hospital stains. MCTs are categorized as round cell tumors because they typically have round cytoplasmic borders, do not cluster, and exfoliate well. Specific cytologic characteristics include a round to ovoid nucleus, a moderate amount of cytoplasm, and the presence of red-purple variably sized intracytoplasmic granules. In heavily granulated cells, the nucleus may stain pale blue due to the high affinity of the mast cell granules for the stain, with subsequent understaining of nuclear DNA. Well-differentiated tumors are typically homogenous in appearance with few malignant characteristics, even though the tumor remains potentially malignant. As tumors become more poorly differentiated, the number and size of granules within the cell may diminish and the degree of cellular pleomorphism will increase. The most poorly differentiated or anaplastic MCTs may have no visible granules on light microscopy and require special stains such as toluidine blue for definitive diagnosis. A subset of tumors remains that is cytologically and histologically defined only as *anaplastic round cell tumors*, with MCT being only one possible diagnosis within a list of differentials that may include lymphoma, transmissible venereal tumor, histiocytic disorder, plasma cell tumor, amelanotic melanoma, and anaplastic carcinoma. Immunohistochemical techniques may be helpful for differentiating these tumors (MCTs are vimentin + and most are alpha-1 antitrypsin +), but electron microscopy of ultrastructural features may be required in some cases for definitive confirmation.[3] Another useful cytologic characteristic supporting the diagnosis of MCT is the presence of a concurrent eosinophilic infiltrate due to chemotactic attraction of these inflammatory cells to histamine.

774

775

Histologic examination of MCTs is important, not only to confirm the diagnosis but also to accurately grade the tumor and evaluate for completeness of surgical resection. Histologic tumor grade plays a substantial role in prognosis by correlating with both recurrence and survival. Four-year survival rates after surgical excision are 83% for Grade 1 tumors, 44% for Grade 2 tumors, and 6% for Grade 3 tumors.[6] Many studies have confirmed the trend that well-differentiated tumors are least likely to metastasize and have longer postoperative survival times. Although it is recognized that even with wide resection, well-differentiated MCTs can locally recur and metastasize, it is usually considered that the metastatic potential of

well-differentiated tumors is low (<10%) and that of intermediate-grade tumors is low to moderate.[2] Poorly differentiated MCTs are associated with the greatest risk of metastasis and shortest survival times.

Clinical staging also provides important information regarding prognosis (Box 186-1). Because metastasis is typically to the reticuloendothelial system, the regional lymph nodes, liver, spleen, and bone marrow are usually targeted for evaluation. The first site of mast cell metastasis is the regional lymph node. If an apparent regional node exists, it should always be aspirated, even if palpably normal in size. Early in the course of disease, MCTs may metastasize without causing a concomitant lymphadenopathy. It is important to remember that a palpably normal node does not rule out metastasis. Conversely, an enlarged regional lymph node may represent only reactive changes associated with lymphoid hyperplasia or secondary inflammatory changes. It is quite common for a peripheral lymph node to contain a small population of normal mast cells, particularly if the animal has allergic or parasitic skin disease, making definitive diagnosis of nodal metastasis problematic. In a population of 56 healthy nontumor-bearing beagles, approximately 24% of lymph node aspirates contained mast cells, with a range of one to 16 mast cells per slide.[11]

Differentiating inflammatory from neoplastic mast cells within a node can be difficult at best. Typically, inflammatory mast cells are spread somewhat evenly throughout a node and on the cytologic preparation. Tumor mast cells have a greater tendency to arrange themselves in groups within a node, and this may be apparent on the smear. Another helpful finding may be noting the degree of differentiation of the mast cells within the node. Inflammatory mast cells are usually well differentiated and heavily granulated. Tumor mast cells may also have this appearance, but if the cells in the node are more poorly differentiated with few granules, the cells are more likely to represent metastatic tumor.

186.3.1.2.1

Box • 186-1 World Health Organization Clinical Staging of Canine Mast Cell Tumors

Stage 0: One tumor incompletely excised from the dermis, identified histologically, without regional lymph node involvement

Stage I: One tumor confined to the dermis, without regional lymph node involvement

Stage II: One tumor confined to the dermis, with regional lymph node involvement

Stage III: Multiple dermal tumors; large infiltrating tumors with or without regional lymph node involvement

Stage IV: Any tumor with distant metastasis (including blood or bone marrow involvement) or recurrence with metastasis

Substage a: without systemic clinical signs

Substage b: with systemic clinical signs

As is true with lymph nodes, buffy coat smears and aspirates of spleen and bone marrow must also be interpreted carefully because small numbers of mast cells can normally be seen in these preparations, particularly if concurrent inflammatory disease exists. When few mast cells are present in potential metastatic sites, it is difficult or impossible to determine if the mast cell infiltrate represents metastatic neoplasia, mast cell hyperplasia, or a nonpathologic condition.[3] Mastocytemia is uncommon in dogs, but unless extensive blood involvement occurs, the number of mast cells seen in blood samples cannot be used to accurately distinguish nonmalignant from malignant disease. Indeed, more than 1000 mast cells per buffy coat preparation were described in nonneoplastic disorders in dogs.[12] A few mast cells may be present normally in a bone marrow smear, and mast cell hyperplasia associated with marrow hypocellularity has been reported.

Because the lymph node is the first site of metastasis, nodal assessment with cytology or histology is the single most important diagnostic step in staging. In the dog with no evident lymph node involvement, evaluation of the spleen, liver, and bone marrow is unlikely to yield useful information. Unfortunately, several areas of the body (particularly on the trunk) do not drain to a single, easily accessible peripheral lymph node. In these cases the regional node may be within the thoracic or abdominal cavities, and access for aspiration or biopsy is more difficult.

Diagnostic evaluation of splenic or hepatic involvement may include radiographs, ultrasound, and aspiration. The bone marrow is most commonly assessed with aspiration cytology; the presence of more than 10 mast cells/1000 nucleated cells can indicate systemic spread of mast cell disease. In a study of 16 dogs with systemic mastocytosis, bone marrow aspiration was deemed superior to blood smear and buffy coat examination.[8] In dogs with low and intermediate-grade cutaneous MCTs, the value of bone marrow examination is questionable due to the low incidence of finding metastasis in this location, particularly if the regional node can be evaluated. Because pulmonary metastasis is rare, thoracic radiographs are only indicated for assessing intrathoracic lymphadenopathy for MCTs located on the cranial portion of the body. A complete blood count (CBC) may show nonspecific eosinophilia, basophilia, and anemia if GI hemorrhage has occurred.

186.3.1.3 Treatment

As is true with most types of neoplasia, the conventional choices for therapy are surgery, radiation, and chemotherapy. Each of these treatment modalities has a role in mast cell disease. The location of the mass, the number of masses, the grade of the tumor, and the presence or absence of metastasis are all important factors in choosing the most appropriate course of therapy for dogs with mast cell disease. However, the unpredictable biologic behavior of MCTs must always be kept in mind when making therapeutic decisions.

186.3.1.3.1 Surgery

Complete surgical excision has been the mainstay of therapy for canine MCTs, and remains the treatment of choice. Curative intent can be expected with surgery of Grade 1 and 2 tumors that have no evidence of metastasis and are located in areas where surgery will allow adequate resection while maintaining cosmesis and function. The preoperative diagnosis of MCT allows the clinician to prepare the dog with prophylactic H_1 and perhaps H_2 receptor blockers, if appropriate. In addition, decisions regarding the size of surgical margins is often altered when the clinician has made a preoperative diagnosis of mast cell disease. Classically, it has been recommended that 2-3 cm margins be obtained if possible when resecting

a MCT due to often inapparent extension of the tumor into surrounding tissues. Equally important is the recommendation that excision include at least one fascial plane beyond the apparent extent of the tumor (i.e., if the tumor is dermal, underlying subcutaneous tissue should be removed; if the tumor is located in the subcutis, at least one layer of underlying muscle should be excised to routinely obtain adequate surgical margins free of tumor cells). All surgical margins should be clearly identified to allow the pathologist to examine for remaining tumor cells. Interestingly, many clinicians have noted that even when adequate surgical margins have not been obtained, a subset of patients exist in which the tumor does not occur.[13] Regardless, the current recommendation remains to widely excise tissue to obtain clean margins or follow with radiation therapy of the tumor bed and immediate surrounding tissues. For low to intermediate-grade MCTs on a distal extremity, limb amputation is also a surgical option for obtaining wide margins (albeit with less remaining function). Alternatives for limb salvage for tumors in this area include radiation alone, or more ideally, a combination of cytoreductive surgery followed by radiation therapy (Figure 186-1). The use of deionized water to treat surgical wounds after MCT removal has been reported, but this approach must not delay the use of more conventional therapy.

186.3.1.3.2

Radiation

Radiation alone for gross mast cell disease has generally been considered poorly effective with variable control rates cited; 1-year control rates using doses of 40 to 45 Gy are approximately 50%.[2] Use of more aggressive doses or different fractionation schemes may improve these results. A palliative course of radiation (coarse weekly fractions of 800 to 1000 Gy) for 3 to 4 weeks may result in responses that improve quality of life and decrease local clinical signs for unresectable MCTs but may also result in GI upset and weakness, most likely associated with mast cell degranulation.[14]

Radiation therapy is best applied as adjunctive therapy for incompletely resected tumors where further surgery is not deemed possible (i.e., Stage 0 disease). The prognosis after radiation for Grade 1 and 2 MCTs is good, with 1-and 2-year disease-free intervals of 79% to 97% and 77% to 85%, respectively.[15–18] Common toxicities associated with the use of conventional radiation include alopecia, haircoat color changes within the treatment field, and temporary moist desquamation. Prophylactic irradiation of cytologically negative regional lymph nodes is controversial with little guidance in the literature to suggest improved survival times with use of this technique. However, after cytoreductive surgery of the primary mass, radiation of regional nodes with metastasis in 19 dogs (16 with Grade 2 tumors) resulted in a median disease-free survival of 1240 days.[19]

Whether surgery or radiation is chosen as local therapy, dogs should be evaluated regularly for local recurrence and metastasis. For dogs with high-grade, poorly differentiated MCTs, surgery, and radiation may be used as local therapies but will not address the high risk of systemic spread that will typically occur within weeks to months of the local therapy. It is extremely important that clients be fully educated regarding the high risk of metastasis in this subset of dogs, prior to initiating surgery or radiation therapy.

186.3.1.3.3

Chemotherapy

With poorly differentiated MCTs or documented metastasis, local treatments such as surgery and radiation may provide only palliative therapy. Systemic adjuvant chemotherapy can be offered in an attempt to decrease the likelihood of systemic involvement or potentially to improve disease-free intervals.[2] MCTs appear to be quite resistant to the effects of chemotherapy, because many different agents have been used

with little reported efficacy and most responses have been of short duration. P-glycoprotein and multidrug resistance–associated protein have been detected in canine cutaneous MCTs.[20]

Prednisone is commonly advocated for treatment of MCTs, but the reported response rates are low. One prospective clinical trial with daily oral prednisone at 1 mg/kg demonstrated disappointing results.[21] Only 4 of 25 dogs had a partial response (PR) and only one dog had a complete response (CR). Most responses lasted only a few weeks. However, it must be recognized that many dogs in this study had poorly differentiated tumors that may respond differently to prednisone than lower-grade tumors, potentially due to differences in numbers of steroid receptors. As an anti-inflammatory agent, prednisone may be helpful by decreasing swelling and edema associated with mast cell degranulation and concomitant inflammation, as well as stabilizing cytoplasmic membranes and helping to prevent further degranulation. Intralesional use of triamcinolone at 1 mg/1 cm of tumor diameter at 2-week intervals has been anecdotally reported to be effective at controlling local tumor volume. Corticosteroids may also be useful in combination with other chemotherapy agents.

Although the response rate to vincristine was low in a study of dogs with Grade 2 and 3 tumors (0 CR and 3 PR) and administration caused an unacceptable rate of GI toxicity, the use of vinblastine has met with more favorable results.[22,23] As adjuvant therapy to incomplete surgical resection, a combination of prednisone and vinblastine conferred a 57% 1-and 2-year disease-free rate. In dogs with evaluable gross disease, the overall response rate was 47% with 5 CR and 2 PR. Lomustine is an oral alkylating agent in the nitrosourea subclass. It was evaluated in 19 dogs with measurable MCT.[24] Eight of the 19 dogs (42%) had a measurable response; one dog had CR for 440 days and 7 dogs had PR for a median duration of 77 days. Six dogs (32%) had stable disease for a median duration of 78 days. The dose-limiting toxicity was neutropenia. Combination chemotherapy may improve response rates.[25,26] Supportive medical management of patients with MCTs may include H_1 and H_2 receptor antagonists, omeprazole, misoprostol, sucralfate, metoclopramide, and prednisone in an anti-inflammatory dose.

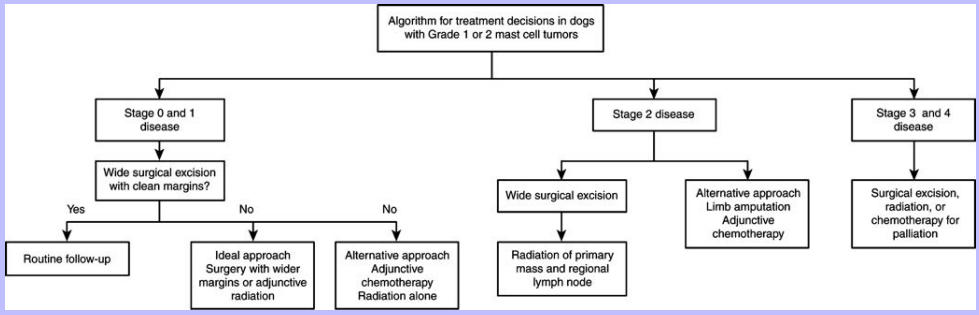
186.3.1.4 Prognosis

Although the biologic behavior of each individual MCT is unpredictable, the prognosis roughly follows the Patnaik grade, with other recognized prognostic factors being the stage of disease, tumor location, tumor duration, and several proliferation markers. As the Patnaik grade increases, average survival times diminish. Dogs with Stage 0 or 1 disease have a better prognosis than those with higher stage disease. Visceral or bone marrow involvement represents advanced disease and a poor prognosis. In 16 dogs with visceral MCT, the median survival was 90 days, and all dogs with follow-up died of their disease.[8] Dogs with systemic signs such as GI ulceration and vomiting do more poorly than dogs with no evidence of illness on presentation, because these signs are associated with more advanced and aggressive forms of mast cell disease.

Dogs with tumors on the extremities may have longer survival than those with tumors on the trunk. Tumors located on the perineal, inguinal, preputial, and subungual areas and noncutaneous sites, such as the oral cavity and GI tract, have a poorer prognosis and are often more poorly differentiated. The growth rate of a tumor can be prognostic, because tumors that remain localized and are present for months without metastasizing are often cured with complete surgical excision. The length of time that a tumor has been present prior to surgical resection is inversely related to survival time.[7] Recent rapid growth is a poor prognostic sign.

Although not routinely performed, at least four laboratory tests can provide further prognostic data: argyrophilic nucleolar organizer (AgNORs), proliferating-cell nuclear antigen (PCNA), Ki-67–positive nuclei, and ploidy. The relative frequency of AgNORs is predictive of postoperative success because higher AgNOR counts are associated with a poor prognosis.[27,28] In addition, a higher percentage of PCNA immunopositivity and a higher number of Ki-67–positive nuclei are associated with a more guarded prognosis.[27,29] These tests represent indirect measures of cellular proliferation. Dogs with aneuploid tumors have a trend toward shorter survivals and higher-stage disease.[30]

Figure 186-1 Algorithm for treatment decisions in dogs with Grade 1 or 2 mast cell tumors (MCTs).



186.3.2 Feline Mast Cell Disease

The three forms of mast cell disease in the cat are (1) cutaneous, (2) visceral (systemic, splenic), and (3) GI. Although mast cell disease is diagnosed less frequently in the cat than the dog, it remains among the four most common skin tumors in the cat (with basal cell tumor, squamous cell carcinoma, and fibrosarcoma) and accounts for 12% to 20% of all skin neoplasms.[31] Visceral MCT and lymphoma are the two most common hematopoietic tumors of the spleen, and MCT is the third most common intestinal tumor in the cat after lymphoma and adenocarcinoma. MCTs are most commonly diagnosed in middle-aged to older cats with no gender predilection, but Siamese appear to be over-represented in many studies.

186.3.2.1 Cutaneous Form

Cutaneous lesions in the cat appear as solitary or multiple dermal nodules that are discrete, nodular, papular, or plaquelike, and occasionally, diffusely swollen. Plaquelike lesions can be confused with eosinophilic granuloma complex, and indeed, some eosinophilic plaques contain mast cells as a part of the inflammatory component. Unlike the dog, feline cutaneous MCTs appear to occur more frequently on the head and neck, although some reports have not documented a site predilection. Occasionally, cutaneous lesions may represent metastasis from the visceral form of the disease, and it is recommended that any cat with multiple cutaneous lesions be evaluated for primary visceral disease. There has been no evidence of a relationship between the development of MCTs and feline leukemia virus (FeLV), but there has been a suggestion of a relationship between multiple cutaneous MCTs and feline immunodeficiency virus (FIV) infection.[1]

Diagnostic techniques used in the dog are similar for cats, with cytology and histology being the most useful for the mast cell variety of MCT. Some feline mast cells have fine granules that are difficult to visualize, even with additional stains such as toluidine blue or Wright-Giemsa. Unfortunately, the histologic grading systems used for canine MCTs do not provide prognostic information in the cat.[32] Metastasis is less common, but when it occurs it is primarily to a regional node. In several studies few cats demonstrated metastasis, but development of new cutaneous lesions occurred in one third to one half of the cats.[31,33,34] A histiocytic variety of MCT exists that has been reported primarily in young Siamese. These cats often have multiple lesions, typically developing in the same region of the body. The mast cells are poorly granulated, and the tumors are often infiltrated by numerous lymphoid aggregates. Many of these tumors are small and may spontaneously regress.

The treatment of choice for feline cutaneous mast cell disease is complete surgical excision. The overall survival of cats with cutaneous mast cell disease is long. If tumors are incompletely resected or evidence of systemic disease exists, radiation and chemotherapy may be considered. Because vinblastine and CCNU (Lomustine) are active agents in canine MCTs, they may have role in the cat. Although histamine may play a role in the clinical signs associated with feline mast cell disease, seratonin may be a more important inflammatory mediator in feline mast cells.[35] Therefore cyproheptadine may be a more effective agent than diphenhydramine for cats with clinical signs related to mast cell degranulation. The effectiveness of corticosteroids is also less clear in cats.

186.3.2.2 Visceral Form

Visceral or systemic mastocytosis is a disease that is relatively unique to the cat. This form of disease has been reported to comprise up to 50% of all feline mast cell disease and typically involves the spleen, liver, and often abdominal lymph nodes; infrequently it has been diagnosed involving mediastinal or peripheral lymph nodes.[1,2] The disease affects older cats (average age of 10 years) with no breed or gender predilection and occurs most often in domestic shorthair and longhair breeds. Clinical signs include a palpable or visible intra-abdominal mass, vomiting with or without hemorrhage, weight loss, anorexia, abdominal discomfort, ascites, and lethargy. GI signs are due to either the space-occupying nature of the large mass or histamine release with resultant gastric ulceration. An acute abdominal crisis can occur with intestinal perforation secondary to ulceration or with splenic rupture. Laboratory abnormalities may include anemia and mastocytemia, with circulating mast cells noted in up to 50% of affected cats. In addition, there may be mast cells noted within body cavity effusions. Neoplastic cells frequently spread from the spleen to the liver, abdominal lymph nodes, and bone marrow. Cytology of these organs is typically consistent with a mast cell infiltrate, and occasionally neoplastic cells will demonstrate erythrophagocytosis. Manipulation of the enlarged spleen for aspiration poses modest risk, and pretreatment with antihistamines and vigilance for precipitation of shock must accompany fine needle aspiration. Use of a 25-gauge needle allows for adequate cellular collection while minimizing the risk of hemorrhage or degranulation. Abdominal radiographs or ultrasound can demonstrate enlargement of the spleen, liver, or mesenteric nodes and may aid in obtaining diagnostic aspirates. Thoracic radiographs may be helpful in identifying pleural effusion that may occur in up to one third of cats with visceral mastocytosis. Treatment of these cats can consist of supportive care (prednisone, H_1 and H_2 antagonists, cyproheptadine), splenectomy, or chemotherapy. In most cases supportive care measures alone fail to ameliorate the clinical signs of disease. The longest survival times have been associated with successful splenectomy, even without the benefit of other therapies and in the presence of overt metastatic disease. Median survival time after splenectomy is between 12 and 19 months, but some cats live 2 to 3 years postsplenectomy.[2] Intraoperative risks include excessive hemorrhage, as well

as hypotension and shock when the splenic mass is manipulated. Prior to splenectomy, cats should be medicated with H_1 and H_2 receptor blockers and cyproheptadine to mitigate the adverse effects of intraoperative mast cell degranulation. Although not reported in the cat, use of chemotherapy may have a role in management of visceral mast cell disease.

186.3.2.3 Gastrointestinal Form

This form of mast cell disease has been infrequently reported and arises primarily from the small intestines. Clinical signs are associated with GI upset, including vomiting, diarrhea, anorexia, and weight loss. Interestingly, ulceration has not been reported, so the vomiting noted in these cats is most likely due to mechanical obstruction.[1] Many cats have a palpable mass that can be localized with imaging to the intestinal wall. Most of these tumors are solitary, but multiple tumors have been reported. Intestinal MCT are often poorly differentiated and may be difficult to definitively diagnose, particularly with cytology. These tumors usually have systemic involvement, so surgical resection is often not curative. Reported sites of metastasis have been the regional lymph nodes, liver, spleen, bone marrow, and lung. Life span is typically less than 4 months, but occasionally cats will survive long-term.

187 CHAPTER • 187 Canine and Feline Histiocytic Diseases

Peter F. Moore

Verena K. Affolter

187.1 OVERVIEW OF CANINE HISTIOCYTIC DISEASES

At least four well-defined histiocytic proliferative diseases have been recognized in dogs. They are a frustrating group of diseases because it may be difficult to differentiate them from granulomatous, reactive inflammatory diseases or from lymphoproliferative diseases by examination of regular paraffin sections. The clinical presentation and behavior and responsiveness to therapy vary tremendously between the syndromes observed. Clinical and pathologic images of canine histiocytic diseases and details of histiocytic lineages are available on a web site maintained by the authors (http://www.histiocytosis.ucdavis.edu). *Canine cutaneous histiocytoma* usually occurs as a single lesion in young dogs and spontaneously regresses. Multiple histiocytomas and metastatic histiocytomas are examples of less common but more aggressive subgroup of this tumor. *Langerhans' cell histiocytosis* (LCH) is a rare disease characterized by extensive regional cutaneous infiltration by histiocytes, which otherwise resemble those in histiocytoma, although rapid systemic metastasis is observed. *Cutaneous histiocytosis* (CH) typically occur as single or multiple lesions, which tend to wax and wane and may even spontaneously regress. Few cases respond to corticosteroids; the remainder persist and may require more aggressive immunosuppressive therapy. *Systemic histiocytosis* (SH) is a familial disease of Bernese mountain dogs and also occurs sporadically in other breeds. SH causes prominent skin manifestations identical to those seen in CH, but mucous membranes (ocular and nasal) and a variety of other organ systems, including lymphoid organs, lung, and bone marrow, may also be involved. Although the lesions may wax and wane, SH is a progressive disease that often requires continuous immunosuppressive therapy. *Histiocytic sarcoma* (HS) and *malignant histiocytosis* (MH) occur with high incidence in Bernese mountain dogs, Rottweilers, flat-coated retrievers, golden retrievers, and sporadically in many other breeds. HSs occur as localized lesions in spleen, lymph nodes, lung, bone marrow, skin and subcutis, brain, and periarticular tissue of large appendicular joints.

HS can also occur as multiple lesions in single organs (especially spleen) and rapidly disseminate to involve multiple organs. Hence, disseminated HS is difficult to distinguish from MH, which is a multisystem, rapidly progressive disease that includes simultaneous involvement of multiple organs such as spleen, lymph nodes, lung, bone marrow, skin, and subcutis. Response of HS and MH to chemotherapy is at best brief.

187.1.1 Histiocytic Differentiation and Canine Histiocytosis

The development of canine-specific monoclonal antibodies for many of the functionally important molecules of macrophages and dendritic antigen presenting cells (DCs) has enabled the identification of the cell lineages involved in canine histiocytic disorders.[1–4] Despite the large variation of clinical and pathologic features of canine histiocytic diseases, the majority represent proliferations of cells of various DC lineages.

Histiocytes differentiate from CD34+ committed stem cell precursors into *macrophages* and several DC lineages, which include *epithelial DCs* or *Langerhans' cells* (LC), *interstitial DCs* in many organs (e.g., dermal DCs in skin), and *interdigitating DCs* of T-cell domains in peripheral lymphoid organs. Cytokines influencing DC development include GM-CSF and TNF-alpha. Macrophage development from CD34+ precursors is influenced by GM-CSF and M-CSF. Blood monocytes can differentiate into either macrophages under influence of M-CSF or into DCs under influence of GM-CSF and interleukin (IL)-4.[5,6] Recently a new human

dendritic lineage of myeloid origin was identified. These DCs differentiate under the influence of GM-CSF and IL-3 and are the major source of nonactivated resident DCs in T-cell domains of peripheral lymphoid organs.[7] They are supplemented by migration of activated DCs from skin and interstitial tissues, which arrive in lymph nodes as veiled cells in afferent lymph after contact with antigen.

Dendritic cells are the most potent antigen presenting cells (APCs) for induction of immune responses in naïve T cells. Canine DCs have been best defined in canine skin. They occur in two major locations: (1) within the epidermis (LC) and (2) within the dermis especially adjacent to postcapillary venules (interstitial DCs or dermal DCs). Canine DCs abundantly express CD1 molecules,[3,4] which together with MHC class I and MHC class II molecules are responsible for presentation of peptides, lipids, and glycolipids to T cells. Hence, DCs are best defined by their abundant expression of molecules essential to their function as APC. Of these, the family of CD1 proteins is largely restricted in expression to dendritic APC in skin; whereas MHC class I and II are more broadly expressed.

The beta-2 integrins (CD11/CD18) comprise the major family of adhesion molecules on leukocytes and as such are useful markers of leukocytic differentiation. CD11/CD18 expression is highly regulated in normal canine macrophages and DCs. CD11c is frequently expressed by DCs; whereas macrophages predominately express CD11b (or CD11d in the splenic red pulp and bone marrow).[8,9] In diseased tissues these beta-2 integrin expression patterns may be diversified.

Langerhans' cells (epidermal DCs) and interstitial DCs are distinguishable by their differential expression of E-cadherin (LC+) and Thy-1 (CD90) (interstitial DC+). Lineage distinctions among histiocytes are best made via immunohistochemistry (IHC) performed on frozen sections (CD1, CD11b, CD11c, CD11d, CD18, CD90, MHC II, and E-cadherin expression). Less definitive but useful distinctions can also be attained via IHC on formalin-fixed paraffin sections with panels of leukocytic markers developed for use in this format (CD3, CD11d, CD18, CD45, CD45RA, CD79a, and E-cadherin).

Regardless, dendritic APC arise in bone marrow and migrate through blood to a variety of epithelial sites (cutaneous and mucosal), where they take up residence either within epithelia or in dermis and lamina propria. 779
In these sites they function as antigen processing cells and ultimately APCs, which interact with T cells. 780
Migration of DCs (as veiled cells) beyond the skin to the paracortex of lymph nodes occurs after contact with antigen. The interdigitating dendritic APCs of lymph node paracortex are partially derived from such migration. Aspects of this developmental and migratory program of cutaneous DCs are recapitulated in the DC proliferative disorders of canine skin.

Successful interaction of dendritic APC and T cells in response to antigenic challenge also involves the orderly appearance of costimulatory molecules (B7 family—CD80 and CD86) on dendritic APC, as well as their ligands (CD28 and CTLA-4) on T cells. Defective interaction of dendritic APC and T cells appears to contribute to the development of reactive cutaneous histiocytic proliferative diseases (CH and SH), which are related DC disorders arising out of disordered immune regulation (see following). Much research is currently directed at the molecular events associated with maturation and migration of dendritic APC and the costimulatory function of dendritic APC. To some extent this research should be of future benefit to understanding the pathogenesis of proliferative diseases of dendritic APC in both human and dog.

187.1.2 Cutaneous Histiocytoma Complex

Several discrete clinical entities exist, in which proliferation of histiocytes, which resemble those encountered in histiocytoma, are seen. *Histiocytoma* is a common, benign, cutaneous neoplasm of the dog. Histiocytomas

usually occur as solitary lesions, which undergo spontaneous regression. The age-specific incidence rate for histiocytomas drops precipitously after 3 years, although histiocytomas do occur in dogs of all ages.[10] Recurrence of histiocytomas at the same or other sites is uncommon. The occurrence of multiple tumors is also uncommon. Epidermal invasion by cells of histiocytoma frequently occurs (incidence about 60%), and intraepidermal nests of histiocytes resemble Pautrier's aggregates, characteristically found in epidermotropic lymphoma (mycosis fungoides [MF]). Epidermal invasion in histiocytoma, or presence of simultaneous *multiple histiocytomas* especially in aged dogs, can present a diagnostic dilemma, and distinction from MF and nonepidermotropic cutaneous lymphoma (NECL) is difficult on purely morphologic grounds.[3,11,12] It is imperative to request IHC stains to resolve these issues particularly in older dogs or if equivocal comments appear in the pathology report.

Multiple histiocytomas can be confused with CH on clinical appearance. Morphologically, however, histiocytomas are consistently epidermotropic and commonly epidermally invasive; these are not features of CH. Multiple histiocytomas appear to be more common in Shar Pei dogs but can occur in any breed. Delayed regression of multiple histiocytomas can occur, and lesions can persist for up to 10 months before onset of regression.

187.1.2.1 Metastatic Histiocytoma

Several dogs with histiocytomas have been observed in which histiocytes had migrated to and completely obliterated draining lymph nodes. Each dog had been diagnosed as having HS, and each was assigned a poor prognosis. However, three dogs had complete spontaneous regression of their lesions within 3 to 4 weeks of diagnosis.[3] In other instances the metastatic lesions of histiocytoma persisted without regression and the dogs were euthanized. The disease course in these dogs extended over several months. Spread from lymph nodes to lung has also been observed in some dogs but is rare. Veterinarians should remember that the primary lesion in most of these dogs looked no different from an uncomplicated histiocytoma.

187.1.2.2 Langerhans' Cell Histiocytosis

The presence of multiple histiocytomas is now a well-recognized syndrome. However, another presentation exists in which widespread cutaneous lesions histologically identical to histiocytoma are observed. Clinically the lesions are almost confluent in affected regions. Rapid internal spread is observed, and affected dogs have all been euthanized. One published account of such a case exists,[13] and the authors have data on four dogs with similar signs. This disease is most like cutaneous LCH of humans.[14]

187.1.2.3 Immunophenotypic Studies

IHC is best performed on frozen sections of tumor or cytologic preparations (not formalin fixed material). Histiocytoma is readily distinguished from other histiocytic disorders and cutaneous lymphoma with the aid of IHC. Histiocytomas have the phenotype of epidermal Langerhans' cells.[3] They express CD1a, CD1b, CD1c, MHC class II, CD11c, and E-cadherin. In leukocytes, E-cadherin expression is unique to Langerhans' cells. Langerhans' cells use E-cadherin to localize in the epidermis via homotypic interaction with E-cadherin expressed by keratinocytes. E-cadherin expression has only rarely been observed in HS in canine skin and subcutis. Histiocytomas lack expression of CD4 and Thy-1, which are consistently expressed by histiocytes in CH and SH. Therefore cutaneous histiocytoma is a localized epidermal Langerhans' cell tumor. The rare dogs with multiple histiocytoma and metastasis to local lymph nodes can be compared with dogs with

confluent histiocytic lesions that occur in many cutaneous sites with rapid systemic spread. These two conditions may represent one disease with a spectrum of diverse clinical behavior and are perhaps best characterized as LCH. LCH is also recognized as a rare disease of humans in which marked variation in clinical behavior is recognized.[14,15]

187.1.2.4 Regression of Histiocytomas

The factors that determine the onset of regression in canine histiocytomas are unknown. Evidence of regression is usually observed in lesions that have been present for only a few weeks, although regression can be delayed for many months. Regardless, CD8+ alpha beta T cells mediate regression; only scant numbers of CD4+ T cells are observed in histiocytoma lesions. Migration of tumor histiocytes, tumor infiltrating reactive DCs to draining lymph nodes, or both could activate CD4+ T cells, which would assist in CD8+ cytotoxic T-cell recruitment. Because massive CD8+ T-cell infiltration is observed in all instances of histiocytoma regression, therapeutic intervention with the aim of immunosuppression should be avoided once a definitive diagnosis of histiocytoma has been reached (to allow unfettered cytotoxic T-cell function).

187.1.3 Histiocytic Sarcoma Complex

The *HS complex* encompasses a number of distinctive clinical entities (see following). Some definitions are in order and reflect the preferred nomenclature of the Histiocyte Society. Histiocytic neoplasia that originates at a single site is called *HS*. This form of HS, which is often encountered on the extremities, has the best prognosis if treated early by surgical excision or by amputation of a limb. When spread to distant sites beyond the local lymph node occurs, the disease is then termed *disseminated HS*; this is more likely to occur unnoticed when primary lesions are located in cryptic sites (e.g., spleen, lung, bone marrow). This latter form of HS is most like MH. MH is an aggressive, histiocytic neoplasm that arises in multiple sites simultaneously. Most lesions previously defined as MH are probably more correctly termed *disseminated HS*. The occurrence of true MH is difficult to establish because the lesions often occur in cryptic sites, and the existence of histiocytic neoplasia is only recognized after clinical signs have appeared and disease progression is advanced. HS and MH are capable of widespread metastasis, hence in time the two syndromes merge clinically and it is not always possible to 780
differentiate true multicentric origin (i.e., MH) from widespread metastasis of disseminated HS. In addition, it 781
is never possible to know exactly how long the disease process has been operative. Hence, the perception is that both disseminated HS and MH follow a rapid clinical progression despite therapeutic intervention. This is certainly true once clinical signs are apparent, but the subclinical period is of unknown duration.

The HS complex of diseases is best recognized in the Bernese mountain dog, in which a familial association is apparent. Other breeds predisposed to HS complex diseases include Rottweilers, Golden retrievers, and flat-coated retrievers. HS complex is not limited to these breeds and can occur in any. Primary lesions of HS occur in spleen, lymph node, lung, bone marrow, skin and subcutis (especially of extremities), and in periarticular tissues of the limbs. Secondary sites are widespread but consistently include liver and lung (with splenic primary) and hilar lymph node (with lung primary). Clinical signs include anorexia, weight loss, and lethargy. Other signs depend on the organs involved and are a consequence of destructive mass formation. Accordingly, pulmonary symptoms such as cough and dyspnea have been seen. Central nervous system (CNS) involvement (primary or secondary) can lead to seizures, incoordination, and paralysis. Regenerative and nonregenerative anemias have been consistently documented in hemophagocytic HS/MH. Lameness is often observed in periarticular HS.

187.1.3.1 Treatment of Histiocytic Sarcoma Complex

Localized HS affecting skin and subcutis have been cured by early surgical excision. In others, surgery supplemented by local radiation therapy has been curative. In the case of periarticular HS, which occurs in the subsynovial tissues of the extremities, amputation of the affected limb is necessitated by the inoperable nature of the primary lesion, which usually ensnare structures vital to limb function. Prior to amputation it is important to support absence of metastasis with thoracic radiographs, abdominal ultrasound, and draining lymph node aspiration cytology. Disseminated HS (including MH) is not readily treated surgically, because even in the splenic form, early metastasis to the liver has been documented. Response to chemotherapy has been at best brief, and the disease progresses rapidly (weeks to months) to death or euthanasia.

187.1.3.2 Morphologic Features of Histiocytic Sarcoma

Lesions of HS are typically destructive mass lesions with a uniform, smooth cut surface and a white or cream to tan color. Lesions have a soft consistency and may contain discolored areas (typically yellow and extensive), which indicate area of necrosis. Lesions can be solitary or multiple within an organ (especially spleen). Periarticular HS has a distinctive appearance: it occurs as multiple tan nodules located in the subsynovium. These lesions may encircle the affected joint. Hemophagocytic HS does not initially form mass lesions in the primary sites (spleen and bone marrow). Typically, diffuse splenomegaly and ill-defined mass lesions are observed; the cut surface is dark red and the consistency is firm. The liver is usually bile stained (jaundice), and disruption of the lobular pattern due to metastasis is observed—marked liver involvement can occur before destructive liver masses are noticeable.

The histological appearance of HS lesions is consistent regardless of location. Lesions are most frequently composed of sheets of large, pleomorphic, mononuclear cells and multinucleated giant cells, which show marked cytologic atypia and numerous bizarre mitotic figures. Some lesions may include spindle cell forms either alone or mixed with the mononuclear cells and multinucleated giant cells. Pure spindle cell lesions resemble spindle cell sarcomas of diverse cell lineage. Confirmation of histiocytic lineage can only be achieved with IHC in these instances. Phagocytosis of red cells, leukocytes, and tumor cells occurs but is not prevalent in most forms of HS. However, in *hemophagocytic HS* this behavior is amplified. Neoplastic histiocytes manifest marked erythrophagocytosis, and the infiltrates obliterate the splenic red pulp and invade red pulp sinuses. Foci of extramedullary hemopoiesis (EMH) occur within and adjacent to the tumor infiltrates in the splenic red pulp. Simultaneous involvement of bone marrow is frequent, and erythrophagia is observed here as well; these cases are probably equivalent to hemophagocytic MH in recognition of the simultaneous involvement of multiple sites. In some instances the neoplastic infiltrates can be deceptively cytologically bland. The cytologic appearance can be asynchronous between sites (e.g., spleen and bone marrow), which can contribute to diagnostic ambivalence if only one site is evaluated. Invasion of splenic red pulp sinuses portends invasion of the hepatic sinusoids. In the early stages, liver metastases can easily be overlooked grossly and histologically, because histiocytic infiltrates creep along sinusoids and do not form discrete masses until later. Neoplastic histiocytes in hemophagocytic HS express a distinctive surface antigen profile much like that expressed by macrophages in splenic red pulp and bone marrow (see following).

187.1.3.3 Immunophenotypic Studies

MH and HS lesions express leukocyte surface molecules characteristic of DCs (CD1, CD11c, and MHC II). Diffuse expression of E-cadherin, Thy-1, and CD4 has not been observed in HS or MH in skin or other sites; this, together with cytomorphology, assists in the distinction of MH and HS from histiocytoma and reactive

histiocytosis (SH and CH). In histiocytoma the phenotype is quite similar to that of HS, except for the expression of E-cadherin, which occurs in histiocytoma (especially in the cellular infiltrate immediately adjacent to the epidermis). E-cadherin expression is visibly weaker in tumor cells in the deep dermis. In reactive histiocytosis, infiltration and proliferation of activated interstitial (dermal) DCs (CD1+, CD11c+, MHC II+, E-cadherin-), which consistently express CD4 and Thy-1 is observed.

In hemophagocytic HS, histiocytes express CD11d (instead of CD11c) and MHC II. Expression of CD1 molecules is uniformly low or occasionally moderate but with a patchy distribution. This phenotype is consistent with macrophage differentiation rather than DC differentiation, in which abundant expression of CD1 and CD11c is expected.

The exact sublineages of DCs involved in HS have not been determined in most instances. The most likely candidates include interdigitating DCs in lymphoid tissues and perivascular interstitial DCs in other involved tissues. Immunophenotyping and careful morphologic assessment should also avoid confusion of HS and MH with the large cell form of T-cell lymphoma (CD3+) and with poorly differentiated mast cell tumors (CD18+ variable, CD45+, CD45RA+, Tryptase+, c-kit+).

187.1.4 Reactive Histiocytosis

187.1.4.1 Systemic Histiocytosis

SH was originally recognized in related Bernese mountain dogs.[16] SH is a generalized histiocytic proliferative disease with a marked tendency to involve skin, ocular and nasal mucosae, and peripheral lymph nodes. The disease predominately affects young to middle-aged dogs (2 to 8 years). SH has been observed less commonly in other breeds (Irish wolfhounds, Basset hounds, and others). Clinical signs vary with the severity and extent of the disease and include anorexia, marked weight loss, stertorous respiration, and conjunctivitis with marked chemosis. Multiple cutaneous nodules may be distributed over the entire body but are especially prevalent in the scrotum, nasal apex, nasal planum, and eyelids. Ulceration of the skin overlying the nodules is common. Peripheral lymph nodes are often palpably enlarged. The disease course may be punctuated by remissions and relapses, which may occur spontaneously (especially early in the disease course). In severe disease, lesions become persistent and do not respond to immunosuppressive doses of corticosteroids.

781

782

187.1.4.2 Cutaneous Histiocytosis

CH is a histiocytic proliferative disorder that primarily involves skin and subcutis and does not extend beyond the local draining lymph nodes.[17] CH occurs in a number of breeds. Evidence of spread beyond the skin would invoke the diagnosis of SH—a closely related disorder. Lymphadenopathy has not been emphasized in published reports and has only been documented in a small number of the authors' cases. The lesions occur as multiple cutaneous and subcutaneous nodules up to 4 cm diameter. Overlying skin ulceration is common. Lesions may disappear spontaneously or regress and appear at new sites simultaneously. Topographically, lesions may be found on the face, ears, nose, neck, trunk, extremities (including foot pads), perineum, and scrotum.

187.1.4.3 Treatment Options in Systemic Histiocytosis and Cutaneous Histiocytosis

SH has proven to be a difficult and frustrating condition to treat. Consequently, many dogs were euthanized. Originally dogs were treated with thymosin (derived from bovine thymus) because of reports of its effectiveness in human LCH cases. Some dogs appeared to respond to this but not consistently. The original rationale for using thymosin was that SH was likely an immunoregulatory disorder and not cancer.[16] In the majority of instances, corticosteroid treatment is ineffective, although in about 10% of dogs with CH, steroid administration is effective. Hence, steroids are worth trying in this disease, given the expense of the alternatives.

Intractable cases are best treated with immunosuppressive doses of cyclosporine A (Neoral, Sandoz, East Hanover, NJ) or leflunomide (Arava, Aventis Pharmaceuticals, Bridgewater, NJ). These drugs are potent inhibitors of T-cell activation, and their ability to abrogate clinical disease supports the hypothesis that SH and CH are disorders of immune regulation. Treatment with these drugs is expensive and may be needed for life. It is preferable not to invoke such powerful immunosuppressive therapy until disease progression is evident or troublesome sites are involved, because in some cases of CH (and even SH) spontaneous regression of lesions or episodic disease activation can occur. Cost of treatment can be substantially reduced by coadministration of cyclosporine A and ketoconazole. It is imperative to measure 12-hour plasma trough levels of cyclosporine A (with twice-daily dosing); this is especially important if ketoconazole is coadministered! The 12-hour plasma trough target for cyclosporine A is 500 to 600 ng/mL. Neoral is the preferred cyclosporine A drug, because it is a microemulsion preconcentrate with superior gastrointestinal (GI) absorption compared with Sandimmune (Sandoz) (cyclosporine A in an olive oil base). Hence, Neoral can be used at a lower dose.[18]

187.1.4.4 Microscopic Features of Systemic Histiocytosis and Cutaneous Histiocytosis

The lesions of SH in most tissues consist of perivascular infiltrates of large histiocytes and variable populations of lymphocytes, neutrophils, and eosinophils. The histiocytes frequently invade vessel walls, and this may lead to vascular compromise and infarction of surrounding tissues, which contributes to ulceration of the cutaneous lesions. The widespread distribution of lesions of SH is only fully appreciated at necropsy. Histiocytic lesions have been observed in skin, lung, liver, bone marrow, spleen, peripheral and visceral lymph nodes, kidneys, testes, orbital tissues, nasal mucosa, and other sites.

In skin, the lesions of SH and CH are virtually identical. The lesions usually involve the deep dermis and subcutis. Involvement of the superficial dermis is inconsistent, and epidermotropism of the histiocytes is not observed. In CH the lesions are limited to the skin but may involve the draining lymph nodes.

187.1.4.5 Immunophenotypic Studies

Histiocytes in SH and CH express markers expected of DCs such as CD1, C11c, and MHC II. However, the lack of consistent epidermotropism in SH and CH lesions and the expression of Thy-1 (expressed by dermal DCs) and CD4 (a marker of DC activation) suggest that histiocytes in these diseases are activated interstitial-type DC[1]. In skin, dermal DCs are mostly of interstitial DC type. Expression of Thy-1 and CD4 in SH and CH clearly distinguishes these diseases from histiocytoma, in which an epidermal LC phenotype is observed. LCs are epithelial DCs; they express CD1, CD11c, MHC II, and E-cadherin. LCs lack expression of Thy-1 and do not express CD4 in the nonactivated state.

187.1.4.6 Pathogenesis

The clinical behavior and consistent clinical response to immunosuppressive therapy with agents capable of profoundly inhibiting T-cell activation has reinforced the concept that SH and CH occur in the context of disordered immune regulation arising from defective interaction of DC and T cells. The end result of this dysregulated immune interaction is chronic proliferation of DC and T cells. The initiation of the process is probably antigen driven, although studies to identify the nature of the antigens involved have been unrewarding. Hence, it is important to perform tests to rule out infectious agents in the initial evaluation of a dog suspected of having reactive histiocytosis (i.e., culture, special stains for microorganisms in tissue). The lesions can wax and wane over a considerable period of time, and spontaneous regression without therapy has been observed. The lymphoid component of the lesion consists of predominately CD8+ alpha beta T cells, which have numbers that can vary markedly between lesions. These T cells can comprise up to 50% of the cells in some instances. The role played by T cells is unknown. T cells may be involved in a key way in the exaggerated proliferation and activation of DCs via T-cell-derived cytokines such as GM-CSF and TNF alpha, which are known to influence the proliferation and differentiation of DCs.

187.1.4.7 Concluding Remarks

The continued distinction of SH and CH as separate entities is probably no longer justifiable. It would be preferable to consider them within the spectrum of reactive histiocytoses of interstitial DC origin, in which clinical outcome is predictable more by the distant migratory potential of the proliferating histiocytes beyond the skin. In this view, CH and SH would be regarded as skin-limited and systemic interstitial DC proliferations, respectively. A wide range of clinical behavior is to be expected within each grouping, with SH usually exhibiting more aggressive disease. CH and SH should not be confused with malignant DC disorders (HS and MH), which can occur in the same topographic locations. Cytologic and immunophenotypic differences can distinguish these diseases in most instances. Clear evidence of progression of reactive histiocystosis to HS or MH is not evident.

187.2 FELINE HISTIOCYTIC PROLIFERATIONS

True histiocytic proliferative diseases in cats have not been extensively documented. The lesion referred to as *malignant fibrous histiocytoma* is most likely a soft tissue sarcoma with giant cells; the neoplastic population does not express histiocytic markers. At least two different histiocytic proliferative diseases have been recognized in cats: (1) progressive histiocytosis and (2) HS/MH.

187.2.1 Feline Progressive Histiocytosis

Data on 19 cats with feline progressive histiocytosis have been accumulated since 1995. The incidence and recognition of cases seems to be increasing. Clinical presentation and progressive behavior resemble LCH in humans and multiple persistent histiocytomas or LCH in dogs. Affected cats may have a solitary skin nodule, but usually multiple papules, nodules, or plaques develop, measuring up to 1.5 cm in diameter. The nodules are firm, nonpruritic, and nonpainful. The surface is often alopecic and may be ulcerated. The lesions are mostly located on the head, lower extremities, or trunk. Occasionally, the lesions are limited to one extremity. Feline progressive histiocytosis is a disease of middle-aged to older cats, the age ranging from 7 to 17 years. Sex or breed predilection has not been seen. The lesions may wax and wane, but spontaneous regression does not occur. In general, the nodules progress in size and may coalesce to large plaques. In addition, new lesions may

develop. Some cats develop lesions in lymph nodes and internal organs including the lungs, kidneys, spleen, and liver. Additional clinical signs vary depending on the internal organ systems involved. Feline progressive histiocytosis has a guarded to poor long-term prognosis, because no successful treatment has been recognized to date.

187.2.1.1 Morphologic Features

Lesions consist of diffuse dermal histiocytic infiltrates, which may extend into the subcutis. The overlying epidermis is either intact or ulcerated. Histiocytes have irregular, vesicular nuclei and finely dispersed chromatin. Cytologic atypia is present in a minority of lesions. Multinucleated tumor cells and occasional intralymphatic tumor cell aggregates may be present. The mitotic activity varies, and atypical mitoses are seen. Some cases are epitheliotropic (epitheliotropic progressive histiocytosis), characterized by intraepidermal single cells or cell aggregates, other cases lack epithelial involvement (nonepitheliotropic progressive histiocytosis). As the lesions progress the cells may exhibit numerous cytoplasmic vacuoles and hence have a foamy appearance. The extent of reactive infiltrates, composed of dispersed lymphocytes and fewer neutrophils, varies between cases.

Feline progressive histiocytosis has to be differentiated from xanthomas and from multicentric round cell tumors, such as lymphomas and mast cell proliferations. Xanthomas often have small areas of hemorrhages and deposition of cholesterol crystals, and they are composed of markedly vacuolated macrophages. Xanthomas are usually associated with underlying metabolic disorders such as diabetes mellitus or hypertriglyceridemia. Cutaneous papular mastocytosis (urticaria pigmentosa) is usually composed of well-granulated mast cells and Toluidine blue or Giemsa stains demonstrate their metachromatic granules. However, IHC may be required to rule out xanthomas, lymphomas, or poorly granulated mast cell tumors (“histiocytic” mast cell tumors).

187.2.1.2 Immunophenotypic Studies

Histiocytes of feline progressive histiocytosis consistently express CD18, CD1a, CD1c, and MHC II. This immunophenotype is consistent with a DC origin.[4] However, both the epitheliotropic and nonepitheliotropic forms lack expression of E-cadherin, and Birbeck's granules could not be found in the only case evaluated by electron microscopy. These features indicate that feline progressive histiocytosis is not composed of Langerhans' cells, despite the existence of epitheliotropic infiltrates. The DCs are most likely of interstitial (dermal) type. The admixed reactive lymphocytes are CD8+ cytotoxic T cells.

187.2.2 Feline Histiocytic Sarcoma

Localized HS has been observed in cats. The poorly demarcated tumor masses were located in the subcutis of the ventral abdomen or the extremities. Metastasis to draining lymph nodes occurs. Alternatively, primary HS may occur in the spleen.[19] In essence, feline HS resembles the canine counterpart in terms of location of lesions and disease progression, but the incidence of feline HS is markedly lower. Feline HSs have a guarded to poor prognosis and most cats have been euthanized.

187.2.2.1 Morphologic Features

Feline HS shares morphologic features with canine HS, including variable cytology encompassing mononuclear and multinucleated round cells and discrete to aggregated spindle cells. Anisocytosis and

anisokaryosis exist in tumor cells of all types. A moderate to high mitotic rate with bizarre mitotic figures is common. IHC is required to differentiate between HSs and vaccine-induced sarcomas or anaplastic sarcomas with giant cells (incorrectly referred to as *malignant fibrous histiocytoma*).

187.2.2.2 Immunophenotypic Studies

The round and spindle-shaped tumor cells express CD18, CD1, and MHC II. This immunophenotype is consistent with a DC origin, although the precise sublineage of DC has yet to be determined. The tumor cells lack expression of E-cadherin and hence are not of Langerhans' cell origin.

188 CHAPTER • 188 Urogenital and Mammary Gland Tumors

Ruthanne Chun

Laura Garrett

188.1 KIDNEY

Renal tumors are uncommon in cats and dogs, but they are almost always malignant. The most common renal tumor in cats is lymphoma; up to 50% of these cats are FeLV positive. Affected cats are usually middle aged (6 years) with no breed or sex predilection. In dogs the most common primary renal tumors are epithelial in origin (i.e., carcinoma or adenocarcinoma). Older dogs are affected, with an average age of 9 years, and males are overrepresented (1.5:1). Rare tumors include cystadenocarcinoma with concurrent nodular dermatofibrosis in German shepherd dogs and tumors of embryonal origin (e.g., Wilm's tumor) that are typically recognized in younger dogs. Animals with renal tumors usually have nonspecific signs of weight loss, anorexia, and lethargy. Less commonly, they have abdominal distention, lameness, and pain. Gross hematuria is a possible but uncommon finding. Physical examination may reveal unilaterally or bilaterally enlarged kidneys. A rare physical examination finding in dogs is palpable thickening and warmth in the distal long bones—a finding compatible with the paraneoplastic syndrome of hypertrophic osteopathy. Renal cystadenocarcinoma may be associated with firm, nodular dermal lesions and benign uterine growths. The genetic determinant of this unusual triad has yet to be identified.

Diagnosis may be obtained via cytology, especially in cats with lymphoma. However, biopsy is the gold standard for definitive diagnosis of most renal tumors. Ancillary tests such as a complete blood count (CBC), serum chemistry profile, and urinalysis provide important information regarding the overall health of the pet and the presence of paraneoplastic syndromes. Animals with renal tumors may have either anemia or polycythemia secondary to decreased or increased erythropoietin production, respectively. Another rare paraneoplastic syndrome of uncertain etiology in dogs with renal adenocarcinoma is neutrophilic leukocytosis. Animals with bilateral disease may have renal failure, as evidenced by increases in BUN and creatinine and a low urine specific gravity. Although tumor cells are only infrequently recognized on evaluation of urine sediment, finding RBCs and proteinuria on urinalysis is common. Up to one third of dogs and cats with epithelial renal tumors have radiographic evidence of pulmonary metastases. Abdominal radiographs show renomegaly but abdominal ultrasonography is both more sensitive and specific for identifying renal tumors. Ultrasound may also be helpful in obtaining preoperative biopsy specimens. Renal carcinomas are often bilateral and biologically aggressive, invading into the vena cava and metastasizing to regional lymph nodes, liver and bone.

Treatment with chemotherapy is indicated for cats with renal lymphoma. In addition to being bilateral, this is typically a systemic disease. With treatment, the average survival time is 6 months.[1] A doxorubicin-based combination chemotherapy protocol is recommended with the caveat that doxorubicin may be associated with nephrotoxicity in cats and thus renal parameters should be closely monitored before, during, and after use of doxorubicin.[2] As central nervous system (CNS) involvement has been documented in cats with renal lymphoma, the addition of a drug that reaches effective concentrations within the CNS (e.g., cytosine arabinoside) into a multidrug protocol is recommended. Nephrectomy is the most effective treatment for dogs with unilateral tumors, with average survival of 6 to 10 months. Renal cystadenocarcinomas in German shepherds, although malignant and metastatic, progress more slowly than other renal malignancies and survival times may be longer.[3] Ovariohysterectomy (OHE) is indicated for treatment of the uterine leiomyomas if the animal is symptomatic for those lesions.

188.2 URINARY BLADDER

Tumors of the urinary bladder are uncommon in dogs and rare in cats. Transitional cell carcinoma (TCC) is the most common primary tumor of the urinary bladder in both species. Other differentials include squamous cell carcinoma, leiomyosarcoma, leiomyoma, and rhabdomyosarcoma. The bladder may also be invaded by prostatic neoplasia or metastatic disease (e.g., hemangiosarcoma, lymphoma). Bacterial cystitis and urolithiasis are common differentials for the clinical signs seen, and a rare but important differential diagnosis for mass lesions is benign polyps of the urinary bladder.

Affected cats are usually middle aged and male. No underlying causes have been identified in cats. Older (10 years) female dogs of small breeds such as West Highland white and Scottish terriers, beagles, Dachshunds, and Shetland sheepdogs are reportedly at higher risk. Potential etiologies in dogs include obesity, cyclophosphamide therapy, and organophosphate, carbamate, pyrethrin, or pyrethroid-based flea dips.[4,5] Client complaints of recurrent stranguria, pollakiuria, hematuria, dysuria, urinary incontinence, or any combination of the above signs in an older dog should initiate a search for bladder cancer. In advanced cases, a mass is palpable in the caudal abdomen or abnormalities, such as a thickened urethra or enlarged sublumbar or intrapelvic lymph nodes, are identified on rectal examination. TCC can also metastasize to the inguinal lymph nodes and thus palpation of the inguinal fat pads may reveal firm nodes. Rarely, dogs have shifting leg lameness, or warm, swollen, and painful limbs. Palpation of the affected limbs reveals a firm, irregular, periosteal proliferation—a finding suggestive of hypertrophic osteopathy.

Diagnostic evaluation of any animal with the above clinical signs should begin with careful abdominal palpation and a rectal examination. CBC and biochemistry may be normal or may show azotemia. The urine sediment may reveal carcinoma; the presence of inflammation may cause “reactive” epithelial cells to exhibit criteria of malignancy. When a bladder tumor is suspected, urinalysis should be obtained by free catch, catheterization, or ultrasound-guided cystocentesis, with caution to avoid penetrating the bladder through the tumor mass. Ideally, urine culture and sensitivity should be performed to rule out concurrent lower urinary tract infection. Unless the lesion is mineralized, abdominal radiographs will not reveal urinary bladder disease but may show sublumbar lymphadenomegaly or bony metastases. Although contrast cystography may be indicated for identification of urethral involvement, imaging of the urinary bladder via double contrast cystography has been widely replaced by ultrasonography. Ultrasound (Figure 188-1) is a highly sensitive tool in localizing and defining the extent of disease and for monitoring response to therapy.[6] Cytology may be diagnostic, with the finding of characteristic pink, intracytoplasmic transitional bodies (Figure 188-2). Failing a cytologic diagnosis, biopsy (traumatic catheter, surgical, or cystoscopic) and histologic examination may be necessary. Ultrasound-guided biopsy is not recommended as seeding of the biopsy tract with viable tumor cells is a possible complication.[7]

784
785

TCC often involves the apex of the bladder in cats. As this tumor is uncommon, the disease may go undiagnosed until it is diffusely invasive. However, even in cases of extreme local invasion, metastatic disease is not a common finding. In dogs, TCC typically involves the trigone. Obstruction of the ureters and urethra as well as invasion and disruption of the normal function of the urethral sphincter are common. TCC in dogs is metastatic; up to 40% of cases show spread by the time of diagnosis, 17% involve the lungs.[8]

Localized cases of TCC are treated with surgical resection if possible. TCC is highly exfoliative; caution is warranted to avoid “seeding” the tumor into the abdomen or along the surgery site.[9] The use of stay sutures to lift the bladder out of the abdominal cavity and moistened gauze sponges to pack off the rest of the abdomen can greatly decrease the risk of tumor seeding. Instruments and gloves that touch the tumor are contaminated. Once the

tumor is exposed, use “clean” instruments to resect the tumor, switch gloves and use “clean” instruments to close the abdomen. Because the trigone region is most commonly involved in dogs, complete resection with acceptable postoperative function is rarely feasible. Most dogs with TCC should be managed medically or, less commonly, with radiation therapy.

Although no published studies discuss the medical management of TCC in cats, treatment of dogs is well described. Single agent therapy with piroxicam or cisplatin has a response rate of 20% with median survival times of 6 months.[10,11] Other studies report that single agent mitoxantrone or the combination of doxorubicin and cyclophosphamide have some activity.[12,13] Although cisplatin and piroxicam combination therapy has a response rate of 70%, 12 of 14 dogs treated with this protocol went into renal failure; most required early termination of their therapy and, in spite of the impressive response rate, median time to tumor progression or death was 4 months.[14] Mitoxantrone and piroxicam combination therapy has a response rate of 35% with a median survival time of 11½ months.[15] The current treatment recommendations are either single agent therapy with piroxicam (0.3 mg/kg orally once daily), or combination therapy of piroxicam and mitoxantrone (5 mg/m^2 IV every 21 days) with response to therapy used as a guideline for continued treatment.

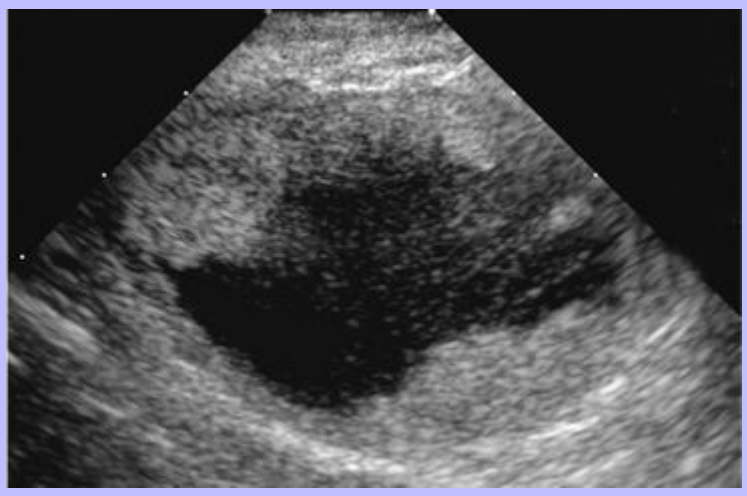

Figure 188-2 Large clustering epithelial cells showing criteria of malignancy from a male neutered Scottie with a urinary bladder mass, note transitional bodies *(arrows)*. Sample obtained via traumatic catheterization. (20×, Diff Quick stain.)

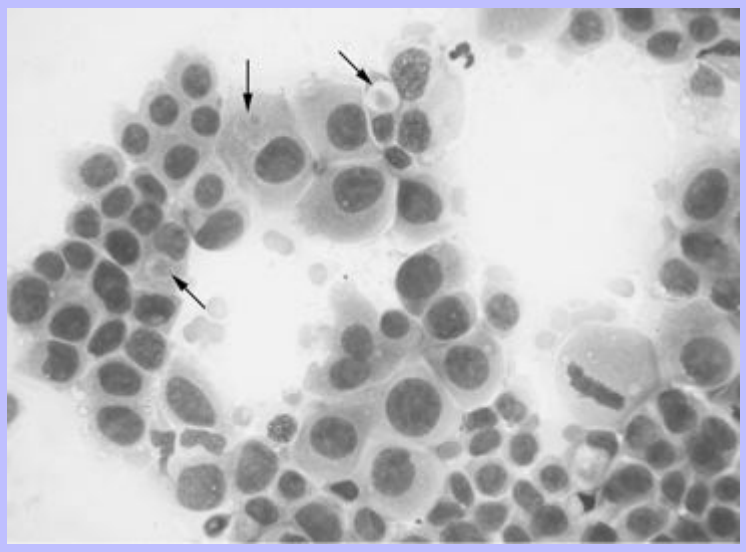


Although radiation therapy may also play a role in the management of TCC, survival times are not reported.[16] Surgical palliation for TCC obstructing the urethra ranges from ureterocolonic anastomosis to tube cystostomy. Ureterocolonic anastomosis has been described but this procedure is commonly associated with neurologic and gastrointestinal complications secondary to hyperammonemia, metabolic acidosis, and uremia, as well as chronic pyelonephritis, and survival times following this procedure ranged from only 0 to 5 months.[17] A tube cystostomy is a much simpler and better tolerated procedure that allows pets to survive an average of 3 months beyond when they would have been euthanized for urethral obstruction.[18] With disadvantages limited to recurrent urinary tract infections and occasional mechanical complications (e.g., tube is pulled out, animal chews through tube), the tube cystostomy is an excellent palliative option.

188.3 PROSTATE

Prostatic tumors are rare in dogs and are even less common in cats. Older, neutered, or intact dogs are typically affected. The most common histologic types are prostatic adenocarcinomas (ADC) and TCC, with many tumors having features of both.[19] Clinical signs include stranguria, hematuria, weight loss, tenesmus, rear limb lameness/pain, lumbar pain, and polyuria/polydipsia. Important differentials to consider are benign prostatic hypertrophy, prostatic cyst, prostatic abcess, and prostatitis. Prostatic carcinomas are aggressive; the majority of dogs have metastatic disease at the time of diagnosis. Metastases may be seen in the regional lymph nodes, vertebral bodies, or lungs.

Figure 188-3 Lateral abdominal radiograph of a male neutered sheltie dog with prostatic carcinoma, note the irregular proliferative changes along the ventral aspects of lumbar vertebral bodies 5 through 7. (Courtesy David Biller, Kansas State University.)

Diagnostic evaluation should begin with a rectal examination. A neoplastic prostate is usually asymmetric, fixed, and firm. Careful rectal palpation for intrapelvic lymph node enlargement is also warranted. The CBC, chemistry profile, and urinalysis do not usually have pathognomonic findings; however, malignant cells may be observed occasionally in the urine sediment. As with any evaluation for metastatic disease, three view thoracic radiographs are recommended. The finding of mineralization in the prostate on abdominal radiographs or ultrasound is suggestive of neoplasia. Other areas that should be examined closely on abdominal radiographs and/or ultrasound include sublumbar lymph nodes and lumbar vertebrae (Figure 188-3), as these are common areas for metastases. Samples for cytologic examination may be collected via traumatic catheterization, prostatic massage, or transrectal needle aspiration. Although ultrasound guided aspiration of the prostate provides an accurate sampling technique, there is a possibility of seeding the tumor with this procedure.[7] Cytology is often diagnostic for malignancy but histologic examination remains the gold standard for diagnosis. Tissue may be obtained surgically or via ultrasound-guided biopsy, but caution is warranted as ultrasound-guided techniques may result in tumor seeding.

Curative treatment has not been identified for prostatic carcinomas. Castration is not beneficial. Palliative therapies including either tube cystostomy or piroxicam (0.3 mg/kg orally once daily) may provide up to 6 months of survival. The role of radiation therapy for the treatment of prostatic cancer is under investigation and seems promising, but the actual value of this therapy in prolonging survival is undefined. The overall prognosis for animals with prostatic neoplasia is guarded.

188.4 PENIS AND PREPUCE

The prepuce is affected by tumors that occur on haired skin elsewhere (e.g., mast cell tumor, squamous cell carcinoma). As with other cutaneous sites, evaluation of regional lymph nodes (i.e., inguinal and sublumbar lymph nodes) is an important component of the diagnostic examination. For the majority of penile and preputial tumors

the diagnostic evaluation and treatment is the same as for other locations. Mast cell tumors tend to be more aggressive when arising on the prepuce, and thus even lower grade mast cell tumors in this location may require systemic chemotherapy for effective management.

The most common penile neoplasm is transmissible venereal tumor. This round cell tumor rarely metastasizes, is readily diagnosed via cytology, and is usually curable with vincristine (0.5 mg/m^2 IV weekly).[20] The number of treatments required varies between cases. Lesions tend to resolve within 2 weeks of the first treatment, but therapy should be continued for a minimum of 2 doses beyond complete visible resolution. Lesions that are resistant to chemotherapy may be successfully treated with radiation therapy.

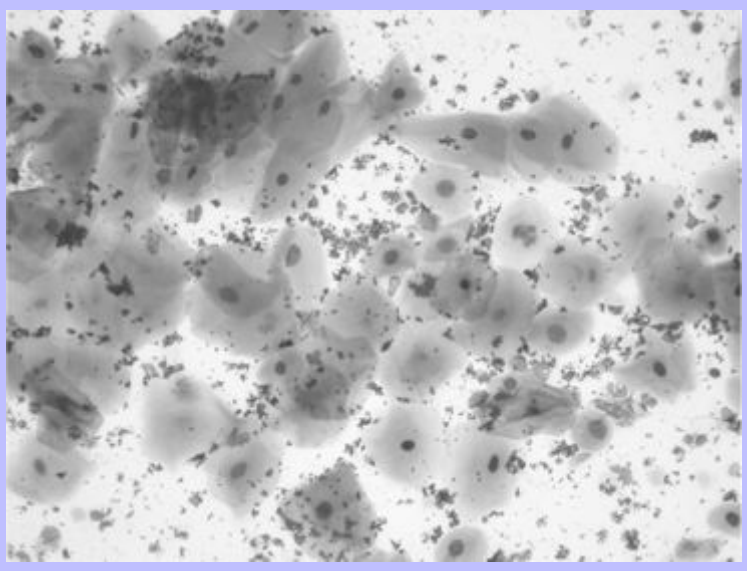
188.5 TESTICLE

Testicular tumors are the second most common tumor of the male dog but are extremely rare in cats. Middle-aged to older dogs (9 to 11½ years) are affected. The three main histologic types seen include Sertoli cell, seminoma, and interstitial cell tumor. These tumors occur with roughly the same frequency, but cryptorchid individuals have 13.6 times greater risk of developing a Sertoli cell tumor or seminoma, and animals can be affected at a younger age. Roughly 25% to 50% of Sertoli cell tumors are functional and can cause hyperestrogenemia. The Sertoli cell tumor is also the type most likely to metastasize, usually to regional lymph nodes, but still with a low rate of 2% to 14%.

Although most testicular tumors are incidental findings on physical examination, clinical signs may include decreased libido, signs of prostatomegaly (e.g., stranguria or tenesmus), and inappetance and/or weakness secondary to anemia. Asymmetric testicles, scrotal or inguinal swellings, prostatomegaly, or signs of hyperestrogenism including alopecia, gynecomastia, a pendulous prepuce, and a poor haircoat may be seen on physical examination. Both testes are palpated simultaneously to compare size, shape, and firmness. A rectal examination should also be performed on these dogs; prostatomegaly secondary to estrogen-induced squamous metaplasia (Figure 188-4) is common.

Evaluation of dogs with testicular tumors should include a CBC with a platelet count and evaluation of regional lymph nodes via radiographs and/or ultrasonography with fine needle aspiration if indicated. Bone marrow suppression is a rare complication of hyperestrogenism. This syndrome is characterized initially by thrombocytopenia and neutrophilic leukocytosis, which ultimately progresses into pancytopenia. As pulmonary metastases are extremely rare, thoracic radiographs may not be cost effective as a staging test; however, they may be indicated for evaluation of concurrent disease in these older patients.

Figure 188-4 Squamous metaplasia of prostatic cells from a mixed-breed cryptorchid dog with a Sertoli cell tumor. Sample acquired via traumatic catheterization, debris in background is lubricating jelly. (20×, Diff Quick stain.)



Castration is curative for most testicular tumors. Scrotal ablation may be necessary if the tumor is fixed to scrotal skin. If the affected testicle is cryptorchid caution is warranted during surgery as the testicle may be friable. Any enlarged lymph nodes should be biopsied and ideally excised at the time of surgery. Cisplatin has been reported to be of benefit in a small number of dogs with metastatic disease.[21] Radiation has been used to treat sublumbar lymph node metastases in patients with seminoma.[22] If estrogen-induced myelosuppression has occurred, the patient may require months of hematologic support; some dogs with such myelosuppression never recover.

188.6 VAGINA AND VULVA

Tumors of the vagina and vulva are the second most common reproductive tumors in female dogs but are extremely rare in cats. Most are benign smooth muscle tumors that arise within the vestibule and occur in older intact dogs, with an increased incidence in nulliparous bitches. Histologic terminology used for these benign tumors includes leiomyoma, fibroleiomyoma, fibroma, or polyp, depending on the amount of connective tissue present in the mass. Lipomas may also be seen in this area. Malignant tumors are rare, with leiomyosarcoma the most likely. Transmissible venereal tumors may also occur (Figure 188-5).

Tumors may be intraluminal or extraluminal. Intraluminal tumors are often associated with stranguria; owners may see the mass protrude during urination or defecation. Other possible clinical signs include bleeding, discharge, dysuria, and licking. Extraluminal tumors are usually slow-growing perineal masses. Diagnostic evaluation of any straining dog should include a rectal and vaginal examination. For intraluminal masses, cytology can often be performed from an impression smear made by gently scraping the mass with a gloved fingertip. Fine needle aspirates can be performed on extraluminal masses or on intraluminal masses that do not exfoliate with the

digital technique. Other diagnostic tests include vaginoscopic exam to determine the local extent of disease as well as abdominal radiographs and/or abdominal ultrasound to evaluate for lymph node involvement.

Figure 188-5 Large, irregular friable vaginal TVT protruding from vulva of mixed breed intact dog.

Chemotherapy with vincristine as described above is the treatment of choice for bitches with TVT, for all other types of vaginal tumors surgical resection and OHE is usually curative. OHE is recommended for these hormonally responsive tumors as recurrence is likely in dogs treated with mass removal only. Excise intraluminal tumors at the pedicle; wide excision is not needed. Approach extraluminal tumors via dorsal episiotomy; these tend to be well encapsulated and are easy to resect.

188.7 UTERUS

Uterine tumors are rare in dogs and cats, likely because the vast majority of female dogs and cats under veterinary care within the United States have undergone OHE. In dogs the majority of uterine tumors are mesenchymal; 85% to 90% are leiomyomas and 10% are leiomyosarcomas. German shepherd dogs may be overrepresented in the literature due to the well-described syndrome of renal cystadenocarcinomas and associated uterine leiomyomas.[23] As expected with their benign nature, most uterine tumors in dogs are slow-growing, non-invasive into surrounding structures, and not metastatic. In cats uterine adenocarcinoma is the most common primary tumor of the uterus, a disease associated with an aggressive biologic behavior and widespread metastases.

Although clinical signs in dogs may be organ-related, such as vaginal discharge or evidence of pyometra, uterine tumors are more commonly an incidental finding. Cats may have specific signs of discharge or suspected

pyometra, or they may have signs related to metastatic disease (e.g., pulmonary distress, lymphadenopathy, anorexia).

Diagnostic evaluation of animals with suspected uterine tumors should include a minimum database to establish overall metabolic status as well as thoracic and abdominal radiographs and abdominal ultrasound. A technique that may be useful in imaging uterine tumors if ultrasound is unavailable is compression radiography.[24] This procedure employs the use of a radiolucent device (e.g., a wooden or plastic spoon or paddle) to apply pressure to the area of interest during the making of a radiograph, increasing visualization of the region by moving overlying structures out of the way. Ovariohysterectomy is often curative for dogs, but due to the aggressive biologic behavior in cats OHE alone is unlikely to provide long-term control. Although the efficacy of chemotherapy in both dogs and cats remains largely unknown, one case report describes the successful use of OHE followed by epirubicin in a young dog with a uterine carcinoma.[25] Thus anthracycline based chemotherapy may be efficacious in the rare cases of uterine malignancy.

188.8 OVARY

Similar to uterine neoplasia, ovarian tumors are rare in dogs and cats, again in part related to the high rate of neutering in companion animals. Asymptomatic ovarian tumors are most commonly found during routine OHE in older animals; an important differential in this situation are ovarian cysts. However, as some ovarian tumors are malignant, any abnormal ovary should be submitted for histologic examination. Specific clinical signs associated with ovarian tumors include a palpable mass, signs of ascites, or systemic effects of hormone production. These tumors may attain a large size prior to detection. Three categories of ovarian tumors are seen, depending on the cell of origin of the neoplasm: epithelial, germ, and sex-cord stroma.[26] All three of these categories include benign and malignant forms. The malignant forms may metastasize to the peritoneum and can cause a malignant effusion; metastases are also seen in the lymph nodes, liver, and lungs.

787 788

In dogs, roughly one half of ovarian tumors fall into the epithelial category and include the histologic diagnoses of papillary adenoma, cystadenoma, papillary adenocarcinoma, and undifferentiated adenocarcinoma. These tumors can occur bilaterally, are rarely functional, and have malignant forms with a metastatic rate of approximately 50%. Epithelial tumors are rare in cats.

Germ cell tumors make up roughly 10% of ovarian neoplasms in dogs, are rarely bilateral or functional, have a metastatic rate of 10% to 30%, and may be seen in young as well as older animals. These tumors are further categorized into three histologic types: dysgerminomas, teratomas and teratocarcinomas. Dysgerminomas (i.e., ovarian seminomas) arise from undifferentiated germ cells and have a similar histologic appearance to their testicular counterpart. Teratomas are made up of more than one germ cell layer (ectoderm, mesoderm, and/or endoderm) and the majority are well differentiated. Teratocarcinomas have differentiated and undifferentiated components; metastatic lesions are composed of the undifferentiated components and have been reported in the abdomen, lung, mediastinum, and bone. In cats approximately 15% of ovarian tumors are dysgerminomas; these may occur bilaterally and are malignant.

Sex-cord stromal tumors make up 35% to 50% of ovarian tumors, are rarely bilateral, are functional in approximately 50% of cases, and have a metastatic rate of less than 20%. These tumors can produce estrogen and progesterone. Clinical signs seen may be related to estrogenic effects (e.g., vulvar enlargement, vaginal discharge, persistent estrus) or progesterone effects (e.g., pyometra). The most common sex-cord stromal cell tumor is the granulosa cell tumor; this is the only tumor in this category that can metastasize. Less commonly, the benign thecoma or luteoma may be diagnosed. In cats germ cell tumors make up roughly 50% of ovarian tumors; greater

than 50% of these are malignant. The most common histologic type in cats is granulosa cell tumors, and hyperestrogenism is commonly seen.

Diagnostic evaluation of dogs or cats with ovarian tumors should include a minimum data base, thoracic radiographs, and abdominal radiographs or ultrasound. If ascites is present, cytologic examination of the fluid may be diagnostic for malignancy. The ultrasonographic characteristics of ovarian tumors in dogs has been reported, with the tumors ranging from solid to cystic in appearance.[27] Uterine changes (i.e., findings consistent with cystic endometrial hyperplasia or pyometra) were commonly found with sex-cord stromal tumors.

Treatment of ovarian tumors relies primarily on OHE and carries, in general, an excellent prognosis. In the rare cases of peritoneal metastases or malignant ascites, intracavitary chemotherapy may be of benefit.[28]

188.9 MAMMARY GLAND

Mammary gland tumors (MGT) are the third most common tumor overall in cats and one of the most common tumors in female dogs. Older females of either species are more likely to develop these tumors. Breeds at risk include Siamese; Poodles; English, cocker, and Brittany spaniels; English setters; and fox and Boston terriers. A hormonal etiology is well described for dogs and is likely for cats. Ovariohysterectomy can greatly decrease the risk of developing mammary gland tumors. Dogs spayed before their first estrus have a risk of 0.5%, after their first estrus the risk jumps to 8%, and after their second estrus the risk goes to 26%. There is no protective effect if dogs are spayed after their third estrus cycle. Estrogen and progesterone receptors have been identified in dog and cat MGT; for dogs the less well differentiated the tumor the more likely the tumor is to be hormone receptor negative. Prolonged administration of estrogens to dogs does not increase the incidence of MGT, although progesterone administration may result in benign nodule formation. However, there is an association between the use of megestrol acetate and the development of MGT in cats.[29]

On physical examination, animals may have single or multiple nodules associated with the nipple or the gland itself. Benign lesions tend to be small, well-circumscribed, and firm on palpation. The caudal mammary glands are most often involved in dogs; feline tumors occur with equal frequency in all glands. MGT may be freely movable or adherent to the skin or abdominal wall. They may be ulcerated (Figure 188-6), inflamed and edematous, or associated with discharge from the nipple. Differentials for MGT include other neoplasms (e.g., mast cell tumors, squamous cell carcinoma), mastitis, lobular hyperplasia, and fibroepithelial hyperplasia in cats.

Diagnostic evaluation of animals with mammary neoplasia should include a CBC, chemistry profile, and urinalysis. Cytologic evaluation of the mass is warranted. Although cytology cannot generally differentiate benign from malignant lesions, it can be helpful in ruling out other differentials. Also, cytology may be diagnostic if strong criteria of malignancy are present. Thoracic radiographs are important to evaluate for pulmonary metastatic disease and sternal lymphadenopathy. Pleural effusion, a common occurrence in cats with metastatic MGT, may also be identified. Assessment of inguinal, sublumbar, mesenteric, and pelvic lymph nodes is an important component of thorough staging. These nodes can be evaluated via physical and rectal examination, fine needle aspiration, and abdominal radiographs, or ultrasound. Biopsy of the mammary mass, typically excisional, will provide a definitive diagnosis.

In dogs 50% of MGT are benign, most often fibroadenomas (i.e., benign mixed tumor). The most common types of malignancies in dogs are solid carcinomas, followed by tubular adenocarcinomas; only about 3% are sarcomas and 1% are inflammatory carcinomas. Of the 50% that are malignant, 50% will recur or metastasize following the first surgical resection. Poor prognostic factors for survival in dogs with MGT include histologic type (poorly differentiated tumors, sarcoma, and inflammatory carcinomas have a worse prognosis), tumor size greater than 3

cm, lymph node involvement, histologic evidence of lymphatic or vascular invasion, minimal to no lymphocytic infiltration into the tumor, ulceration, and distant metastases.

Figure 188-6 Large multi-lobulated and ulcerated MGT in a spayed female domestic shorthaired cat.

The majority of feline MGT are malignant, most often adenocarcinomas, and they exhibit highly metastatic behavior. Prognosis depends primarily on tumor size at the time of diagnosis. Tumors less than 2 cm in diameter are associated with survival times over 3 years, whereas tumors larger than 3 cm are associated with survival times of 4 to 6 months. The type of surgery performed (see below) has been shown to be prognostic for disease free interval but not for survival time.

Surgery is the mainstay of treatment of MGT in dogs and cats. A major contraindication to surgery is in the case of inflammatory carcinomas, as it is virtually impossible to remove the entire tumor and regrowth may occur within days of the surgery. In dogs with MGT the goal of surgery is to remove the entire tumor by the simplest procedure possible. For example, a “lumpectomy” is acceptable for a small (less than 1 cm diameter) and superficial mammary nodule, whereas lesions 1 to 2 cm in diameter may require a mammectomy. If masses are present in multiple glands, they may be resected individually or in a chain mastectomy, again choosing the surgery based on the easiest way to remove all affected tissue. As malignant MGT do rarely express estrogen or progesterone receptors, there is theoretical benefit to spaying the pet; however, no controlled studies have shown an actual therapeutic benefit of OHE at the time of mammary tumor excision. OHE may be recommended at the time of mastectomy to prevent ovarian or uterine diseases in the future. As described above, the majority (75%) of canine mammary gland tumors can be cured with surgery alone. In cats, full chain mastectomy (i.e., removal of all five glands on one side without removal of underlying musculature) is recommended, with bilateral staged mastectomy for bilateral disease. Cats with minimal resections reportedly had recurrent disease sooner than cats with a full mastectomy but had similar survival times. Radiation therapy is not routinely used for this disease in dogs or cats.

Little information is available regarding the efficacy of chemotherapy for canine or feline MGT. In dogs with malignant mammary tumors and the presence of poor prognostic factors, a doxorubicin or doxorubicin/cyclophosphamide protocol is the conventional treatment. Recently, a 5-FU/cyclophosphamide protocol was shown to be of benefit in a small case series. Additionally, piroxicam has been shown to have some effect against this disease and may be particularly indicated for inflammatory carcinomas. Since the vast majority of feline mammary tumors are malignant and metastatic, chemotherapy postoperatively is recommended. As in

dogs, single agent doxorubicin or a doxorubicin-based protocol is used. 5-FU should not be administered to cats as the drug is associated with neurotoxicity.

189 CHAPTER • 189 Paraneoplastic Syndrome

Frédéric P. Gaschen

Erik Teske

Paraneoplastic syndromes (PNS) result from indirect effects of tumors due to the production and release of biologically active substances such as hormones, growth factors, and cytokines. The immune system may be affected, and autoimmunity, immune complex production, or immune suppression can occur. Occasionally, PNS may have a higher morbidity than the original tumor itself.

PNS are divided in different categories depending on their target organ. They include endocrinopathies, disorders of hematopoiesis and hemostasis, neuromuscular disorders, and cutaneous syndromes. Cancer cachexia is usually treated separately as it affects multiple organ systems.

A timely detection of PNS is essential for several reasons: (1) they may be the first clinical manifestation of tumor, and early diagnosis may improve the prognosis for the underlying neoplasia; (2) the severity of the PNS can reflect the activity of the tumor cells, and give information on the progressive or regressive nature of the tumor; (3) the clinical signs caused by a PNS could be falsely interpreted as direct effects of the tumor itself or side effects of treatment, and lead to false prognostic considerations; (4) finally, PNS may affect the general condition of the animal, and significantly alter the prognosis of a specific tumor.

189.1 GENERAL MANIFESTATIONS OF CANCER

189.1.1 Cancer Anorexia-Cachexia

The cancer anorexia-cachexia syndrome (CACS) affects more than one half of all human cancer patients and represents the most common paraneoplastic disorder. A decline in body weight of more than 10% in these patients negatively influences survival, in part due to secondary infections and wound healing complications.[1,2] In addition to CACS, anorexia and weight loss are often compounded by the side effects of treatment in cancer patients. Although no comparable epidemiologic data are available in small animal oncology, CACS is also recognized in canine and feline cancer and is likely to adversely affect prognosis.

Anorexia, nausea, and weight loss clinically characterize CACS. In contrast to wasting due to severe starvation, a massive decrease in muscle protein mass accompanies body fat depletion in CACS. In addition to wasting, this syndrome is frequently accompanied by changes in food perception (taste, smell), which diminishes the pleasure of eating. The metabolic alterations associated with CACS are, at least in part, mediated by the production of substances such as IL-1β, TNF-α, IL-6, IFN-γ, and serotonin by both the tumor and the host immune system.[1] The pathophysiologic mechanisms triggered by these cytokines include alterations in carbohydrate, fat, and protein metabolism as well as in energy expenditure.

Several studies have investigated the metabolic alterations associated with lymphoma in dogs. Abnormalities in *carbohydrate metabolism* include an increased concentration of insulin and lactate in response to an intravenous glucose challenge[3], which does not resolve when complete clinical remission following doxorubicin chemotherapy is achieved.[4] Moreover, intravenous infusions with lactated Ringer's solution seem to exacerbate this aberration and should therefore be avoided in canine lymphoma patients.[3] The authors of these studies

concluded that an insulin receptor or post-receptor defect is present in dogs with lymphoma, and that hyperlactatemia is the result of preferential anaerobic glucose metabolism by lymphoma cells. Large amounts of lactate produced by anaerobic glycolysis in tumor cells are then reconverted into glucose via the hepatic Cori cycle, which creates a futile energy-consuming cycle for the host.[2]

Abnormalities in *lipid metabolism* associated with CACS result in severe loss of body fat. Decreased lipoprotein lipase activity impedes the extraction of fatty acids from plasma lipoproteins by adipocytes. Moreover, increased hormone-dependent lipase activity, which acts in concert with a recently isolated lipid mobilizing factor in some tumors, contributes to lipolysis and lipid mobilization.[5] In dogs with lymphoma, lipoprotein profiles were found to be altered and did not improve following complete remission with doxorubicin therapy.[6]

Studies on *resting energy expenditure* (REE) in cancer patients have yielded disparate results. Although some tumors in humans are associated with an increased REE, others are not. Similarly, despite a decreased REE observed in canine lymphoma patients, dogs with osteosarcoma (OSA) were found to have a higher REE before limb amputation than healthy controls.[7] In addition to the abnormalities in glucose metabolism, an altered expression of uncoupling proteins has recently been postulated to be an important determinant in the increase in REE associated with cancer. Uncoupling proteins are mitochondrial membrane proteins that impede the coupling of respiration to ADP phosphorylation, which results in the generation of heat instead of ATP.[5]

The effects of CACS on *protein metabolism* encompass both increased protein catabolism and decreased protein synthesis and result in significant muscle atrophy. Dogs that suffer from OSA were found to have a negative nitrogen balance following limb amputation.[7] In these animals, the rate of protein synthesis was only 72.4% that of healthy dogs, whereas the urinary nitrogen excretion was 65% greater.[7] The role of cytokines, such as TNF-α, IL-6, and IFN-γ, as mediators of muscle catabolism and abnormal protein metabolism has been called into question, and these substances may merely serve as markers of these phenomena. Moreover, a recently isolated circulatory skeletal muscle proteolysis-inducing factor (PIF) is thought to play a central role in eliciting cancer-associated protein catabolism. Indeed, human cancer patients with severe weight loss were found to frequently excrete PIF in their urine.[5]

The objectives of nutritional support in cancer patients are to limit the adverse effects of CACS and enhance immune system function as well as the response to and tolerance of cancer therapy. Recently, a diet rich in polyunsaturated omega-3 fatty acids was found to have beneficial effects on the disease-free interval and survival of dogs with stage-III lymphoma treated with doxorubicin.[8] This fish-based diet was also associated with a more rapid decline in circulating levels of the inflammatory cytokines IL-6 and TNF following treatment. Moreover, insulin resistance and hyperlactatemia diminished to a greater extent and more rapidly in dogs fed with this diet than in control animals.[8] In addition to aspects of diet composition, current treatment recommendations for CACS in human patients emphasize the advantages of gastrointestinal over parenteral nutritional support.[1]

The metabolic alterations responsible for CACS are usually present in cancer patients long before clinical signs of CACS are recognized. This implies a need for early nutritional support. In persistently anorectic animals, naso-esophageal, esophagostomy, or gastrostomy tubes are recommended to administer food safely and provide adequate nutrients. Most pharmacologic interventions aimed at prevention of weight loss in human cancer patients have thus far been largely unsuccessful and are unlikely to be beneficial in veterinary cancer patients.[1,2]

189.1.2 Fever

Although common in human cancer patients, fever is rarely a genuine PNS. In patients with neutropenia, fever is often the consequence of an infectious process. Paraneoplastic fever is generally suspected in human patients who are not neutropenic, and those affected by certain neoplasms, including renal cell carcinoma, hepatoma, and non-Hodgkin's diseases.[1] The pathomechanisms of paraneoplastic fever include the elaboration of pyrogenic cytokines by the tumor and/or host immune system. In particular, IL-1, IL-6, and TNF may act as endogenous pyrogens on the thermoregulatory center of the anterior hypothalamus. Despite the lack of studies on the prevalence of paraneoplastic fever in dogs and cats, numerous case reports and experience indicate that it also occurs in small animals.

189.2 HEMATOLOGIC PARANEOPLASTIC SYNDROMES

Tumors, or their metastases, can have profound effects on hematopoietic cell lines by infiltration of the bone marrow. Further suppression of the bone marrow can be caused by treatment with cytostatic drugs. In addition to these direct effects on the bone marrow, mechanisms involved in PNS sometimes have even more serious effects on hematopoiesis, which may be better understood when data from ongoing research on hematopoietic growth factor are available.

189.2.1 Anemia

Anemia is one of the more common PNS in dogs and cats. Although exact figures are not available for all tumor types, anemia has been reported to occur in 30% to 40% of dogs with malignant lymphoma and up to 69% of those with splenic hemangiosarcoma. Different mechanisms are involved: anemia of chronic disease, immune-mediated hemolytic anemia, myelophtisis, blood loss, and microangiopathic hemolytic anemia.[9]

Anemia of chronic disease (ACD) is caused by shortening of the erythrocyte life span and is a mild, normocyticnormochromic, nonregenerative anemia. It is not associated with particular types of cancer and its cause is unknown. The characteristic features of ACD are disordered iron metabolism as manifested by a low serum iron, decreased serum transferrin, decreased transferrin saturation, increased serum ferritin, increased reticuloendothelial iron stores, and reduced iron absorption.[9] In humans, erythropoietin production is usually normal but the responsiveness of erythroid progenitor cells to the hormone is impaired by inflammatory cytokines. The anemia is mild and disappears after treatment of the tumor.

When *immune-mediated hemolytic anemia* (IMHA) occurs as a PNS in dogs and cats, it is usually associated with hematopoietic tumors, especially lymphoid malignancies and less frequently with solid tumors. Cross-reacting antibodies against cell-membrane antigens or direct interference with the immune system through suppressor T-cells lead to a premature destruction of red cells by the reticuloendothelial system.

790

791

The anemia can be acute or chronic, mild or severe and is regenerative in most cases. The most common clinical signs are lethargy, weakness, pale mucous membranes, icterus, hepatosplenomegaly, hemoglobinuria, and anorexia. Diagnosis is made by a direct antiglobulin test for detection of erythrocyte-bound immunoglobulin (IgG and IgM) and complement (C3). Treatment with corticosteroids, with or without immunosuppressive agents such as azathioprine or cyclophosphamide, has been evaluated mainly in dogs with primary idiopathic IMHA, but not in cancer patients. Elimination of the primary tumor remains as the most important factor for control of the IMHA.

Blood loss anemia associated with paraneoplastic gastroduodenal ulceration occurs with mast cell tumors and gastrinomas as well as primary gastrointestinal neoplasms. The anemia is initially regenerative but becomes nonregenerative, microcytic, and hypochromic, accompanied by decreased serum iron concentration and increased iron-binding capacity. Blood loss anemia occurs with some renal tumors and with any tumor in which bleeding occurs, such as splenic or hepatic tumors. Treatment should be directed at the primary tumor. Supportive treatment with transfused blood and oral ferrous sulfate is usually not necessary in animals with chronic blood loss, unless they undergo surgery for the tumor.

Microangiopathic hemolytic anemia is usually associated with microvascular tumors but can occur with any tumor that leads to disseminated intravascular coagulation (DIC). Fragmentation of erythrocytes can be caused by abnormal vascular structures with fibrin deposits, fibrin threads formed in the course of DIC, pulmonary intraluminal tumor emboli, or narrowing of pulmonary arterioles by intimal proliferation.[10] Hemangiosarcoma is the most frequent tumor associated with this type of anemia in dogs.

189.2.2 Erythrocytosis

Erythrocytosis, or polycythemia, is a rare PNS in dogs and cats. It is usually associated with primary or secondary tumors of the kidney, but it has also been documented in dogs with nasal fibrosarcoma, bronchial carcinoma, and cecal leiomyosarcoma. In contrast to primary eryrhocytosis (polycythemia vera), in which there is a neoplastic disorder of the erythroid cell lines in the bone marrow, the cause of secondary erythrocytosis is an increased level of erythropoietin. Possible mechanisms are ectopic erythropoietin production by the tumor,[11] increased erythropoietin production by the kidney in response to hypoxia of the kidney caused by tumor compression, and increased production of so-called *hypoxia-inducible transcription factors*, which stimulate erythropoietin production.[12] The clinical signs result from hyperviscosity of the blood and dilatation and decreased perfusion of small blood vessels, which result in tissue hypoxia, bleeding, polyuria, and thrombosis.

189.2.3 Leukocytosis

Increased peripheral granulocytosis without evidence of infection or leukemia has been reported to occur in association with several tumor types in humans but less frequently in the dog and cat. The excessive leukocytes are mature neutrophils and there are usually no clinical signs. In the dog, neutrophilic leukocytosis has been reported as a PNS with renal carcinoma, malignant lymphoma, metastatic fibrosarcoma, rectal adenomatous polyps, and pulmonary carcinoma. It has been described in a cat with dermal tubular adenocarcinoma. The diagnosis is made by exclusion of other causes of leukocytosis and resolution of the leukocytosis after removal of the tumor. Differentiation from a coexistent chronic myelogenous leukemia can be difficult. In paraneoplastic leukocytosis the tumor itself produces colony-stimulating factors (CSF). With the help of immunohistochemical staining techniques and reverse transcription polymerase chain reactions, the presence and production of both granulocyte-CSF (G-CSF) and granulocyte-macrophage-CSF (GM-CSF) have been demonstrated in tumor tissue in the dog, while in the cat only G-CSF could be demonstrated.[13,14]

Hypereosinophilia is a rare manifestation of cancer. Although it has been found with T-cell lymphoma,[15] mammary carcinoma, and oral fibrosarcoma, it is usually associated with disseminated mast cell tumors. Thoracic and abdominal eosinophilic effusions may accompany the peripheral blood eosinophilia.[16] The hypereosinophilia appears to be a response to cytokines such as IL-2 and IL-5. It is associated with disseminated, metastatic disease and hence signifies a poor prognosis.

189.2.4 Thrombocytopenia

Thrombocytopenia is one of the most common hemostatic abnormalities in cancer patients. It has been reported to occur in 10% to 36% of dogs with solid cancers and up to 50% of animals with malignant lymphoma.[17,18] Myeloproliferative neoplasms are responsible for 20% of the cases of thrombocytopenia in cats. Several different mechanisms may be responsible for thrombocytopenia in cancer patients. The life span of platelets can be shortened, especially in animals with metastatic tumors. Proposed mechanisms for this include binding of platelets to abnormal endothelium of blood vessels in tumors such as hemangiosarcomas, and accelerated removal from the circulation because of tumor-stimulated microaggregation of the platelets or because of binding of tumor proteins to the platelets. Immune-mediated thrombocytopenia (ITP) is another frequent cause of depletion of platelets in animals with cancer. It may result from anti-platelet antibody production or cross-reactivity between platelet and tumor antigens. Another cause of increased platelet destruction is microangiopathy, which leads to fragmentation of both red cells and platelets. Thrombocytopenia can also be the result of decreased platelet production caused by massive tumor infiltration of the bone marrow. Clinical signs of thrombocytopenia do not usually become evident until the platelet count decreases below 30,000/μL. Treatment of thrombocytopenia associated with cancer should be directed at removal of the tumor. ITP is treated with immunosuppressive drugs such as corticosteroids.

189.2.5 Thrombocytosis

Thrombocytosis (platelet counts above 500,000/μL) is a very common PNS in humans but is rare in dogs and cats. It has been described in animals with osteosarcoma, gingival carcinoma, chronic myeloid leukemia, bronchoalveolar carcinoma, and metastatic squamous cell carcinoma. It can cause thrombotic or hemorrhagic tendencies, but in most cases there are no clinical signs. The mechanism leading to the thrombocytosis is still unclear. Although elevated levels of IL-6, GM-CSF, and G-CSF have been found in some human patients, the levels were generally lower than required for *in vitro* induction of megakaryocytic differentiation. There may be other thrombopoietins in affected patients that have not yet been identified.[19] For the diagnosis of thrombocytosis as a PNS, other causes of thrombocytosis such as vinca alkaloids, splenectomy, iron deficiency, and myeloproliferative disorders should be ruled out.

189.2.6 Thrombocyte Hyperaggregability

Functional changes in platelets have also been demonstrated in patients with cancer. Hyperaggregation of platelets was demonstrated in a study of 59 dogs with cancer.[20] Proposed explanations for hyperaggregation include (1) an increase in serum factors that induce platelet aggregation, (2) a change in plasma membrane lipid composition, and (3) increased numbers of younger platelets, which have a higher activity. Platelet hyperaggregability may not only lead to thromboembolism but may also aid metastasis by the release of factors influencing stroma and blood vessels.

189.2.7 Pancytopenia

In dogs, bone marrow aplasia can be caused by administration of estrogens and by estrogen-producing tumors such as Sertoli cell tumors of the testis and granulosa cell tumors of the ovary. Although the exact pathomechanism is unknown; estrogens may not directly damage the bone marrow granulocyte-macrophage progenitor cells. A myelopoiesis-inhibitory factor produced by canine thymic stromal cells is probably a

mediator of the bone marrow suppression.[21] The prognosis is guarded, for the pancytopenia is often irreversible in spite of removal of the tumor. In addition to large individual differences in sensitivity to estrogens, age is a major factor that influences the prognosis.[22]

189.2.8 Coagulation Disorders

Coagulation disorders often develop in late stages of aggressive malignancies. The mechanism of this cancer-related hypercoagulability is not completely understood. It has been postulated that tumor-specific physiologic changes such as decreased oxygenation (tumor hypoxia) stimulate expression of blood-clotting regulators such as tissue factor and plasminogen activators, by both tumor cells and host cells.[23] In dogs and cats, however, disseminated intravascular coagulation (DIC) is the most frequent clinical abnormality and is probably caused by a complex of factors. As in humans, coagulation-activating substances can be produced by tumor cells. Hemangiosarcoma can release tissue thromboplastin into the circulation causing increased platelet aggregation. Tumor necrosis factor (TNF), produced by inflammation-activated macrophages, can change the endothelium of blood vessels, which increases the tendency for intravascular coagulation. The DIC-induced depletion of coagulation factors and the inhibitory properties of fibrinogen degradation products may cause hemorrhagic diathesis. DIC is often associated with hemangiosarcomas, thyroid carcinomas, and mammary gland carcinomas. Hemostatic abnormalities occurred more frequently with canine mammary carcinomas in the presence of extended tumor necrosis, inflammatory carcinoma, infiltration of the stroma by tumor cells, and distant metastases.[24]

189.2.9 Hyperproteinemia

Hyperproteinemia occurs as a PNS more often in animals with multiple myeloma or chronic lymphatic leukemia (CLL).[25,26] In approximately 75% of cases of multiple myeloma there are monoclonal immunoglobulins, usually IgG or IgA, which can be secreted in large quantities, producing paraproteinemia. Incomplete molecules, heavy or light chains, may also be secreted. The light chains have molecular weights ranging from 20,000 to 25,000 Daltons and are readily excreted in the urine. They are referred to as *Bence Jones proteins* and in patients with multiple myeloma are either only kappa type or only lambda type. Excretion of Bence Jones proteins occurs in about 30% to 40% of dogs with monoclonal gammopathy. In many dogs with CLL, serum globulin concentrations are normal, but in most a monoclonal gammopathy is revealed by serum protein electrophoresis. IgM is the most frequent paraprotein and these monoclonal gammopathies are described as *Waldenström's macroglobulinemia*. Bence Jones proteinuria can also be found. Hyperviscosity in these patients results from the protein-protein interactions of large, long molecules with high intrinsic viscosity, such as IgM M-components, or from high concentrations of specific IgG or IgA M-components, which have a tendency to form multimolecular aggregates. It rarely or never occurs in patients with light-chain-only myeloma, because of the small molecular size of Bence Jones proteins.

Multiple clinical signs of variable severity are associated with paraproteinemia. Bleeding disorders occur as the result of poor platelet aggregation and release of platelet factor III secondary to platelet coating by immunoglobulins. Prolongation of PT and APTT sometimes occurs as the result of interference by the immunoglobulins with the function of coagulation factors. There may be an increased susceptibility to infections because of severe depression of immunoglobulin levels.

Serum hyperviscosity causes sludging of blood and tissue hypoxia, which may lead to a plethora of clinical signs. Both the increased vascular volume and bleeding tendencies may lead to ocular changes, including distended and tortuous retinal vessels, cysts of the pars plana, papilledema, and retinal hemorrhage and

detachment. These changes can result in acute blindness. Severe central nervous system deficits (dementia with concurrent deficiency in midbrain or brainstem reflexes) were reported in 11% of dogs with myeloma. The cause of cardiac disease or failure associated with hyperviscosity is thought to be the large volume of hyperviscous blood. It is rare in the dog, more frequent in the cat. In patients with hyperviscosity of the serum, plasmapheresis may be necessary to reduce paraprotein concentration.[27] Therapy consists of treating the underlying cause of hyperproteinemia, multiple myeloma or CLL, with chemotherapy.

189.3 ENDOCRINE MANIFESTATIONS OF CANCER

Hormonally active tumors can arise in endocrine tissues, including the parathyroid glands, adrenal cortex and medulla, and pancreatic islet cells, as well as in tissues of nonendocrine origin. PNS associated with primary endocrine neoplasia are discussed in more detail in the section dealing with endocrine disorders. The following paragraphs focus on PNS due to ectopic hormone production by neoplasms of nonendocrine tissues.

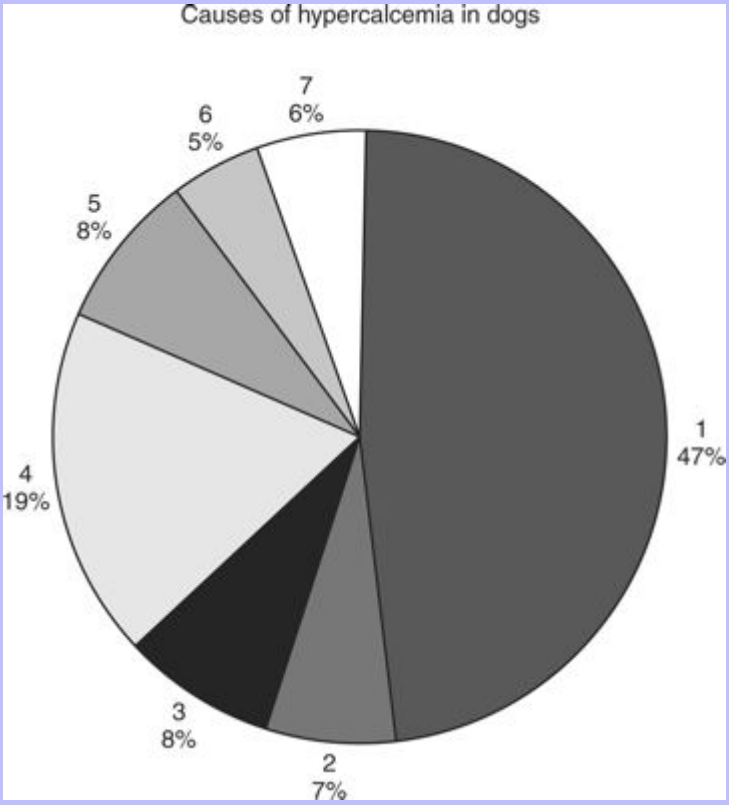
189.3.1 Hypercalcemia of Malignancy

Hypercalcemia is a relatively uncommon problem in small animals, diagnosed more often in dogs than in cats. Numerous disorders are associated with increased serum calcium concentrations, and the general approach to and differential diagnosis of hypercalcemia is discussed in detail in Chapter 237. The most common cause of hypercalcemia in dogs is hypercalcemia of malignancy (HM), which is diagnosed in 57% to 67% of hypercalcemic dogs (Figure 189-1).[28,29] In contrast, neoplasia is diagnosed in only 30% of hypercalcemic cats.[30]

The central mechanism of HM is the promotion of bone resorption by osteoclasts and subsequent release of calcium into the circulation. Patients with primary hyperparathyroidism are predictably affected with HM resulting from increased parathormone (PTH) levels. Interestingly, a variety of tumors originating outside of the parathyroid glands cause increased serum calcium concentrations. The most widely documented mechanism of tumor-associated hypercalcemia is humoral hypercalcemia of malignancy due to the synthesis of PTH-related peptide (PTHrP) by neoplastic cells. PTHrP shares structural homology with PTH in the first 13 amino acids of its N-terminal portion, which bind to the PTH receptor with an affinity equal to that of PTH and result in similar biologic effects.[31]

Other mechanisms of HM are more complex and have not been investigated in much depth in dogs and cats. They include tumor production of various substances that stimulate bone resorption, including cytokines, notably interleukin-1, and growth factors such as transforming growth factor beta (TGF-β). Furthermore, a recently elucidated novel pathway for HM involves the production of soluble forms of receptor activator of nuclear factor kappa B ligand (RANKL), a membrane-associated protein capable of stimulating the activity of osteoclasts by binding to a receptor on their surface. Hypercalcemia occurs when the interactions between ligand, receptor, and their natural inhibitors allow osteoclastic activation to predominate.[32]

Figure 189-1 Causes of hypercalcemia in 86 dogs. 1. lymphoma; 2. anal gland adenocarcinoma; 3. other neoplasias (2 mammary tumors, 1 of each anaplastic carcinoma, lung tumor, malignant histiocytosis, osteosarcoma, thymoma); 4. hypoadrenocorticism; 5. renal disease (2 acute, 2 chronic renal failure); 6. miscellaneous (primary hyperparathyroidism, vitamin D intoxication, panniculitis); 7. no diagnosis. (Compiled from references 28 and 29.)



HM in dogs is most frequently associated with lymphoma (10% to 40% of all cases), anal sac adenocarcinoma (ASAC, 25% to 53% of all cases), and multiple myeloma (15% to 20% of cases). In ASAC, a linear correlation was found between serum concentrations of calcium and PTHrP, attesting to the central etiological role of PTHrP in causing hypercalcemia by this tumor. No such correlation could be detected in dogs with lymphoma, suggesting that PTHrP is only partially responsible for HM in this neoplasia.[33] In canine lymphoma, hypercalcemia occurs most frequently in dogs with T-cell lymphomas and anterior mediastinal masses. In canine multiple myeloma, hypercalcemia is thought to be the result of local processes that increase bone resorption in the immediate proximity of neoplastic foci. HM is less prevalent in cats and has been associated with a variety of tumors, the most frequent of which are lymphoma and a variety of carcinomas. In squamous cell carcinomas, HM was most often detected in cases involving the mandible with radiographic evidence of bone lysis.[30]

The most significant effects of hypercalcemia are those exerted on the kidneys. Furthermore, dogs with HM are more frequently azotemic than those with parathyroid-dependent hypercalcemia.[34] Decreased responsiveness of the distal tubules to antidiuretic hormone (ADH) and subsequent polyuria and polydipsia are early features of hypercalcemia in dogs. Moderate to severe hypercalcemia may lead to decreased renal plasma flow and glomerular filtration rate, which significantly decrease renal function. In addition, parenchymal calcium salt deposition leading to nephrocalcinosis can compound azotemia.[34]

Clinical signs observed in hypercalcemic dogs are relatively nonspecific and include inappetence or anorexia, polyuria and polydipsia, weakness, vomiting, twitching and shaking, and weight loss. In cats, hypercalcemia also causes anorexia and lethargy, but the frequency of polyuria and polydipsia, and gastrointestinal signs is markedly lower than in dogs. Moreover, signs of lower urinary tract disease were observed in approximately one quarter of hypercalcemic cats and were probably associated with calcium oxalate urolithiasis, although there was not always a clear explanation for their appearance.[30]

Once spurious hypercalcemia has been ruled out, several parameters may provide useful diagnostic clues in elucidating the cause of hypercalcemia. These include serum phosphorus and ionized calcium concentrations, as well as circulating levels of PTH and PTHrP. Typically, dogs and cats with HM have increased serum ionized calcium, normal or low serum phosphorus, low PTH and increased PTHrP concentrations. In addition to these specific laboratory parameters, a systematic search for malignancy should be undertaken, including a meticulous clinical examination, CBC, chemistry profile, imaging of both body cavities, and bone marrow cytology.

Treatment of hypercalcemia of malignancy includes symptomatic therapy to avert or curtail complications of hypercalcemia as well as treatment of the primary disease. A detailed review of therapy is available in Chapter 181. Among the particularities for the treatment of HM, glucocorticoids may hamper diagnosis, especially in lymphoma, and should be avoided until a diagnosis is reached. Alternatively, in cases with a high level of suspicion of lymphoma, the administration of cytostatic drugs with few side effects, such as L-asparaginase may result in both diagnostic confirmation and resolution of hypercalcemia.

The prognosis is generally guarded to poor in animals with HM and depends greatly on the prognosis of the primary neoplasia. Relevant factors are the rapidity of onset, duration, and severity of hypercalcemia, and the degree of renal involvement. In dogs with lymphoma, hypercalcemia has been identified in the past as a negative prognostic factor. However, several studies have demonstrated that the shorter survival is only due to the frequent association of HM with T cell tumors in these dogs.

189.3.2 Hypoglycemia

Hypoglycemia is recognized infrequently in dogs and only rarely in cats. The most common cause of hypoglycemia is insulin-producing islet cell pancreatic tumor. Diagnosis and therapy of insulinomas and associated hypoglycemia are described in detail in Chapter 240. Hypoglycemia associated with other neoplasia is unusual PNS in humans[1] and small animals. In dogs, it has been described in association with hepatoma, hepatocellular carcinoma, intra-abdominal leiomyoma or leiomyosarcoma, and hemangiosarcoma of the liver and spleen.

Paraneoplastic hypoglycemia is probably caused by tumor production of insulin-like growth factors (IGFs) or somatomedins, a family of peptide hormones normally produced in the liver under growth hormone regulation.[1]

Increased levels of IGF-II have been documented in hypoglycemic humans with various cancers as well as in one dog with leiomyoma of the gastric wall.

Treatment of hypoglycemia caused by non–islet cell cancers optimally resides in the surgical removal of the neoplasm. However, management of hypoglycemia is also essential. If signs of neuroglycopenia are present, treatment includes the immediate administration of glucose and glucagon infusions,[35] followed by feeding of diets with complex carbohydrates. Low doses of corticosteroids (0.5 to 1 mg/kg/day) can be administered to curtail further hypoglycemic episodes.

189.3.3 Miscellaneous Endocrine Paraneoplastic Syndromes

The syndrome of inappropriate ADH secretion (SIADH) is characterized by hyponatremia, serum hyposmolality, and urine hyperosmolality in the absence of renal function disorders or adrenal dysfunction. Only very rare clinical cases of paraneoplastic SIADH in dogs have been reported. SIADH probably occurs very exceptionally in dogs and cats but should be considered when typical laboratory findings are observed.

793
794

189.4 GASTROINTESTINAL MANIFESTATIONS OF CANCER

189.4.1 Gastroduodenal Ulceration

Although gastroduodenal ulceration is not a very frequent problem in small animals, the diagnostic workup of gastric and/or duodenal ulcers includes a thorough search for neoplasia. Beside primary gastrointestinal tumors, the presence of mast cell tumor (MCT) and gastrinoma must also be ruled out. The latter two stimulate gastric acid secretion through histamine release and activation of histamine-type 2 (H2) receptors, or binding to the gastrin receptors on the basal wall of the gastric parietal cells, respectively.

Mast cell tumor is a common neoplasm in dogs and accounts for up to one fifth of all skin and subcutaneous tumors in that species. MCT can be difficult to differentiate clinically from other skin tumors as they sometimes mimic the appearance and the indolent behavior of benign subcutaneous tumors such as lipomas. Mast cell granules contain biologically active substances such as histamine, heparin, and proteolytic enzymes, and canine MCT have been associated with a variety of complications of which gastrointestinal ulceration is probably the most frequently encountered.

To date, two studies have investigated the role of hyperhistaminemia associated with MCT in a total of 28 dogs.[36,37] Although only 10 of 28 dogs with MCTs confirmed histologically had gastrointestinal signs at initial presentation, plasma histamine concentrations were increased in 21 animals, mostly those with macroscopically evident MCT. An inverse relationship between plasma histamine and gastrin concentrations was documented in one study, providing indirect evidence for gastric hyperacidity secondary to hyperhistaminemia.[36] Severe hyperhistaminemia and increasing histamine levels following surgery represent a negative prognostic factor in dogs with MCT.[37] Dogs affected with MCT should receive treatment with an H2 receptor blocker such as ranitidine, famotidine, or cimetidine at the time of diagnosis.

Gastrinomas are rare pancreatic islet cell tumors that secrete excessive amounts of gastrin.[38] A discussion on diagnosis, biologic behavior, and treatment of gastrinoma can be found in the section on pancreatic tumors.

189.5 RENAL MANIFESTATIONS OF CANCER

In human cancer patients, glomerular disorders may be associated with non-renal neoplasia, especially in the elderly. Neoplasia is also an important differential diagnosis in dogs and cats with glomerulonephritis due to the potential for tumor-related immune complexes to be deposited in the renal glomeruli. In addition, hypercalcemic nephropathy can affect dogs and cats with paraneoplastic hypercalcemia (see above).

189.6 CUTANEOUS PARANEOPLASTIC SYNDROMES

PNS affecting the skin are rare in dogs and cats and mostly affect older animals.

Superficial necrolytic dermatitis (SND) is a condition reported rarely in dogs and cats.[39] Other names previously used to describe this disorder are *necrolytic migratory erythema, hepatocutaneous syndrome,* and *diabetic dermatopathy*. Cutaneous lesions associated with SND include erythema, crusting, exudation, ulceration, and alopecia without severe pruritus. These lesions may involve the face, anogenital region, and pressure points on the trunk and extremities. Additionally, marked crusting, fissuring and ulceration of the footpads is observed in most dogs with SND, and secondary infections with bacteria, yeast, or dermatophytes are common. Histopathologic examination typically reveals epidermal parakeratosis, inter-and intracellular edema, degeneration of keratinocytes in the upper epidermis, and hyperplastic basal cells. Plasma amino-acid concentrations were severely decreased (as low as 30% of the normal plasma concentrations) in all dogs affected with SND that were examined. Underlying conditions observed in dogs with SND include glucagon-producing pancreatic tumors, hepatic disease, and diabetes mellitus. Dogs with SND often have a poor to guarded prognosis. Treatment is aimed at fighting the primary cause if it can be identified. Surgical removal of pancreatic tumors has been associated with resolution of SND and intravenous administration of amino-acid solutions has been effective in prolonging survival in some cases.

Nodular dermatofibrosis is a rare paraneoplastic disorder typically affecting middle-aged to older German shepherd dogs (GSD) with hereditary multifocal renal cystadenocarcinomas. Skin nodules are typically small (2 to 5 mm), very firm, and round. They can easily be overlooked initially and grow slowly. Most are located subcutaneously on the limbs and head region, are freely mobile, and consist of densely packed collagen fibers.[40] At the time of diagnosis, abnormal kidneys are detected on abdominal palpation in 60%, and on radiographs in more than 85% of dogs. Additionally, uterine tumors can be detected in a high proportion of affected bitches. The prognosis is poor due to renal disease and no curative treatment is known for this disorder. The syndrome seems to be inherited as an autosomal dominant trait in some GSD families.[40]

189.7 NEUROMUSCULAR MANIFESTATIONS OF CANCER

Neurologic paraneoplastic disorders occur in less than 1% of human cancer patients and encompass diseases affecting the brain, cerebellum, peripheral nerves, and neuromuscular junction.[1] Neurologic PNS are also infrequently reported in dogs and cats, and clinical relevance is limited to the peripheral neuropathies, myasthenia gravis, and polymyositis.

Myasthenia gravis (MG) has been reported in up to 50% of dogs affected with thymoma.[41] Among the associated clinical signs, megaesophagus was present in many reported cases and was frequently associated with aspiration pneumonia. Detection of circulating auto-antibodies against the acetylcholine receptor (AchR) and, to a lesser degree, the edrophonium (Tensilon) test and electromyography with repetitive nerve stimulation were helpful in

confirming the diagnosis. Megaesophagus is a negative prognostic factor that significantly shortens median survival in dogs with thymoma.[41] Surgical removal of the tumor is associated with improvement of the clinical signs, although anti-AchR titers do not always significantly decrease. Conservative treatment using immunosuppressive doses of glucocorticoids and/or cholinesterase inhibitors may be attempted in cases in which surgery is not an option (see Chapter 192).

Peripheral neuropathy has been reported in association with a variety of tumors in dogs, including multiple myeloma, lymphoma, and various carcinomas and sarcomas. The disease is likely due to auto-antibodies targeting antigens shared between the tumor and the peripheral nerves. Expected clinical signs are weakness and progressive paraparesis to tetraparesis, characterized by lower motor neuron type disease. Polyneuropathy, a generally rare and subclinical disease, may be present. Besides screening tests for cancer, electrodiagnostics (such as electromyography and motor nerve conduction studies) may also be of value.

794

795

189.8 MISCELLANEOUS SYNDROMES

189.8.1 Hypertrophic Osteopathy

Hypertrophic osteopathy (HO) is a well-documented paraneoplastic disorder in dogs and occurs only rarely in cats. HO is characterized by progressive periosteal hyperostosis that occurs on the bones of distal extremities and occasionally on other long bones of the appendicular skeleton. The disease is associated with chronic space-occupying lesions located in the thorax or, rarely, in the abdomen. These include a variety of intrathoracic tumors as well as non-neoplastic processes such as abscesses, granulomas, foreign bodies, and parasites. The pathogenesis of HO is still largely unknown but is believed to be associated with irritation of the vagal and/or intercostal nerves and subsequent enhanced blood flow to the distal extremities.

Animals with HO are typically presented with a history of shifting leg lameness and reluctance to move especially if several limbs are affected. Frequently, a painful swelling of the distal extremities is clinically detected. At the time of diagnosis of HO, clinical signs attributable to the primary disease process are usually discrete. The diagnosis of HO is confirmed on radiographs and should be followed by a search for a space-occupying intracavitary process. The focus of treatment of HO is the removal of the thoracic or abdominal lesion. Administration of steroidal or non-steroidal anti-inflammatory drugs may be useful in the management of pain associated with HO.

Michael Podell

190.1 GENERAL PRINCIPLES

Systemic diseases can induce a variety of neurologic manifestations that affect the central (CNS) and peripheral nervous system (PNS) in small animals. In theory, identification of a systemic illness as the underlying cause of the neurologic sign(s) is diagnostically simple, with historical signs that suggest a multi-organ problem that can be quickly identified with appropriate laboratory tests. In reality, when the neurologic signs are the sole manifestation of the illness, or when an unrelated, coincidental metabolic disease is present, the diagnosis of a systemic disease as the underlying cause can be challenging. Manifestation of a metabolic encephalopathy should be taken as a warning sign of organ deterioration or failure. The purpose of this chapter is to help clinicians identify the presence of a systemic disease associated with preceding neurologic signs and to realize the potential neurologic complications associated with systemic illnesses. The goal is to develop an efficient diagnostic plan to provide rapid reversal of many of the neurologic signs resulting from the metabolic derangement before permanent deficits occur.

Metabolic-induced neurologic disorders (MIND) of the CNS (metabolic encephalopathies, ME) or PNS (myopathies and/or neuropathies) are syndromes that are not due to primary structural problems of that part of the nervous system. The underlying mechanisms are either the inability to generate energy, to use energy in a normal fashion, changes in baseline excitability of the membrane potential, or direct toxic effects. A common mechanism of pathogenesis is the cascade phenomenon related to excessive glutamate neurotransmission in the brain, known as excitotoxicity[1] (Figure 190-1). As extracellular glutamate uptake increases in the brain secondary to hypoxia, ischemia, hypoglycemia, and other metabolic disturbances, calcium channels open to raise intracellular calcium concentration, leading to neuronal death. Differential sensitivity exists, however, between patients, and within the nervous system of each patient. This selective vulnerability is most apparent in the brain. Here, the more metabolically active regions are most susceptible to injury, so that gray matter is more vulnerable than white matter, and within the gray matter, layers 3, 5, 6 of the neocortex, and portions of the hippocampus, amygdala, thalamus, basal ganglia, and cerebellum are highly sensitive to the effects of metabolic derangement. Although the brain makes up only 2% of body mass, it receives 20% of the cardiac output and oxygen supply of the body, with 75% of this oxygen consumed by the gray matter for aerobic glycolysis.[2] Over 60% of the body's glucose is used in the brain, with the majority of this energy used to preserve normal ionic gradients responsible for maintaining the delicate balance of excitation and inhibition of the nervous system.

In general, the clinical signs of MIND are initially diffuse, non-fixed in time, and reversible. The onset of clinical signs of ME ranges from peracute (e.g., hypoxia) to chronic (e.g., hepatic encephalopathy). Waxing-waning behavior changes are the predominant early clinical signs in the majority of small animal ME. Aimless wandering, non-directional circling, and disorientation are common early changes.[3] As the disease progresses, clinical signs progress in a rostral (cerebrocortical) to caudal (brain stem) fashion. Over time, animals can develop stupor or coma with untreated ME. Oculomotor abnormalities are common and range from symmetric, reactive miosis in early ME, to symmetric, fixed mydriasis with prolonged hypoxia. Marked motor abnormalities are unusual early in the course of ME, with the exception of epileptic seizure activity. As more brain stem involvement occurs, ataxia and paresis can be seen. Respiratory pattern irregularities are common with ME. Diffuse cortical disease can result in an irregular cycle of hyperventilation followed by apnea (Cheynes-Stokes respiration). The presence

of ataxic breathing (very irregular inspiratory and expiratory pattern) indicates caudal brain stem involvement, a poor prognostic sign.

In the PNS, similar mechanisms, as seen in the brain, are responsible for loss of function. Long and large diameter nerve fibers are affected first via disruption in axonal transport of integral substances necessary for nerve viability. Nerves will then undergo a dying back process, with degeneration of the axons in a distal to proximal fashion.[4] The clinical signs include a chronic systemic disease, preferential lower and pelvic limb involvement, sensory loss prior to motor loss, muscle wasting, and slow return to normal with treatment. In contrast, in myopathies, the proximal muscles are typically affected, muscle mass is preserved, and muscles may be painful. Since muscle contraction and relaxation are both energy dependent activities, failure to maintain normal ionic gradients is a common mechanism for myopathies associated with systemic illness.

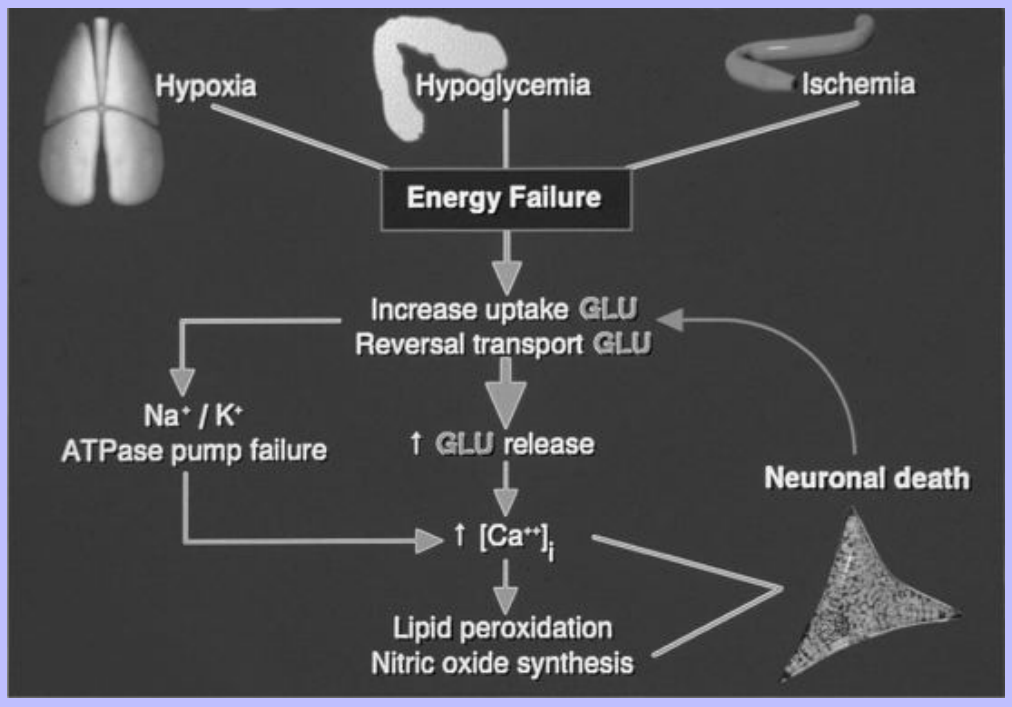
Five major classifications of systemic diseases are listed in Box 190-1. Examples of the more common systemic diseases associated with neurologic manifestations in the cat and dog are presented with emphasis placed on the pathophysiology and identification of the disease process.

190.2 FUEL DEPRIVATION

190.2.1 Oxygen Deprivation

Hypoxic-ischemic encephalopathy is the result of loss of cerebral oxygen supply either through decreased arterial oxygen tension (PaO_2 <50 mm Hg), or reduced to absent cerebral blood flow. Irreversible brain injury occurs within 20 seconds after anoxia, and 2 to 4 minutes after hypoxia-ischemia. Moreover, in dogs, a PaO_2 less than 45 mm Hg is sufficient to cause heart failure and systemic hypotension, thus exacerbating the condition with cerebral perfusion deficit.[5] This circulatory collapse cascade phenomenon in acute hypoxia is due to a primary CNS-induced reflex depression of cardiac function. In this setting, a common cause of hypoxia-ischemia in small animals is an anesthetic complication. Other causes for acute respiratory insufficiency include pneumonia, pulmonary thromboembolism, pneumothorax, and bronchospasm. Surviving animals may initially be comatose with fixed dilated pupils, leading to dementia, cortical blindness, and motor abnormalities. Since the degree of necrotic neuronal death is proportional to the lack of oxygen, the prognosis is greatly dependent upon the total duration of the hypoxic-injury. The longer the duration of hypoxia, the greater the chance for brain stem signs to occur.

Figure 190-1 Schematic diagram of glutamate (GLU)-induced excitotoxicity secondary to fuel deprivation of the brain.[1]



190.2.1.1 Box • 190-1 Classification of Systemic Diseases With Neurologic Manifestations

I. Fuel deprivation

A. Oxygen

1. Hypoxia

a) Primary pulmonary disease

b) Decreased O_2 transport

c) Secondary heart failure

2. Vascular disease

a) Ischemia

(1) Decreased peripheral vasomotor tone (shock)

(2) Decreased cardiac disease

(3) Thromboembolic disease

b) Hemorrhage

(1) Vessel rupture secondary to hypertension

(2) Coagulopathies

(3) Vasculitis

B. Glucose utilization (hypoglycemia)

1. Increased uptake

a) Hyperinsulinemia

(1) Islet cell tumors

(2) Insulin overdose

b) Non-islet cell neoplasia (hepatoma, leiomyoma)

c) Excessive metabolism (sepsis, breed or activity-related)

2. Decreased output or metabolism

a) Primary liver disease

b) Malnutrition

c) Thiamine deficiency

3. Increased uptake of amino acids by extrahepatic tissues

II. Water and ionic imbalances

A. Water

1. Hypoosmolar states (retention of free water)

a) Hyponatremia

2. Hyperosmolar states (loss of free water)

a) Hypernatremia (diabetes insipidus)

b) Hyperglycemia (diabetes mellitus)

B. Ions (excess or deficiency)

1. Potassium

2. Calcium

III. Endogenous neurotoxins

A. Renal failure

B. Hepatic failure

C. Endocrine disease

1. Adrenal

a) Cortisol and mineralcorticoid dysregulation

(1) Hyperadrenocorticism (Cushing's disease)

(2) Hypoadrenocorticism (Addison's disease)

b) Adrenergic dysregulation

(1) Pheochromocytoma

2. Thyroid

a) Hypothyroidism (myxedema, neuromyopathy)

b) Thyrotoxicosis

IV. Exogenous neurotoxins

A. Sedative depressant drugs (e.g., antiepileptic drugs)

B. Plant toxicity and poisons

C. Heat stroke

V. Remote neurologic manifestations of cancer

A. Metastases to the nervous system

B. Vascular accidents and infection

C. Adverse effects from therapy

D. Paraneoplastic syndromes

Therapy consists of reversal of the underlying event and supportive care to reintroduce energy to the brain by instituting proper ventilation and oxygenation, maintenance of normal hydration, and early enteral nutritional support. Steroid therapy does not improve neurologic recovery in people,[6] and in general, increases metabolic demand on the body, produces adverse effects, and has minimal benefit to the brain. Many animals may become functional pets over time and take several weeks to recover.

Cerebrovascular disease that results in focal lesions often is related to underlying systemic illness in the cat and dog.[7] Historical signs may be vague initially (e.g., lethargy, inap-pettance), leading to acute, focal cerebrocortical signs. Thromboembolic disease from sepsis, tumor metastasis, atherosclerotic disease, and hemorrhage from systemic causes of hypertension have been documented.

190.2.2 Glucose Deficiency

Hypoglycemia is a common cause of neurologic signs associated with systemic diseases. The brain requires an average of 100 g of glucose/day to function. Blood glucose below 40 mg/dL induces a stress response to release counter-regulatory hormones and induce gluconeogenesis. Progressive and/or persistent hypoglycemia results in cerebrovascular constriction, thus reducing oxygen delivery. Eventually, neuronal cell death occurs. Neuroglycopenic effects range from behavior changes (e.g., hiding) and weakness early and progress to tremors, partial and generalized seizures, blindness, and unresponsiveness.

The most common causes of hypoglycemia in small animals are increased uptake or decreased output. Increased uptake is seen with insulinoma, non-islet cell tumors, excessive exogenous insulin, and excess metabolism in certain toy and sport breed dogs. Most dogs with pancreatic islet cell tumors have clinical signs for several months with multiple episodic events interspersed with normalcy. In addition to neuroglycopenic signs, affected dogs may develop weakness secondary to a paraneoplastic peripheral neuropathy[8] and lacunar infarcts related to cerebral microangiopathy.[9] No correlation exists between severity or frequency of clinical signs, degree of hypoglycemia, and survival time post-treatment.[10] Non-islet cell tumors that arise from the

liver, smooth muscle, and other areas can produce insulin-like growth factor or other counter-regulatory hormones, which results in reversible hypoglycemia once the tumor is removed.[11]

Insulin overdosing is a serious complication of diabetes mellitus management. This problem appears to be more common in heavier cats receiving more than 6 U per injection of insulin, regardless of type.[12] Persistent cortical blindness and epileptic seizures after restoration of euglycemia may occur. Initial treatment is an IV bolus of 50% dextrose at 1 g/kg over 3 to 5 minutes, followed by continuous rate infusion of a dextrose containing solution to maintain blood glucose more than 80 mg/dL. Thiamine supplementation should be provided to allow for proper mitochondrial aerobic glycosis to occur.

190.2.3 Thiamine Deficiency

Thiamine (vitamin B1) is essential for the oxidative decarboxylation of pyruvic acid in the Kreb's cycle. Failure to complete this cycle will result in decreased gluconeogenesis. Thiamine deficiency occurs in cats and dogs fed primarily diets of over-cooked meats or fish that contains thiaminase, or with prolonged anorexia. Clinical signs are related to a progressive, bilateral, symmetric polioencelomalacia, which predominantly involves the subcortical gray matter. Cats can initially develop central vestibular disease, head tremor, mydriasis, and cervical ventroflexion, which may progress to opisthotonus, coma, and death. In dogs, ataxia, paresis, vestibular signs, and seizures have been observed. Parenteral administration of thiamine (10 to 20 mg IM for cats; 25 to 50 mg IM for dogs) will resolve clinical signs early in the course of the disease.

190.3 WATER AND IONIC IMBALANCES

190.3.1 Hypoosmolality with Hyponatremia

Hyponatremic encephalopathy is the result of an osmotic shift between extracellular fluid and brain cells, which results in a net movement of water into the brain, with its associated cerebral edema. Although the cause of hyponatremia may differ depending on the patient's volume status, the clinical signs are more dependent on the onset of the osmolar shift. Acute hyponatremia (hours) can lead to pressure necrosis of the cerebral hemispheres after an expansion of at least 5%, followed by brain herniation.[13] Little intracranial compensation can occur during the acute stage. With chronic (days) hyponatremia, the brain compensates with a loss of cation to lower intracellular osmolality with minimum water gain. Animals may exhibit little to no clinical signs. A rapid correction in serum sodium of at least 20 mEq/L of hyponatremia (<130 mEq/L) over 24 to 48 hours can lead to a potentially fatal demyelination of the brain stem, known as *central pontine myelinolysis*.[14]

Sodium replacement with 0.9% NaCl in volume depleted patients is calculated by the following equation:

$$\text{Na Deficit (mEq)} = 0.3 \times \text{BW kg} \times (\text{Normal Na} - \text{Patient Na})^{15}$$

Appropriate volume correction is simultaneously administered. The goal is to raise serum sodium at a rate of 6 to 12 mEq/L per day.

190.3.2 Hyperosmolality

Acute plasma hypoosmolarity leads to shifting of intracellular water into the extracellular space, which results in disruption of the neuronal ionic gradients, cell shrinkage, progression to brain shrinkage, and potentially leading to tearing of arachnoid blood vessels, with intracranial bleeding. With chronic hyperosmolar shifts, the

brain adapts by *de novo* synthesis of idiogenic osmoles to increase intracellular osmolarity. Rapid correction of the resultant hypernatremia can lead to cerebral edema, as the brain is now hyperosmolar to the plasma.

Common causes of plasma hyperosmolality with neurologic signs include central (CDI) or nephrogenic diabetes insipidus (free water loss) and diabetes mellitus (hypotonic fluid loss). Antecedent clinical signs include intense polydipsia and polyuria. Since CDI may cause similar neurologic signs indirectly through fluid shifts or directly from a pituitary mass, brain imaging is recommended after diagnosis of CDI in all dogs.[16]

Neurologic complications associated with diabetes mellitus related to CNS changes related due to hyperosmolality, electrolyte imbalances, and metabolic acidosis and to PNS changes with chronic inability to maintain Na-K ATPase activity in the nerve membranes. Diabetic neuropathy is typically a subclincal, electrophysiologic phenomenon in the dog[17] but results in a pronounced tibial neuropathy in the cat. These cats have a marked, symmetric plantigrade stance with pelvic limb weakness. Many cats will improve after sustained euglycemia.

Initial correction of hypernatremia to replace total body water can be calculated with the following formula:

$$\text{Water deficit} = \text{BW (kg)} \times [(\text{Patient Na}/\text{Normal Na}) - 1]^{15}$$

The deficit should be given over a 48-hour period to prevent cerebral edema starting with 0.45% NaCl/2.5% dextrose solution. A 5% dextrose in water solution can be used if serum sodium is not declining adequately.

800

801

190.3.3 Ionic Imbalances

Potassium and calcium imbalances have a direct effect on muscle membrane stability. Hypokalemia (≤3.0 mEq/L) from excessive urine loss or dietary depletion decreases membrane excitability, which leads to episodic weakness, cervical ventroflexion, and bizarre postures in the cat[18] (Figure 190-2) but can also be seen in the dog. Clinical signs resolve with appropriate potassium supplementation. Oral potassium gluconate supplement at an initial dose of 5 to 10 mEq/day is preferable, as parenteral supplementation may exacerbate the hypokalemia through volume expansion and enhanced potassium diuresis.

Generalized weakness with or without tetanic muscle contractions are commonly seen with hypocalcemia (ionized calcium <5.0 mg/dL in dogs and <4.5 mg/dL in cats) due to increased membrane excitability. The more acute the onset, the more severe the clinical signs, with progression to status epilepticus possible. Initial treatment consists of 10% calcium gluconate IV at dosage of 0.5 to 1.5 mL/kg over 10 to 20 minutes while heart rate is monitored.[19] Identification and treatment of the underlying cause is essential to prevent recurrence.

190.4 ENDOGENOUS NEUROTOXINS

The blood-brain barrier is a highly specialized, integrated network of capillaries and glial cells to maintain the internal environment of the brain and cerebrospinal fluid. Certain endogenous neurotoxins and/or consequences of systemic diseases have been identified to alter the brain's neurochemical balance by either bypassing the blood-brain barrier or through direct changes in neurotransmitter activity.

190.4.1 Uremic Encephalopathy

Neurologic clinical signs associated with acute or chronic renal failure can be seen when glomerular filtration rate decreases below 10% to 20% of normal. Extensive data suggests that parathyroid hormone is the putative

neurotoxin.[20] Clinical signs in cats and dogs include depression, stupor, myoclonic movements, generalized weakness, and partial and generalized seizures. Animals may not have prolonged antecedent mental depression prior to more pronounced neurologic signs, as seen in people.[21] Calcitriol (1,25 dihyroxyvitamin D, 1.5 to 3.5 ng/kg/day), by lowering parathyroid hormone serum concentration, reverses the neurologic depression in the majority of chronically treated uremic small animals.[20] Attention to blood pressure control should also be provided.

Figure 190-2 Cervical ventroflexion in a 2-year-old female spayed DSH cat with hypokalemic polymyopathy secondary to potassium-losing nephropathy.

190.4.2 Hepatic Encephalopathy

Advanced congenital or acquired liver disease can produce a complex of neurologic signs, known as hepatic encephalopathy (HE). Waxing-waning bizarre, unpredictable behavior, dementia, progressive loss of arousability, myoclonus, and seizures can all occur. Clinical signs can worsen after protein digestion. Although most animals with HE will have an elevated plasma ammonia concentration, there is minimal correlation between the severity of clinical signs and ammonia level. Irish wolfhound pups can exhibit hyperammonemia of a metabolic and non-hepatic origin, with a low likelihood of a portosystemic shunt (PSS) if the ammonia level is less than 120 mumole/L.[22] There are several potential pathophysiologic causes of the neurologic syndrome of HE, which include (1) hyperammonemia, (2) synergistic neurotoxins, (3) altered monoamine (tryptophan) and “false” neurotransmitter synthesis, (4) alterations in amino acid neurotransmitters, and (5) increased cerebral concentrations of an endogenous benzodiazepine.[23] Recent studies demonstrated increased cerebrospinal fluid concentrations of tryptophan, tryptophan metabolites, glutamine, and quinolinic acid in dogs with naturally occurring PSS as compared with control dogs. The results support the theory of an increased flux and metabolism of tryptophan through the CNS serotonin metabolic pathway as a contribution to the neurologic complications with PSS and ensuing encephalopathy in dogs.[24]

Medical therapy for HE is directed to the reduction of by-products of protein metabolism and subsequent neurotoxins. Initial medical therapy includes a low-protein diet, antibiotic therapy to reduce ammonia producing bacteria, lactulose to decrease production and absorption of ammonia, and H_2-blockers as needed to treat for gastrointestinal bleeding. Surgical correction of congenital porto-caval shunts is most successful in dogs less than 2 years of age for reduced mortality[25] and neurologic morbidity. Generalized seizures may persist post-ligation despite lack of other evidence of HE.[26] The recommended antiepileptic drug therapy for these dogs is either potassium bromide at an initial maintenance therapy at 40 mg/kg/day or gabapentin at 20 mg/kg/day with increases to 60 to 80 mg/kg/day divided TID as needed. Both of these drugs are renal excreted, non-protein bound drugs with good antiepileptic properties in the cat and dog. Bromide therapy should be used with caution in the cat due to the potential for induction of an allergic induced asthmatic reaction.[27] Continuous rate infusion of sodium bromide at 600 to 1200 mg/kg/24 hours for 1 day is an alternative method to rapidly raise bromide serum concentrations to a therapeutic range.[28] Benzodiazepine therapy should be avoided to prevent potentiation of inhibitory neurotransmission in the brain. Sarmazenil, a benzodiazepines antagonist and partial inverse agonist, at 3 to 8 mg/kg IV ameliorated neurologic signs in dogs with experimentally induced HE secondary to PSS.[29]

190.4.3 Thyroid Diseases

Primary hypothyroidism is a common endocrinopathy of the older dog with multiple neurologic manifestations. The most severe form is myxedema, associated with bradycardia, hypothermia, dementia, stupor or coma, generalized lower motor neuron weakness, and possible seizures. Concurrent complications of hyponatremia, hypoventilatory hypoxia, and cerebral ischemia make this a life-threatening condition. Treatment consists of gradual rewarming, correction of serum sodium and osmolarity, steroid therapy (prednisolone sodium succinate 10 mg/kg IV BID for 24 hours), and injectable levothyroxine replacement (5 ug/kg IV once), followed by maintenance thyroid supplementation. Marked improvement is usually seen within 24 hours.

801 802

Chronic, progressive peripheral or central vestibular disease can also occur in hypothyroid dogs.[30] These dogs are typically older (more than 7 years), with progressive ataxia and head tilting as primary signs. Other clinical syndromes are related to motor unit dysfunction. Generalized lower motor neuron weakness with exercise intolerance can be the result of hypothyroid neuro-myopathy. Concurrent or separate signs of megaesophagus and facial and/or laryngeal paralysis may be present. Many, but not all, dogs will improve with appropriate thyroid supplementation.[31]

Thyrotoxicosis (hyperthyroidism) in cats can produce multiple neurologic abnormalities. Predominant behavior changes include irritability, hyperactivity, aggression, and reduced sleep cycles. Some cats may exhibit a paradoxic “apathy,” characterized by excessive dullness. Progressive neuromuscular weakness with cervical ventroflexion, exercise intolerance, and loss of jumping ability can be seen with more advanced disease, and associated muscle wasting. Signs are reversible with appropriate treatment of the underlying hyperthyroid condition.

190.4.4 Adrenal Diseases

Adrenal hormone excess or deficiency has been associated with a variety of neurologic disturbances. Signs attributed to hypoadrenocorticism (Addison's disease) include episodic, progressive lethargy, dullness, tremors, vomiting, and possible acute collapse.[32] Glucocorticoid deficient hypoglycemia may exacerbate these signs.

Rapid reversal of neurologic signs is seen with mineral-and/or glucocorticoid replacement and restoration of metabolic homeostasis.

Cushing's disease (hyperadrenocorticism) can produce CNS and PNS abnormalities through direct or indirect mechanisms. Direct compression of a pituitary macroadenoma onto the brain results in early signs of dullness and dementia, with progression to obtundation, tetraparesis and ataxia, visual impairment, and seizures. Up to 35% of dogs with pituitary dependent Cushing's with a visualized (CT or MRI scan) tumor of more than 4 mm may develop neurologic signs.[33] Cerebrovascular accidents may also occur, secondary to systemic arterial hypertension or thromboembolic disease. In the PNS, an irreversible progressive fibrosing myopathy can occur, regardless of duration, severity, or onset of treatment with canine Cushing's disease. A progressive stiff gait leading to inability to flex the limbs is characteristic of this condition.

Pheochromocytoma can induce neurologic signs in approximately 10% of clinically symptomatic dogs.[34] Generalized weakness, pelvic limb weakness, focal forebrain signs, and seizures may develop. Signs can be the result of direct intracranial metastasis or secondary intracranial hemorrhage due to hypertension.

190.5 EXOGENOUS NEUROTOXINS AND INJURY

A variety of environmental or iatrogenic substances will produce diffuse forebrain disturbances. More common conditions are toxic reactions to antiepileptic drugs, rodenticides, and heat stroke. Removal of the inciting cause and appropriate supportive care are often corrective.

190.5.1 Neurologic Complications of Cancer

More neurologic complications secondary to systemic cancer are being observed with the advancement of diagnostic and treatment capabilities in veterinary oncology. These complications can be serious to life-threatening, may be diagnostically challenging, yet early treatment can be quite beneficial to the patient. Moreover, the nervous system problems are unique to the rest of body, in that small lesions can create major clinical signs (as compared with the liver), heterogeneous function is present, barriers must be kept intact for proper function, and damage to CNS tissue has limited capacity to repair itself, so that clinical signs may be irreversible.[35]

Direct and extensional metastases to the nervous system are the most common neuro-oncologic complications in the cat and dog. Hemangiosarcoma, mammary and thyroid carcinoma, and melanoma, spread preferentially to the end-arterial vasculature of the gray-white matter regions of the cerebrum.[36] Clinical signs are related to tumor location and the secondary effects. Dogs with intracranial extension of nasal carcinoma may present only with CNS signs. Chemo-and radiation therapy can directly or indirectly affect the nervous system. Paraneoplastic disorders are due to autoimmunity as a result of tumor cells expressing “onconeural” antigens identical or antigenically related to molecules normally expressed by neurons or other receptors.[37] In small animals, the primary paraneoplastic syndromes recognized are related to PNS disease, including neuropathy (e.g., secondary to insulinoma, carcinoma, sarcoma) and myasthenia gravis (e.g., secondary to thymoma, osteogenic sarcoma).

191 CHAPTER • 191 Brain Disease

Dennis P. O'Brien

Todd W. Axlund

"All the most acute, most powerful, and most deadly diseases, and those most difficult to be understood… fall upon the brain." Hippocrates

For as long as people have been aware of disease, they have been frustrated by brain disease. Recent advances in brain imaging and molecular approaches to understanding disease hold the promise of changing these concerns. This chapter will outline the diagnostic approach to brain disease and discuss the major diseases of dogs and cats that primarily affect the brain.

191.1 RESPONSE OF THE BRAIN TO DAMAGE

The nervous system has relatively few ways to respond to damage, and the complexity of neurologic signs depends upon the localization of that response within the nervous system. Because neurons are excitable cells, one potential response to disease is excessive discharge of these cells. The most dramatic example of this is seizure activity. Conversely, if the disease destroys the neurons of a functional system, there will be a loss of function of that system. For example, the destruction of a cranial nerve nucleus in the brain stem will lead to paralysis of the muscles innervated by that nerve. If the system that is lost happens to be an inhibitory pathway, then the system that is no longer inhibited may show an exaggerated response. The classic example of such disinhibition is the exaggerated reflexes seen with upper motor neuron (UMN) loss. When dealing with higher brain functions, such responses can be complex. For example, the paradoxical aggression sometimes seen with benzodiazepines or barbiturates in dogs may represent a disinhibition of aggressive behavior.

In addition to local effects, a disease process in the brain can produce generalized effects secondary to increased intracranial pressure. Because the calvarium is a rigid structure, the three major components within it (brain, cerebrospinal fluid [CSF], and blood) are confined to a fixed volume. Any increase in one of these components would then have to be accompanied by a decrease in one of the others (the Monro-Kellie doctrine). A gradual increase in volume of one component, such a slowly progressive hydrocephalus, can be compensated for to some extent, in this case by atrophy of brain tissue. More acute disease would not allow time for compensatory atrophy, and even chronic disease, such as a brain tumor, will eventually exceed the ability of the other components to compensate. The result is increased intracranial pressure. With increasing intracranial pressure, generalized forebrain signs will develop, even if the inciting cause is a localized process such as neoplasia. As intracranial pressure increases, blood pressure will increase to maintain cerebral perfusion. This can sometimes result in a reflex increase in vagal tone and bradycardia (the Cushing's response). Vomiting may also occur.

Continued increases in intracranial pressure will lead to herniation. Brain tissue can herniate laterally under the falx cerebri, or it can herniate caudally under the tentorium or through the foramen magnum. Tentorial herniation leads to a progressive rostral-caudal deterioration of neurologic status when the midbrain, pons, and terminally the medulla are compressed. The progression can be rapid or can evolve slowly over a mater of hours or even days. Herniation is most commonly associated with forebrain lesions, such as neoplasia or trauma. Increased pressure arising below the tentorium (e.g., a cerebellar tumor) will cause herniation of the cerebellum through the foramen magnum, mimicking the terminal events of tentorial herniation without any of the earlier signs.

191.1.1 Neurologic Examination

Regardless of whether the signs reflect focal damage or diffuse disease, the first step in diagnosing any neurologic disease is to localize the lesion. The neurologic exam requires care to perform, but it is the most cost-effective diagnostic procedure available. A neurologic exam form can be used to ensure a complete exam and to accurately record observations (Figure 191-1). Even in cases with obvious brain disease, a complete neurologic exam should be done to rule out multifocal disease. The focus of this chapter is on the aspects of the neurologic exam that are important for evaluating brain function: (1) observation of behavior, posture, and gait; (2) postural reactions; and (3) cranial nerves. Although not technically a part of the neurologic exam, a fundic exam should be considered. Because the retina and optic nerve are basically extensions of the brain, the clinician should take advantage of the one place where they can look directly at the nervous system (Figure 191-2). A disease process visualized in the fundus is likely to be the same process producing signs elsewhere in the nervous system.

191.1.1.1 History and Behavior

Because changes in behavior or episodic events like seizures will be important clues to brain disease, an adequate history is essential. The clinician must elicit descriptions of the animal's behavior that will allow identification of the changes without leading the client. Clients will misinterpret the nature of many neurologic signs, including seizures, so they should be encouraged to describe what they observed rather than their conclusions. Many clients have access to video cameras, and a tape of an episodic event can be useful in determining the nature of the episode.

If allowed to freely roam the exam room, the animal's behavior can be observed while a history is being taken. Looking at how an animal interacts with the environment assesses the mental status. A normal animal will be aware and observant of its surroundings. How the animal interacts with its owner or other people should be noted. Any spontaneous noises or movements may be used to see if the pet is attentive to these stimuli. The odors of the exam room floor can also be an interesting stimulus to many animals. An animal that is lethargic or obtunded will withdraw from its surroundings unless stimulated. A stuporous animal responds only to strong or noxious stimuli, and the response may not be at all appropriate. A comatose animal does not respond even to noxious stimuli. A demented animal may appear alert, but its response to its environment will be inappropriate.

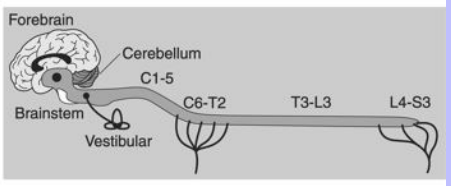
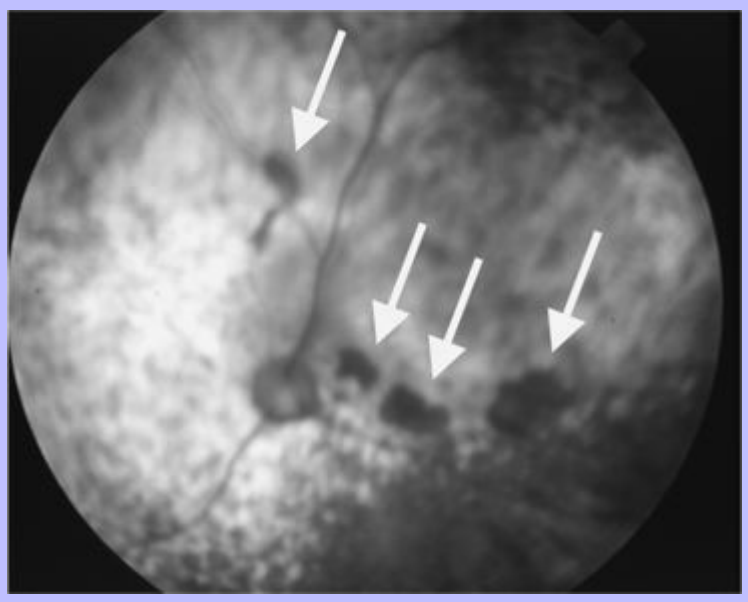
***LESION LOCALIZATION/SUMMARY:**



***DDx:**

***Plan:**

Figure 191-2 The retina is a direct extension of the brain. Thus retinal hemorrhages (*arrows*) in this dog with histoplasmosis suggest the same process is occurring within the brain. (Photo courtesy Dr. Elizabeth Giuliano.)



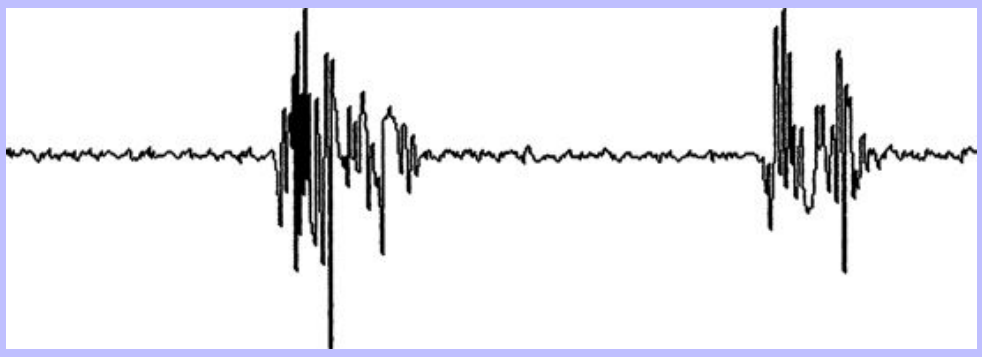
Because a tendency to circle can reflect asymmetrical damage to the brain, the direction the animal turns when it reaches a corner should be noted. If the animal is not clearly circling but has a bias toward turning one direction, the clinician should set up situations in which a turn in the opposite direction is required and see if the animal does so effortlessly. The character of the circling can provide clues to the localization. Forebrain disease tends to produce larger, wandering circles (sometimes the animal only makes a turn when it reaches a place where it cannot continue forward). Typically the circling will be toward the side of the forebrain lesion. Brain stem disease will more commonly produce tight circling or a tendency to lean against the wall with one side. The direction can be variable with brain stem lesions.

191.1.1.2 Abnormal Movements

While observing the animal's behavior in the exam room, any abnormal movements should be noted. In addition to the character of the movement, it is important to note when the abnormal movement occurs, whether at rest, when standing still, or when moving.

Tremors are probably the most common abnormal movement because they can be the result of a wide variety of causes. A tremor is a rhythmic oscillation of at least one functional region of the body such as a limb or the head. Tremors can be classified based on the frequency of the tremor, the part of the body affected, and the activity that precipitates the tremor.

Figure 191-3 Myoclonus is visible as brief bursts of muscle activity in the electromyography (EMG) of a dog with canine distemper.



Normally a subclinical tremor called the *physiologic tremor* occurs in all muscles. This is a high-frequency tremor (6 to 12 Hz) that disappears when the muscles are at rest. A variety of diseases can produce an enhanced physiologic tremor. Such a tremor is still a high-frequency tremor, and it tends to be most noticeable when the animal is standing quietly (postural tremor).

Goal-directed movements activate an intention tremor. This is seen most clearly in the head when the animal attempts to eat or drink or otherwise tries to fix its attention on something. Such tremors are characteristic of cerebellar disease but may be seen in other conditions such as hypocalcemia. The tremors are courser and slower (3 to 5 Hz) than physiologic tremors.

Myoclonus refers to a brief contraction of a muscle, group of muscles, or occasionally the entire body. Although myoclonus can repeat rhythmically, it does not have the oscillating character of tremors. Instead a rapid jerk occurs, followed by a quiet period (Figure 191-3). Myoclonus is seen most commonly in dogs after distemper infection but can be seen in other conditions such as myoclonic epilepsy, toxicities such as lead poisoning, or metabolic encephalopathies.

Dyskinesia is a general term to describe abnormal movement. The specific dyskinesias described in human neurology, such as chorea, ballism, or athetosis, have not been well characterized in animals. It is important to recognize that in a quadruped, fine motor control is more important in the head and facial muscles than the limbs. For example, star thistle toxicity in horses produces a degeneration of the substantia nigra comparable to Parkinson's disease of humans. The tremors and motor difficulties in the horse, however, are most dramatic in the facial muscles.

191.1.1.3 Gait and Posture

The posture of a normal animal should be square with the feet directly beneath the body and the head straight. A wide-based stance would indicate a problem with proprioception or balance. Unilateral balance or motor problems, usually related to a brain stem or inner ear lesion, may cause the animal to lean toward one side, possibly against a wall for support. With forebrain disease, the animal may tend to curl toward the side of the lesion as they orient toward that direction. With vestibular disease, the head tends to be rotated on the long axis so that one ear is lower than the other. The nose may be kept straightforward or sometimes turned away from the lower ear. Except for the paradoxical vestibular syndrome seen with cerebellar disease, the

head tilt will be toward the lesion (Figure 191-4). If abnormal head posture occurs in forebrain disease, the head will be pulled around to the side but usually not rotated. This type of head posture is sometimes referred to as an *adversion*, but the direction of the movement is typical toward the side of the lesion. *Dystonia* refers to a sustained abnormal contraction or posturing from basal ganglia disease.

Figure 191-4 With vestibular disease the head is rotated on its long axis with one ear lower than the other. This can be compared with a head adversion shown in Figure 191-17 in which the nose is pulled around toward the flank. (From O'Brien DP: Circling. In August JR, editor: *Consultations in feline internal medicine*, Philadelphia, 1994, WB Saunders Co, p 449.)

If the animal is stuporous or comatose, it may adopt abnormal postures that help to localize the lesion. A lesion affecting the midbrain will produce decerebrate rigidity. The neck is extended dorsally, and all four limbs are extended. Lesions of the cerebellum can sometimes produce a similar posture (decerebellate posture). The neck and thoracic limbs are extended, but the pelvic limbs are flexed.

The gait can be observed while the animal explores the exam room or while the owner walks the animal on lead. Walking in tight circles or up and down stairs may exacerbate subtle deficits. If an animal is weak from brain disease, it will be a UMN weakness. As a result, the limbs will tend to be stiff and the stride lengthened as opposed to the short, shuffling stride and buckling of the limbs seen with lower motor neuron (LMN) weakness. An animal with cerebellar disease will have normal strength with dysmetria. This is most apparent in the thoracic limbs as a goose-stepping gait, but the pelvic limbs may also show hyperflexion. Typically marked truncal ataxia is also noted as a swaying of the pelvis. Truncal ataxia may also be observed with proprioception deficits, but limb ataxia is different. An animal with proprioception deficits tends to drag the

toes and may stand with the foot knuckled under. It misplaces the feet and may cross over or step on itself, especially during tight circles.

191.1.1.4 Postural Reactions

The postural reactions are complex responses requiring integration of sensory information and coordination of motor responses at the brain level (Figure 191-5). Thus they are more involved than simple reflexes but still occur in direct response to a sensory stimulus, usually a perturbation of proprioception or balance. This makes them useful for evaluating brain function and spinal tracts.

Figure 191-5 Postural reactions, such as hopping, assess the ability of the brain to integrate sensory information and produce a coordinated motor response. The entire circuit (sensory afferents, long tracts, higher integration, and motor efferents) must be functional for a postural reaction to be executed. (From O'Brien DP; Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004.)

Conscious proprioception is evaluated by balancing the animal with one hand under the thorax or abdomen and knuckling one foot under so that the animal bears weight on the dorsum of the paw. Although clinicians are mainly interested in the perception of the sensation, they are looking for a motor response (replacing the foot to a normal position), thus this qualifies as a postural reaction. Proprioception deficits with forebrain disease may not be as obvious as the deficits seen with spinal cord disease. An alternative method for assessing proprioceptive awareness is placing a sheet of paper under one foot and slowly pulling the paper laterally. An animal with proprioception deficits may allow the foot to slide far laterally, even though it may replace the foot when knuckled.

Hopping also assesses proprioception, specifically where the foot is relative to the animal's center of gravity. The required motor response is more complex and thus allows the clinician to assess motor function and sensory perception. A small animal may be held with all its weight on one paw, whereas in a larger animal, only one paw is lifted and the animal pivoted. As the animal moves laterally, it should begin to hop to the side before its center of gravity passes over the paw. Proprioception deficits result in a delayed or absent initiation of the response. Cerebellar disease would result in an exaggerated movement, whereas UMN lesions would result in a weak or absent response.

Hemistanding and hemiwalking are good for comparing strength and coordination on one side of the body versus the other. First, both legs on one side are lifted off the ground so that the animal has to support all of its weight on one side and strength can be assessed. Then the animal is moved laterally so that it has to walk sideways on one side. This is a sensitive test of the ability of the contralateral forebrain to control those limbs.

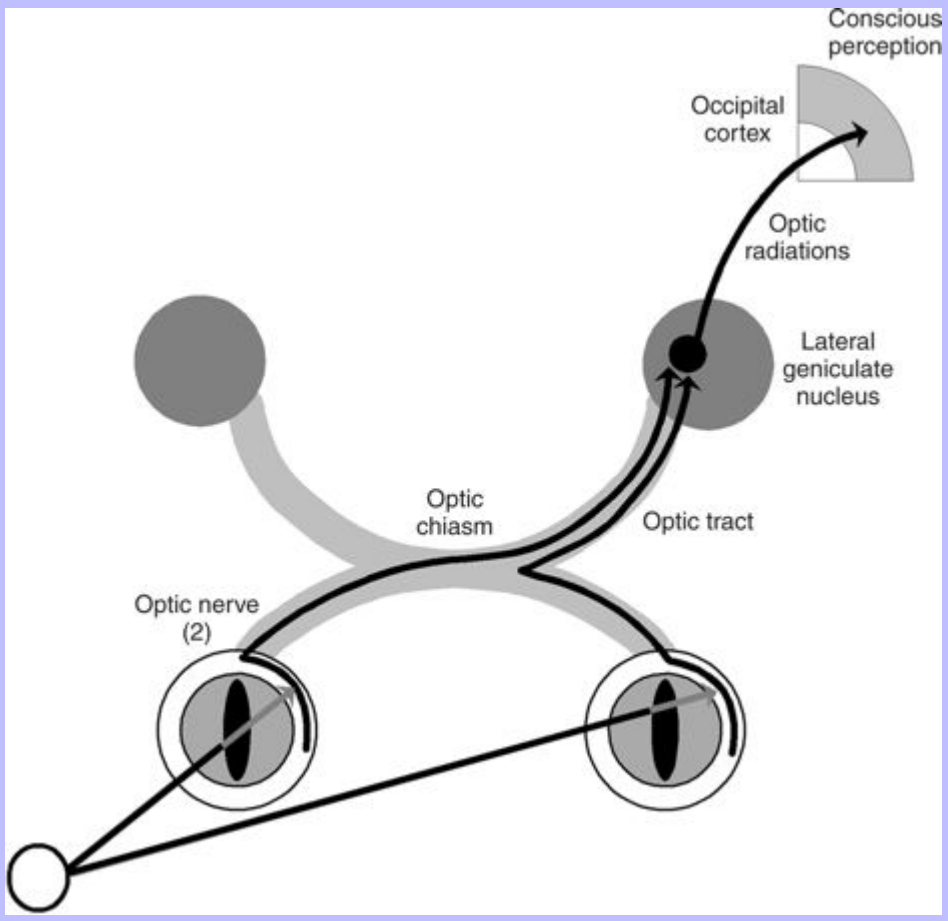
807

808

Visual placing assesses the animal's ability to use a visual stimulus to coordinate a motor response. As with proprioceptive positioning, the clinician is mainly interested in the sensory perception, in this case, vision. The animal must be small enough to be lifted off the ground, and then it is brought forward and downward toward the edge of a table. The normal response is to reach out and place one or both thoracic paws on the table. Tactile placing can be used to evaluate light touch perception of the thoracic limbs. The procedure is like visual placing, except the animal is blindfolded and the dorsum of the paw lightly touched against the table. Perception of touch in the pelvic limb is evaluated by the extensor postural thrust. The animal is picked up under the axilla and slowly lowered down. The normal response when the paws touch the ground is an extension of the limb and a shuffle to get the feet underneath the body.

The righting response is also a postural reaction. In this case the main sensory modality evaluated is the vestibular system. Proprioception and vision can also play a role, particularly in animals with vestibular deficits. Blindfolding the animal to remove visual compensation will exacerbate a vestibular deficit. Suspending the animal by the pelvis with the head down removes most proprioception clues, and the clinician can assess the animal's ability to orient to gravity. A normal animal will attempt to keep the head upright, whereas an animal with vestibular deficits may curl or move the head regardless of orientation to gravity. Alternatively the animal can be placed in lateral recumbency and allowed to right itself. A normal response would be a rostral-caudal righting, whereby the animal brings up the head, then neck, then shoulders, and sometimes also the pelvis.

Figure 191-6 The decussation of fibers within the optic chiasm ensures that images from one visual field are transmitted to the contralateral visual cortex.



191.1.1.5 Cranial Nerves

Because the cranial nerves originate in the brain, careful evaluation assesses the function of not only the nerve itself but also the associated brain areas. Although there can be UMN type of deficiencies in cranial nerves (just as for spinal reflexes), these are difficult to detect in animals. Thus with a few exceptions (see following discussion), a deficiency in a cranial nerve reflects damage either to the nerve itself or the brain area where the nucleus resides. Cranial nerve deficits will generally be ipsilateral to the lesion with the exception of the optic (II) and trochlear (IV)[4] nerves, which may be contralateral. Forebrain lesions may produce a loss of response to sensory information originating from the contralateral side.

The olfactory nerve (I) is the only sensory nerve that does not relay through the thalamus. Instead, it projects to the pyriform cortex and limbic areas such as the septal nuclei and amygdala, areas important in emotional

responses. This may explain why odors can have a profound emotional effect. Evaluating olfactory function can be difficult. If the animal investigates an odor, such as concealed food or urine odor on the exam room floor, then they have some olfactory function, but a unilateral loss could not be ruled out. A failure to orient to an odor could reflect a loss of the sense of smell or simply a lack of interest in the odor. Any withdrawal from an odor must be interpreted cautiously, because irritating substances such as alcohol could stimulate pain receptors in the nasal mucosa (carried by the trigeminal nerve [V]).[5]

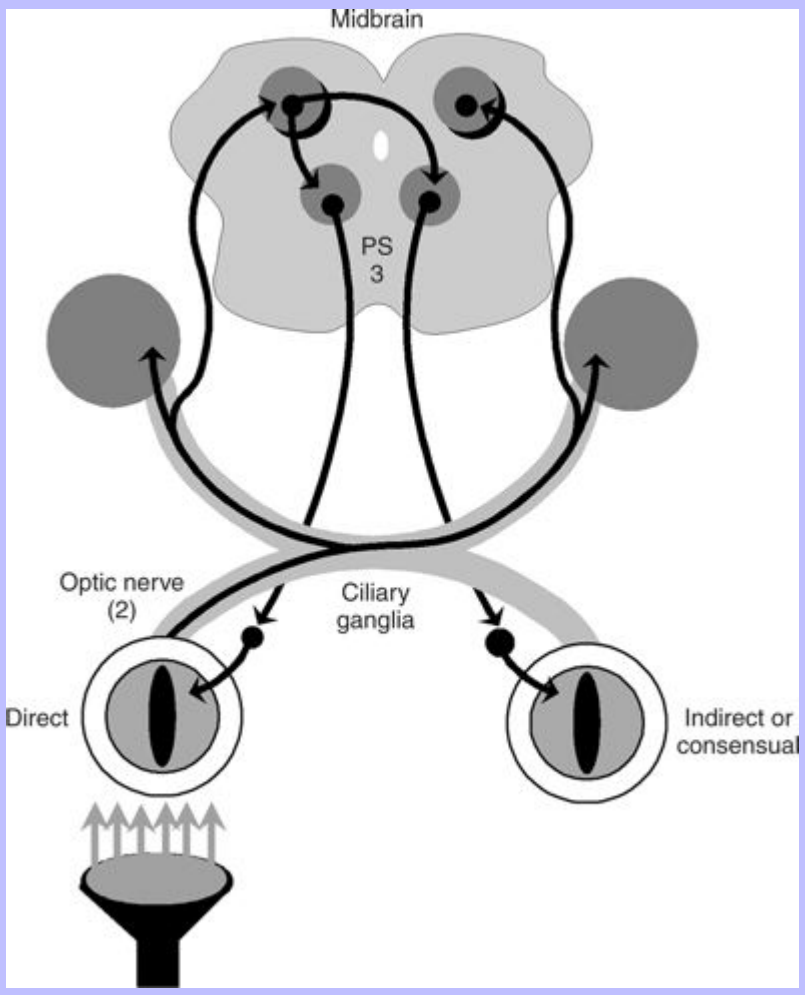
The optic nerve (II) is evaluated by assessing vision and the pupils. *Vision* refers to the conscious perception of a visual stimulus, so clinicians rely on observing a behavioral response to determine if the animal has perceived the stimulus. The decussation of the optic nerves ensures that all visual information from one side goes to the contralateral visual cortex (Figure 191-6). The most effective way to evaluate vision is by tossing a cotton ball from behind, toward one side or the other, and observing whether the animal tracks the cotton ball (Figure 191-7). By avoiding the area directly in front of the animal where stereoscopic vision occurs, it is easier to differentiate loss in one visual field. The cotton ball will not create any noise and will typically surprise the animal enough to elicit some response.

808

809

Figure 191-7 Most normal animals will track a cotton ball tossed from behind them. By keeping the cotton ball off to the side, vision in the left and right fields can be independently evaluated.

Figure 191-8 Light in one eye activates afferents in the optic nerve *(2)*. These synapse on efferents for the parasympathetic portion of the oculomotor nerve *(PS3)*, which in turn synapse in the ciliary ganglia. Crossover in the optic chiasm and the midbrain ensure that both the ipsilateral (direct response) and contralateral (indirect or consensual response) pupils constrict. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).



The ability of the animal to negotiate obstacles in the exam room, such as the exam table or a chair, can also assess vision. One eye can be covered to detect unilateral deficits. If the animal appears blind, the room can be darkened to dilate the pupils and the door opened to a bright hallway. If it cannot perceive the doorway,

then it is unlikely that the animal has any functional vision. If the animal is small enough to be picked up easily, visual placing can be used to assess vision.

The menace response is an acquired and complex response, not a simple reflex. It is one of the last cranial nerve responses to develop and may not be apparent until the animal is 12 weeks of age. It is best assessed with a quick movement of the hand parallel to the head, starting from behind the ear outside the animal's visual field. By moving parallel to the head, the whiskers can be avoided and fewer air currents are generated. By staying lateral, the stereoscopic field is avoided and one visual field evaluated. Most animals will respond to a quick movement from outside their vision with a blink. Because it is a complex pathway, a menace loss does not precisely localize a lesion without clues from the rest of the examination.

The optic nerve (II) provides the sensory afferents for the pupillary light reflex (PLR). These fibers synapse in nuclei in the midbrain and control the parasympathetic constriction of the pupil via the oculomotor nerve (III). In mammals, crossover in the optic chiasm and the midbrain ensures that both pupils respond together (Figure 191-8). Thus a light in one eye produces a constriction of the ipsilateral eye (direct response) and the contralateral eye (indirect or consensual response). A unilateral lesion of the retina or the optic nerve distal to the optic chiasm will produce blindness in that eye; thus if the other eye is blindfolded, the animal will have no vision. Shining a light in the affected eye will not produce a response in either pupil. Because the consensual innervation from the unaffected eye would be intact, pupil size and consensual response in the affected eye would be normal. With bilateral disease, both pupils would be dilated and completely unresponsive to light in either eye. A lesion affecting the parasympathetic third nerve, either in the brain stem or peripherally, would cause a dilated pupil in the ipsilateral eye that did not respond to light in either eye. Vision in that eye, however, would be normal, and shining a light in the affected eye would still elicit constriction of the contralateral pupil (consensual response).

809

810

The sympathetic innervation of the pupil controls dilation. The first sympathetic fibers to leave the spinal cord at the T1–T2 cord segments run cranially in the vagosympathetic trunk to synapse in the cranial cervical ganglia at the base of the skull. From there, the postganglionic fibers course through the middle ear and into the calvarium, where they join with the ophthalmic branch of the trigeminal nerve and project through the retrobulbar area to innervate the eye. A lesion anywhere along this path can produce the classic signs of Horner's syndrome. The pupil cannot dilate normally in darkness but constricts normally in response to light, so the anisocoria will be most evident in dim lighting. Loss of sympathetic innervation to other structures around the eye would produce enophthalmos, ptosis, elevated third eyelid, and vasodilation.

Eye movements are controlled by the oculomotor (III), trochlear (IV), and abducens (VI) nerves. Damage to one of these nerves results in deviation of the eye (strabismus), because the muscles innervated by the functioning nerves pull the eye away from the denervated muscles. Thus with loss of the oculomotor nerve (III), a ventrolateral strabismus occurs. Trochlear nerve (IV) loss results in an outward rotation of the top of the eye. In an animal with a round pupil like the dog, this can be detected by the position of the vessels in the fundus. The trochlear nerve (IV), like the oculomotor nerve (III), originates in the midbrain, but it is the only cranial nerve to completely decussate. The abducens nerve (VI) originates near the vestibular nucleus in the medulla. Loss of this nerve results in a medial strabismus. The abducens nerve (VI) also innervates the retractor bulbi muscle; thus lesions will abolish retraction of the globe when the cornea is touched. With lesions sparing one or two of the nerves, some eye movement will be apparent even though the eye is deviated. With retrobulbar or cavernous sinus lesions, all three nerves may be lost, resulting in an eye that is positioned normally but unable to move (external ophthalmoplegia).

The doll's eye reflex (physiologic nystagmus or oculocephalic reflex) can be used to induce eye movements, and thus evaluate the vestibular system, and the innervation of the extraocular muscles. The vestibular

apparatus detects movement of the head. The vestibular nuclei feed information about the direction and speed of movement to the third, fourth, and sixth nerve nuclei, which move the eyes in the opposite direction at exactly the same speed. This allows the animal to maintain a fixed image on the retina even when the head is moving. Once the eyes have reached the limit of their range of movement in that direction, a center in the pons takes over to quickly flick the eyes back in the direction of the head movement, and the process begins again. Clinicians can observe this physiologic nystagmus by rotating the head to one side at a moderate speed and observing the eye movements. It is often easier to see the eye movements if the eyelid is pulled back to reveal the sclera. Because the pathway between the vestibular nucleus in the medulla and the third and fourth nerve nuclei in the midbrain (the medial longitudinal fasciculus) runs through the area of the reticular activating system, it is also a useful reflex in animals with stupor or coma.

Facial sensation is carried by the three branches of the trigeminal nerve (V). The ophthalmic branch innervates the skin medial to the eye and the cornea. Touching the medial canthus of the eye or the cornea will produce a blink (the palpebral or corneal reflex, respectively) if sensation is present and the motor innervation of the eyelid muscles by the facial nerve (VII) is intact. Because the sympathetic fibers to the eye travel with the ophthalmic branch, Horner's syndrome can accompany the sensory loss. The maxillary branch innervates the skin of the side of the face and the nostrils. A blink can frequently be elicited by touching the dog on the lateral aspects of the muzzle as well. Alternatively, maxillary sensation can be evaluated by touching the inside of the nostril. A normal animal will withdraw the head, but this response is sensitive to altered consciousness and nerve damage. The mandibular branch carries sensation for the skin of the chin and just ventral and rostral to the ear.

The muscles of mastication are innervated by the motor portion of the mandibular branch of the trigeminal nerve (V). Bilateral trigeminal paralysis will result in a dropped jaw and an inability to prehend food. The animal will be able to swallow normally when food is placed into the back of the mouth because pharyngeal function is normal. With unilateral paralysis, the animal will be able to eat normally, and the only sign will be atrophy of the temporalis and masseter muscle on the ipsilateral side.

Facial nerve (VII) palsy results in loss of function of the small muscles of the face. The most obvious sign will be an inability to blink the eye on the ipsilateral side, either spontaneously, in the palpebral and corneal reflex, or in the menace response. The lip and cheek may sag, and food may become lodged in the cheek. The nostrils will not flair with respiration, and cats will not be able to move their whiskers forward. The animal will not be able to lay the ear back, and in droop-eared dogs the ear will sag further. With chronic denervation, the muscles may contract, producing a grimacing facial expression.

Because the parasympathetic innervation of the lacrimal glands is also carried by the facial nerve, a dry eye may accompany the loss of blinking, predisposing the eye to exposure keratitis. Tear production can be evaluated by the Schirmer's tear test. The facial nerve also conveys taste sensation from the rostral two thirds of the tongue. Taste can be evaluated by touching the lateral aspect of the tongue just behind the canine tooth with a cotton tip soaked in a bitter substance like atropine. If the animal can taste, it immediately begins to salivate and lick. Taste from the caudal one third of the tongue is carried in the glossopharyngeal nerve but is more difficult to evaluate in animals. Finally, sensation from the skin in the concave surface of the pinna is carried by the facial nerve.

The vestibular portion of the eighth cranial nerve transmits information about the position of the head relative to gravity and head movement from the inner ear. The vestibular nuclei use this information to control eye movements (discussed previously) and maintain balance. Acute unilateral lesions affecting the vestibular apparatus will cause profound disruption of balance. The imbalance in vestibular input between the two sides creates the perception of spinning, leaning, or both. In response to this, the animal will be

anxious and may be nauseated and vomit. It will lean and may even roll toward the side of the lesion. There will be a head tilt toward the affected side, sometimes dramatically. If able to walk, affected animals may circle or lean against a wall for balance. When lifted off the ground, they may curl toward the side of the lesion with the contralateral limbs extended and the ipsilateral limbs flexed.

810

811

Spontaneous nystagmus occurs because the imbalanced vestibular input creates a perception that the animal is spinning when it is not. With peripheral vestibular disease, the nystagmus may be horizontal or rotary with the fast phase away from the lesion. With time, the animal can compensate even if vestibular function does not return on the affected side. The disorientation and rolling will subside within a few days, and within 1 week the nystagmus may stop. Often signs like nystagmus can be precipitated again by rolling the animal onto its back or quickly extending the neck with the nose pointed toward the ceiling. Blindfolding will exacerbate the balance problems. With time, a residual head tilt may be the only sign that the vestibular system has not recovered completely. When the head is tilted, the eye position appears normal. If the clinician straightens the animal's head, the eye ipsilateral to the lesion will deviate ventrally. This is referred to as a *positional strabismus*.

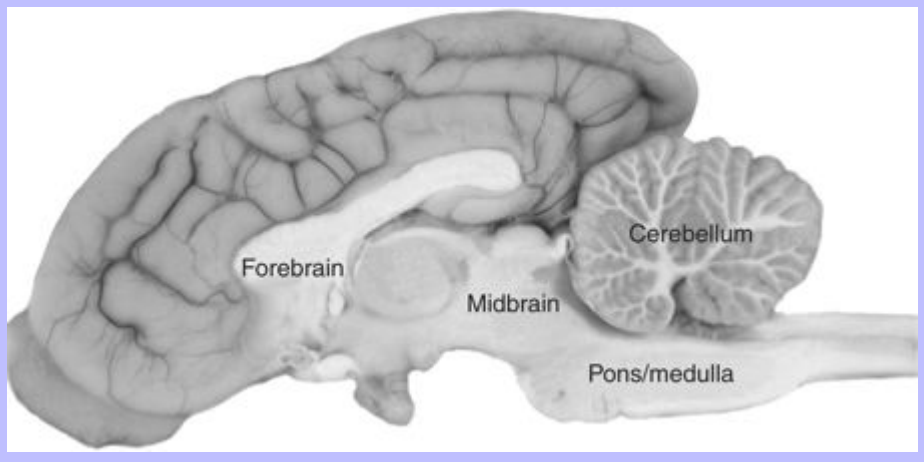
Because no asymmetry exists in the vestibular afferents, bilateral vestibular lesions do not produce the classic vestibular signs of nystagmus, head tilt, and circling. Instead the animal is wide based and apprehensive. It may hug the ground, refusing to move. Head movements are exaggerated. The doll's eye response is absent, and when blindfolded the animal has deficient righting responses.

The auditory portion of the eighth cranial nerve mediates hearing. Like vision, *hearing* refers to the conscious perception of a sensory stimulus and is assessed by observing the response to a noise such as clapping or a squeaky toy. When assessing the animal's ability to orient to a sound, it is important to avoid vibrations, shadows, or air currents that might provide a nonauditory cue. Animals with unilateral hearing loss may orient abnormally, turning away from a sound, but some can locate sound accurately even with unilateral hearing loss. The brain stem auditory evoked response (BAER) can detect unilateral damage to the cochlea or auditory pathways, but only a behavioral response truly tests hearing.

Swallowing entails coordination of the tongue, pharynx, larynx, and esophagus. The glossopharyngeal nerve (IX) and cranial branches of the vagus nerve (X) innervate the pharyngeal muscles and carry sensory information from the caudal tongue and pharynx. Damage to these nerves would affect the ability to swallow but not the ability to prehend food. Clinicians can use the gag reflex to assess pharyngeal function by placing the finger or a tongue depressor on the caudal aspect of the tongue. A normal animal will gag and swallow, whereas an animal with glossopharyngeal paralysis will not respond. An animal with unilateral damage may still be able to swallow, but it will choke, gag, or lose food through the nostrils. Regurgitation of swallowed food occurs with disorders of esophageal motility. The vagus nerve (X) is the major nerve of the esophagus. Contrast radiography may be necessary to evaluate esophageal motility.

Figure 191-9 Unilateral hypoglossal paralysis interferes with swallowing. The ipsilateral half of the tongue will atrophy, and the tongue will deviate. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).

Figure 191-10 For purposes of localization, the brain can be divided into four areas: the forebrain, midbrain, pons and medulla, and cerebellum. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).



The larynx is also innervated primarily by the vagus nerve (X) through the cranial and recurrent laryngeal nerves. Unilateral paralysis produces laryngeal hemiplegia and inspiratory stridor. Because the left recurrent laryngeal nerve follows a longer course through the thorax, that side is more susceptible to some disease processes, such as dying back neuropathies. Observing the movement of the vocal folds under light sedation will confirm paralysis. Voice change and dysphagia may also accompany laryngeal paralysis.

The spinal accessory nerve (XI) may contribute to some of the laryngeal and pharyngeal muscles, but it primarily innervates the trapezius, brachiocephalicus, and sternocephalicus. Denervation of these muscles is difficult to detect clinically.

The intrinsic and extrinsic muscles of the tongue are supplied by the hypoglossal nerve (XII). Unilateral damage will denervate the ipsilateral muscles and result in deviation of the tongue (Figure 191-9). Bilateral lesions abolish tongue movement, preventing normal prehension and swallowing.

191.1.2 Localizing the Lesion

Once a neurologic exam has been performed, that information is synthesized to localize the lesion. For localization purposes, the brain can be divided into four broad areas: (1) the forebrain (cerebrum and diencephalon), (2) the midbrain, (3) the pons and medulla, and (4) the cerebellum (Figure 191-10). It is often possible to further localize within these areas, but placing the lesion within one of the broad divisions is sufficient to have a reasonable list of differential diagnoses and diagnostic plan. When localizing the lesion, the first question the clinician must answer is whether the signs reflect focal, diffuse, or multifocal disease. A focal lesion is suspected if strong lateralization to the clinical signs occurs (e.g., circling, focal onset seizures, lateralized cranial nerve deficits). A focal lesion suggests localized damage to the brain as might occur from a neoplasia, vascular disease, or localized infection. A metabolic or toxic insult or a degenerative process would be expected to affect the brain more generally and not preferentially affect one side or the other. Although symmetrical forebrain signs suggest a diffuse disease process, they do not rule out focal disease. Focal disease can produce diffuse signs through mechanisms like obstructive hydrocephalus and increased intracranial pressure. Every effort should be made to explain the clinical signs based on a single lesion. If a single lesion cannot explain some signs; multifocal disease is suspected. For example, a single lesion cannot explain an animal that has both seizures (cerebral cortex) and unilateral facial palsy (medulla or facial nerve).

811

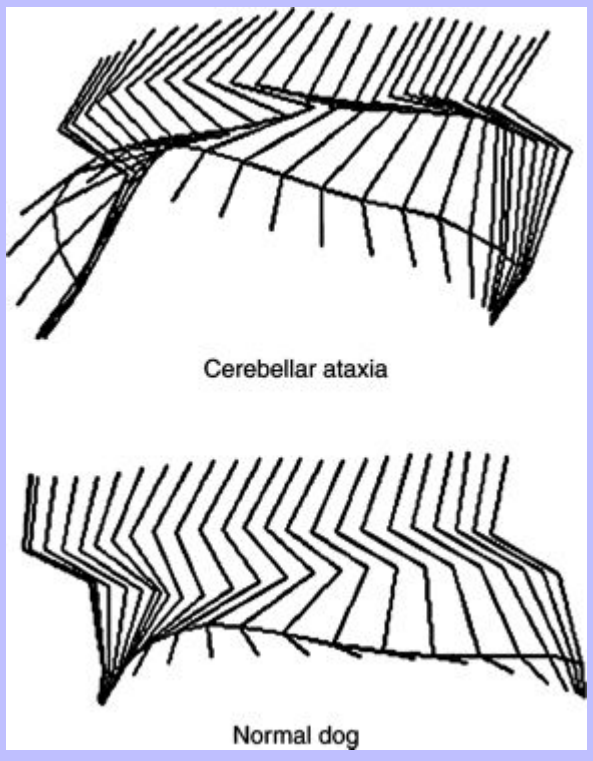
812

191.1.2.1 Cerebellum

The cerebellum receives input from higher motor command centers and sensory feedback from proprioceptive afferents and the vestibular system. It uses this information to coordinate movement and help maintain balance. The connections to and from the cerebellum via the cerebellar peduncles form a large part of the pons. A disease affecting the cerebellum or its peduncles will produce dysmetria, tremors, and vestibular signs. Dysmetria is most noticeable in the thoracic limbs as a goose-stepping gait (Figure 191-11) but will also be apparent as a wide base, truncal swaying, and exaggerated flexion of the pelvic limbs. The tremors of cerebellar disease are coarse tremors that disappear at rest. In acute cerebellar disease the tremors can be almost constant and the most dramatic manifestation of dysfunction. In more chronic disease, such as congenital cerebellar deficits, the tremors may be more subtle and only noticeable when the animal attempts to make a directed movement such as eating (intention tremors). The cerebellum works intimately with the vestibular system to control balance and eye movements. Lateralized lesions, such as in one cerebellar peduncle, can produce head tilt, imbalance, and horizontal or rotary nystagmus similar to a peripheral vestibular lesion. With cerebellar disease, the direction of the head tilt (away from the lesion) and nystagmus

(fast phase toward the lesion) are the opposite direction as in peripheral vestibular disease. This is referred to as *paradoxical vestibular syndrome*. With more diffuse disease of the cerebellum, a vertical nystagmus can be present as in central vestibular disease. In either case the animal may also lose its balance, especially in response to quick movements, such as shaking the head or sudden turns. Severe cerebellar lesions can produce decerebellate posturing, extension of neck, and thoracic limbs with flexion of the pelvic limbs. Because the menace response is a learned motor response and the cerebellum plays an important role in motor learning, animals with cerebellar disease may lose the menace response.

Figure 191-11 Lesions of the cerebellum disrupt the control of movement, resulting in dysmetria. This is most obvious as a goose-stepping gait in the thoracic limbs demonstrated by this stick figure representation of the limb in a Chinese crested dog with multiple system degeneration compared with a normal littermate. The line connecting the limb positions follows the trajectory of the carpus. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).



191.1.2.2 Pons and Medulla

The pons and medulla are the most caudal portions of the brain stem (Figure 191-12). The sensory and motor tracts of the spinal cord traverse these areas as well; thus lesions in this area can produce deficits in these long tracts similar to cervical spinal cord disease. Lateralization to the weakness or proprioception deficits would be common, and the side affected would depend on where the lesion was relative to the decussation of that particular tract. Because the respiratory centers reside in the medulla, an animal with a lower brain stem lesion producing complete paralysis would die from respiratory compromise. In addition to respiration, other autonomic centers reside in the brain stem, although clinical signs associated with their malfunction may not be as readily apparent.

Cranial nerve deficits are the signs that point most directly to a brain stem lesion. In isolation, such deficits could reflect a peripheral nerve lesion or small focal brain stem disease. Multiple nerve deficits or concurrent long tract signs (e.g., hemiparesis, proprioception deficits) point toward brain stem involvement. Cranial nerves V to XII arise from the pons and medulla. They all remain ipsilateral, and thus a lateralized deficit will be on the side of the lesion. The facial nerve (VII), vestibulocochlear nerve (VIII), and nerves controlling the pharynx, larynx, and tongue (IX, X, XII) run laterally from the brain stem out their respective foramina. Thus a lesion on the lateral aspects of the brain stem, such as a meningioma of the cerebellopontine angle, may affect combinations of these nerves (Figure 191-13). The trigeminal nerve (V) originates from the pons in close proximity to these nerves but runs rostrally to exit retrobulbar. The abducens nerve (VI) also runs rostrally from the medulla to innervate the lateral rectus and retractor bulbi muscles. A lesion produces a medial strabismus.

191.1.2.3 Midbrain

In addition to the nuclei of cranial nerves III and IV, the midbrain contains important motor nuclei and serves a major role in regulation of consciousness (Figure 191-14). The red nucleus is the origin of one of the major UMN tracts in quadrupeds, and damage to this nucleus in the midbrain will cause paresis or paralysis. Because the vestibulospinal tracts originate in the medulla and would be spared by a midbrain lesion, their excitatory effects on extensors of the limbs and neck would be unopposed by the normal inhibitory effects of the rubrospinal tracts. Thus midbrain lesions can produce decerebrate rigidity, a posture with dorsal extension of the neck and extension of the limbs. Because the respiratory centers reside more caudally in the medulla, the animal can continue to breathe even if completely paralyzed from a midbrain lesion. Conscious proprioception tracts must also course through the midbrain on their way toward higher centers. Thus deficits in postural reactions may be apparent with a midbrain lesion if the animal is still capable of voluntary movements.

812
813

Figure 191-12 Lesion of the pons and medulla can affect cranial nerves V to XII, proprioception, and motor tracts. Severe lesions cause death by affecting respiratory centers. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).

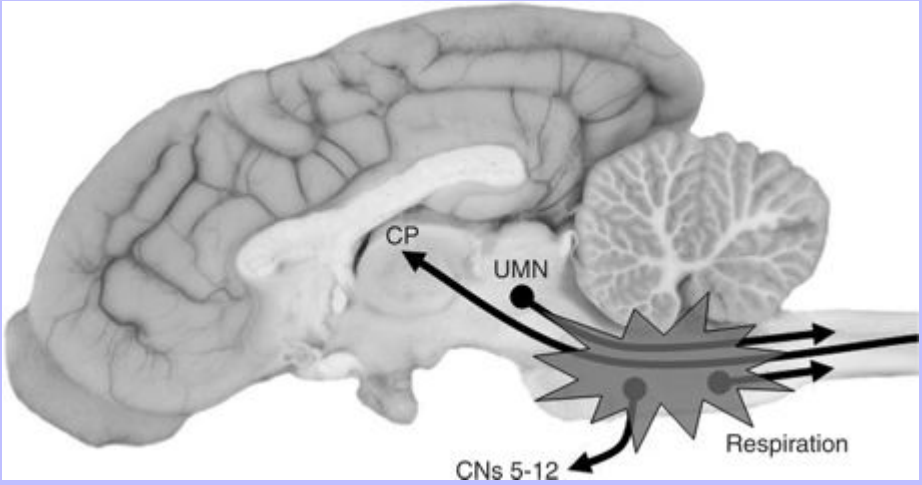


Figure 191-13 The cranial nerves form two anatomic clusters. Cranial nerves VII to XII run laterally from the brain stem and could be affected by a lesion such as a meningioma of the cerebellopontine angle. Cranial nerves II to V course rostral below the forebrain to exit in the retrobulbar area. Thus lesions in the cavernous sinus or retrobulbar area could affect combinations of these nerves. The olfactory nerve *(1)* crosses the cribriform plate and projects directly to the limbic areas. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).

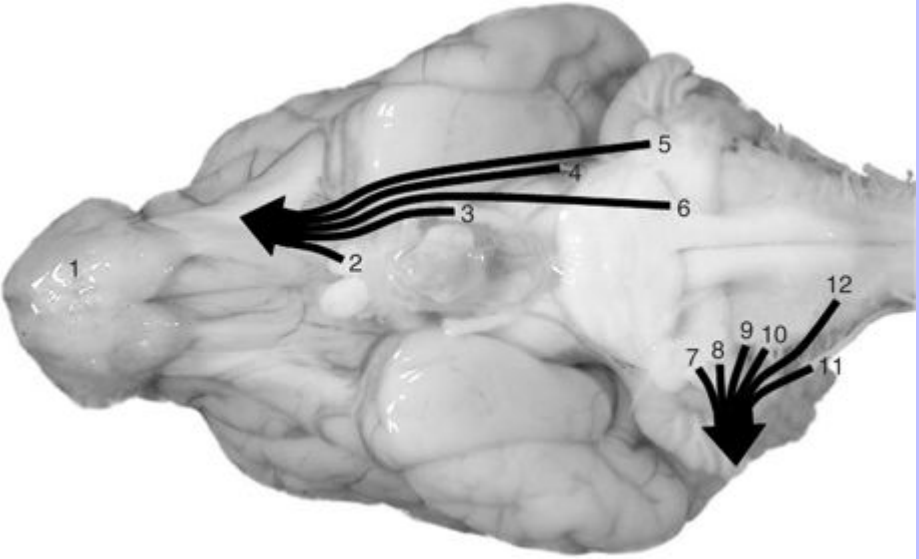
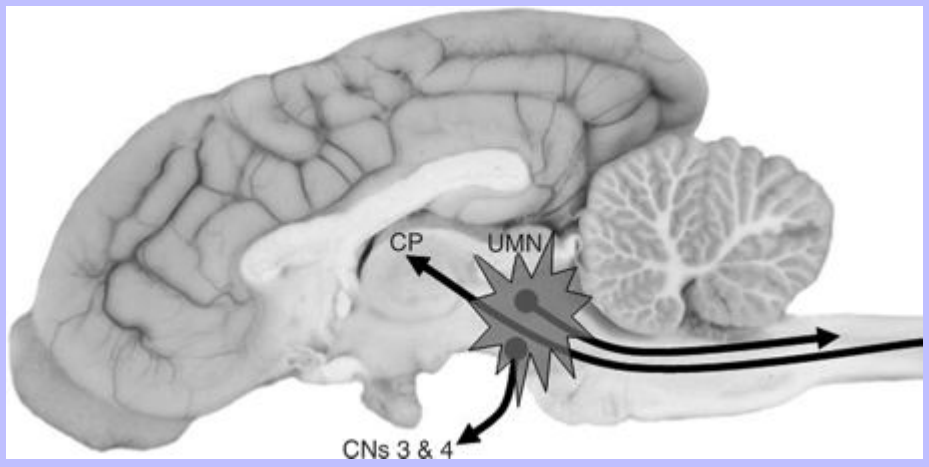


Lesions below the midbrain may produce complete paralysis and respiratory compromise but may not directly alter consciousness or behavior. The midbrain marks the beginning of the reticular activating system (RAS), a group of loosely defined areas that project from the cranial pons, midbrain, and hypothalamus to the cerebral cortex and regulate consciousness and goal-directed behavior. Lesions of the midbrain will affect these functions (see following discussion).

Figure 191-14 Lesions of the midbrain affect cranial nerves III and IV. Damage to the origin of upper motor neurons (UMNs) in the red nucleus can lead to decerebrate rigidity and damage to the reticular activating system (RAS) will affect consciousness. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).



The trochlear nerve (IV) innervates the dorsal oblique muscle. Deficits result in outward rotation of the eye and, because the trochlear nerve is the only cranial nerve to completely decussate, a midbrain lesion will produce strabismus in the contralateral eye. In animals with round pupils such as the dog, this can only be detected by looking at the orientation of the vessels in the fundus. Because the trochlear nerve will seldom be damaged without affecting other cranial nerves, this is usually not an issue. The oculomotor nerve (III) innervates the remaining extraocular muscles. Damage results in ventrolateral strabismus and loss of the normal doll's eye response in the ipsilateral eye. The third nerve also contains the parasympathetic fibers to the pupil. Damage to these fibers will produce mydriasis and loss of the PLR, although vision is unaffected.

813 814

191.1.2.4 Forebrain

The forebrain encompasses the cerebral cortex, basal nuclei, thalamus, and hypothalamus. These areas mediate higher brain functions such as personality and learned behavior, motor planning, sensory processing, and emotional, endocrine, and autonomic functions, respectively. The olfactory (I) and optic (II) nerves are also primarily forebrain nerves. All the nerves of the eye and extraocular muscles (II, IV, VI), along with the trigeminal nerve (V), course rostrally along the floor of the calvarium to exit through their retrobulbar foramina. Thus a lesion in the area of the cavernous sinus may produce deficits in combinations of these nerves and affect the overlying forebrain. These nerves can also be affected after they exit the calvarium by retrobulbar lesions.

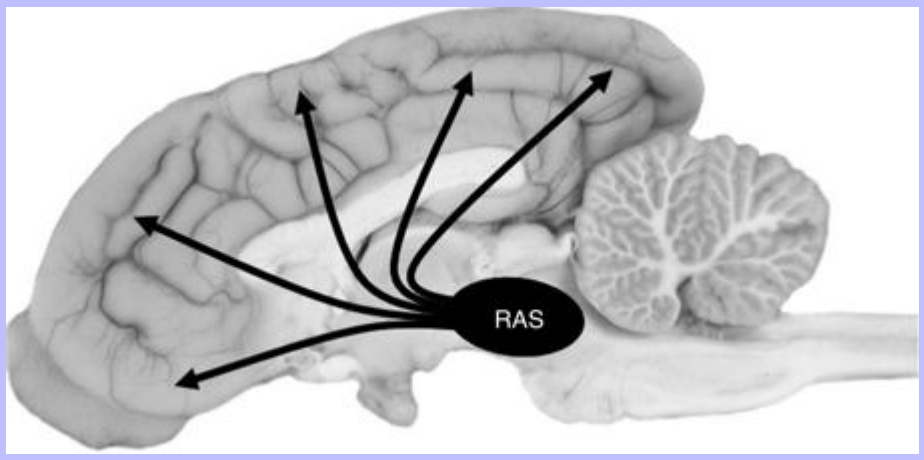
Although the pupilomotor fibers of the optic nerve project to the midbrain to control the PLR, the main projection of the optic nerve to the forebrain mediates vision. Lesions of the optic tract, lateral geniculate

nuclei, or occipital lobes can produce a loss of vision with normal PLR (central blindness). If unilateral, the vision loss is limited to the contralateral visual field.

In addition to vision, other sensory modalities such as conscious proprioception or hearing are relayed through the thalamus to the appropriate area of the cerebral cortex. Thus the ability of the animal to respond meaningfully to a sensory stimulus may be disrupted by lesions of the appropriate thalamic nuclei or region of the cerebral cortex. Like the PLR, some other simple responses such as the startle response to a loud noise or the dazzle response to a bright light are mediated at a subcortical level. Vision appears to be the most sensitive to diseases such as hypoxia that diffusely affect the forebrain. The olfactory nerve projects directly to the olfactory bulbs and from there to the limbic areas of the forebrain, thus bypassing the thalamus. Olfactory deficits, however, are difficult to detect in animals.

The hypothalamus controls endocrine function through the pituitary gland. It also regulates a variety of other homeostatic functions such as body temperature, osmolality, and autonomic functions. Together with limbic areas, the hypothalamus is also involved in learning and memory, goal-directed behaviors, and emotions.

Figure 191-15 The nuclei of the reticular activating system (RAS) in the rostral brain stem project to the cerebral cortex and regulate attention and goal-directed behavior. Lesions of either the cortex or the RAS can affect consciousness. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).



Epileptic seizures are caused by abnormal electrical activity in the cerebral cortex; thus they should be considered an unambiguous sign of forebrain disease. Either focal damage to the cortex or diffuse metabolic effects can produce seizures (see Chapter 48).

Alterations of consciousness and behavior are hallmarks of forebrain disease. The traditional view of regulation of consciousness is that the RAS in the brain stem projects to the cerebral cortex and “activates” it to produce normal consciousness (Figure 191-15). This concept is useful when considering causes of stupor

and coma. Such profound alterations of consciousness can result from either a lesion in the brain stem affecting the RAS nuclei, the projections pathways of these systems toward the cortex, or diffuse disease affecting the cerebral cortex. Lesions of the brain stem caudal to the RAS can render the animal quadriplegic without necessarily disrupting consciousness.

The function of these RAS systems, however, is more complex than just turning on or off the cerebral cortex. Different nuclei and neurotransmitter systems are responsible for different aspects of attention, arousal, and goal-directed behavior. One of the main projections from the RAS nuclei to the cerebral cortex is the medial forebrain bundle—a tract running from the midbrain through the lateral hypothalamus to project diffusely to the cortex and limbic forebrain. Brain damage can lead to complex behavioral abnormalities, which are a manifestation of functional subsystems of behavior operating without direction toward a goal.[1,2]

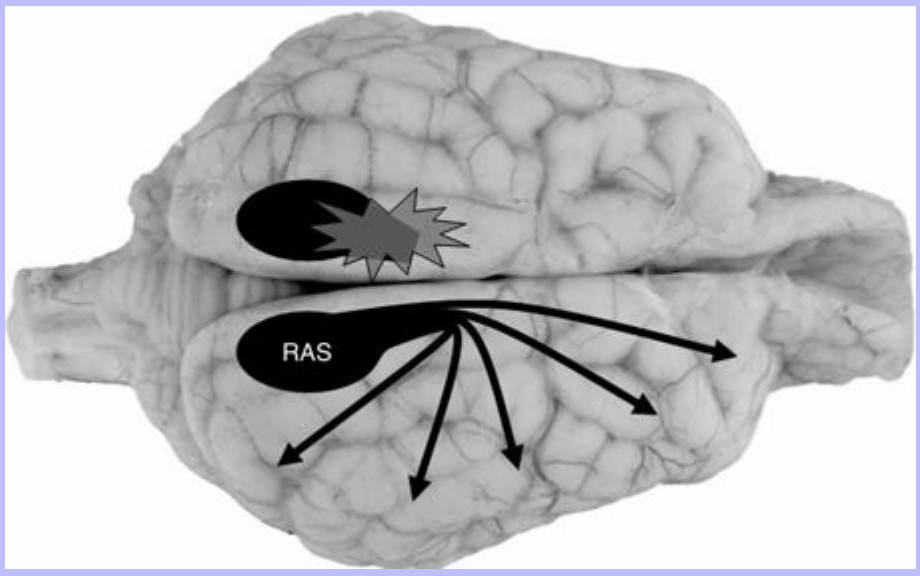
Sensory neglect refers to a loss of meaningful response to stimuli in multiple sensory modalities without a lesion in the classic sensory pathways or a significant depression of consciousness. With unilateral lesions of the medial forebrain bundle or cerebral hemisphere, these signs can be limited to one side (hemineglect or hemi-inattention).[3] Unilateral loss of hearing and proprioception with tumor of the medulla would not fit the definition of hemineglect. The classic sensory pathways are affected in this example, and other sensory modalities, such as vision, are unaffected. Likewise, a comatose animal has simply severely altered consciousness and not neglect.

Hemineglect provides the most interesting illustration of the difference between sensory neglect and loss of consciousness or classic sensory or motor pathway lesions. The decussation of sensory and motor pathways means that all sensory information originating from the right half of the animal's perceptual world goes to left forebrain, and all control of motor activity directed toward the right side of that world originates from the left forebrain. The reader should note that this motor control extends beyond simply control of the right limbs. The activation of the left cortex is necessary for the animal to direct its attention and behavior toward the right half of the world (Figure 191-16). Thus a unilateral lesion may be immediately apparent as a tendency to circle (Figure 191-17). Such circles can be large, wandering circles where turning only occurs when the animal reaches a corner or other obstacle that requires a decision. Because all their attention is directed toward the side of the world associated with the functional cortex, they orient and turn in that direction (i.e., they circle toward the side of the lesion).[1,4]

814

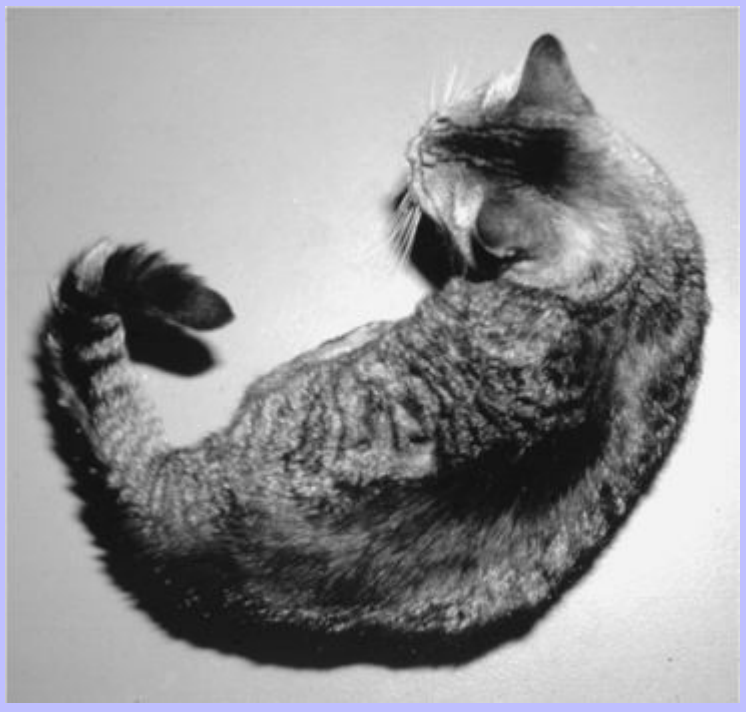
815

Figure 191-16 The RAS nuclei project to the ipsilateral cortex. A focal lesion of the RAS or diffuse cortical disease on one side will produce hemineglect. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).



Conversely, they neglect all sensory information arising from the side contralateral to the lesion. They do not track cotton balls or menace in the contralateral visual field. They have deficient conscious proprioception and postural reactions on that side. They do not orient to sounds in that direction but may turn a circle in the opposite direction to localize the sound. Noxious stimuli may produce arousal, but no meaningful behavior (e.g., biting the clinician) will be directed toward the source of the pain.[1,4,5]

Figure 191-17 With forebrain lesions the animal may curl and circle toward the side of the lesion. In contrast to vestibular disease (see Figure 191-4), the ears are level but the nose is pulled around toward the flank (adversion). (From O'Brien DP: Circling. In August JR, editor: *Consultations in feline internal medicine*, Philadelphia, 1994, WB Saunders Co, p 449.)



In humans the difference between neglect and simple sensory deficits is readily illustrated by asking the patient to perform tasks such as drawing a picture (they would only draw the half corresponding to the functional half of the brain).[3] In animals this splitting of the world into neglected and normal halves is most apparent at feeding time. A hungry animal with sensory neglect will eat the food from half the food bowl (Figure 191-18). Olfactory inputs would tell them that food is around, but they will not eat from the neglected half because they cannot direct their attention toward that side of the world.[1,4,5]

The red nucleus in the midbrain is responsible for generating the gait in quadrupeds, and the corticospinal system is less important than in humans. Postural reactions require forebrain control and may be deficient, but an animal with bilateral forebrain damage that is not severe enough to produce stupor may still be able to walk relatively normally. The walking, however, may not be directed toward any meaningful goal; instead the animal may pace aimlessly. As in the hemineglect cases, it may not respond to sensory stimuli. In the extreme case, it will not even be aware of the fact that it has walked into a corner and will continue to push forward, head pressing against the corner.

815
816

Figure 191-18 An animal with hemineglect will eat the food from half the food bowl. Even though still hungry, the dog cannot direct its attention toward the food contralateral to the lesion. (From O'Brien DP. Comparative Neurology http://www.cvm.missouri.edu/academic/neurology/vm604, 2004).

Forebrain lesions disrupt higher control, releasing some subcortical behaviors from their normal regulation.[2] For example, dogs and cats have a bite reflex whereby they will turn and snap at anything that touches them around the mouth. Normally this reflex is regulated by higher centers, activated when needed, such as in a fight, and inhibited when not needed, as in nuzzling the owner. Like a spinal reflex, it can be exaggerated when released from inhibition, and the animal with forebrain disease may snap without warning or emotion when touched around the mouth. In contrast to sensory neglect, where the animal ignores all stimuli, some brain-damaged animals develop magnet responses, whereby they compulsively orient and move toward a stimulus. These orienting responses are subcortical responses released from normal forebrain control and become autonomous. Emotional responses such as rage or fearfulness are also subcortical, and it is not unusual for a demented animal to respond excessively (e.g., when restrained).

Many behaviors such as sleeping and feeding are goal-directed behaviors that can be disrupted by forebrain disease. The same way the animal cannot direct its attention toward external stimuli, it cannot respond to internal needs to accomplish these behaviors. Thus it may be insomniac or anorexic.[1,2] Learned behaviors, such as tricks or housebreaking, may also be lost with forebrain disease. The micturition response is mediated in the pons, thus the animal is able to empty its bladder but is unable to regulate when micturition occurs.

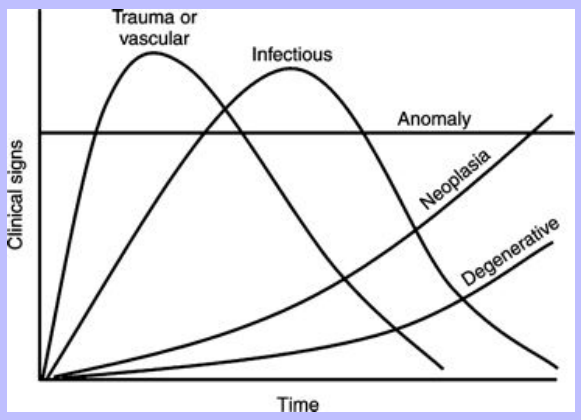
191.2 DIFFERENTIAL DIAGNOSES

Once the lesion has been localized, a list of differential diagnoses can be generated and a diagnostic plan developed. The signalment provides the first clues to organizing the differential list. Congenital and hereditary diseases will be much more frequent in young, purebred animals. Although infectious diseases, traumatic injury, and toxicities can occur anytime, young animals are more likely to be affected. Some diseases, such as idiopathic epilepsy, will have their onset in young adulthood. With increasing age neoplasia, metabolic encephalopathies, and degenerative diseases become increasingly common. Breed predilections are most noticeable in hereditary diseases. Tables of breed predilections are available.[6,7]

Onset and progression of signs is the other important clue to ordering the differential diagnosis list (Figure 191-19). A congenital malformation would be present from birth and relatively static, although some, such as hydrocephalus, could progress over time. An acute onset of signs would be expected with vascular disease, trauma, most toxins, and many infectious, inflammatory, and metabolic diseases. Some infectious and inflammatory or metabolic diseases will be chronic and progressive, as will most neoplastic or degenerative conditions.

Finally the neurologic exam will suggest the type of disease process. Some diseases will have predilection for specific parts of the brain (see following discussion). Generally, lateralized neurologic signs such as circling, hemiparesis, or unilateral cranial nerve deficits suggest a localized disease process such as an infection, vascular disease, neoplasia, or traumatic injury. Likewise, focal onset seizures would suggest localized cortical damage, although idiopathic epilepsy can rarely produce focal seizures.[8,9] Infectious and inflammatory, vascular, or metastatic neoplasia would be the most likely to produce multifocal signs. A metabolic or toxic insult should not affect the brain asymmetrically, and diffuse, symmetrical signs would be expected. Because the cerebral cortex is the most metabolically demanding part of the brain, forebrain signs tend to predominate. As discussed in the introduction, however, a localized disease process can result in diffuse forebrain signs through increased intracranial pressure.

Figure 191-19 The progression of signs over time provides important clues to the underlying cause. A mental "sign-time graph" can help to categorize diseases. (From Lorenz M, Kornegay JN: *Handbook of veterinary neurology*, ed 4, Philadelphia, 2004, WB Saunders Co.)



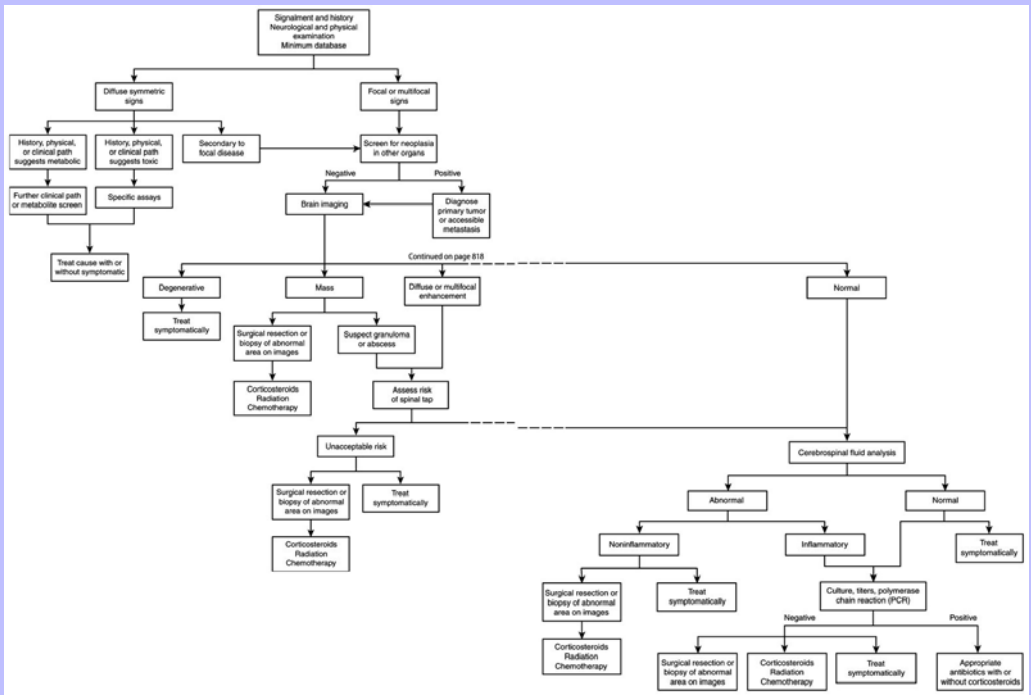
191.3 DIAGNOSTIC APPROACH TO BRAIN DISEASE

When considering the diagnostic approach to diseases affecting the brain (Figure 191-20), the clinician must weigh cost, availability, risks, and potential yield. The value of a thorough history and neurologic examination should never be underestimated. Even if advanced imaging reveals a clear lesion, if that lesion does not correspond to the localization on the neurologic examination, its significance needs to be questioned.

Routine clinical pathology is the most readily available, most cost-effective, and least invasive procedure. Even though the yield may be low with focal disease, it is still an important minimum data base for any ill animal, and in cases with diffuse disease, ruling out a metabolic cause is essential. A complete blood count (CBC) may suggest infectious causes and provide clues to other causes. It is important to recognize, however, that a normal blood count does not rule out encephalitis as a cause. Serum biochemistry profile and urinalysis will be essential to rule out energy deficiencies, electrolyte disturbances, or accumulation of endogenous toxins. Particularly with diffuse forebrain signs or seizures, a liver function test such as bile acids or ammonia tolerance should be included. If inborn errors of metabolism are suspected, urine assays for abnormal metabolites may be necessary. Assays for specific exogenous toxins, such as lead or organophosphates, may be indicated if signs and history suggest likely candidates, but a screen for all possible neurotoxins is not feasible. Because neurologic signs can accompany endocrine diseases such as hypothyroidism and hyperadrenocorticism, endocrine function tests should be considered if the clinical signs and signalment warrant. Thoracic and abdominal imaging will be important, particularly in geriatric animals, to rule out metastatic or cardiac disease.

816
819

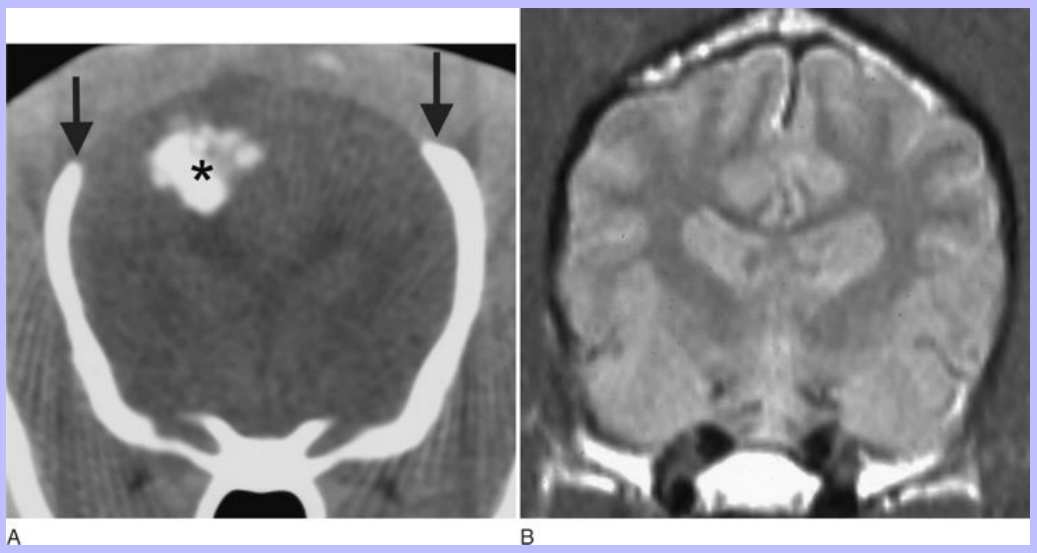
Figure 191-20 Diagnostic approach to brain disease.



The increasing availability of advanced brain imaging techniques for animals has revolutionized the practice of neurology. Although advanced imaging is expensive, the high return usually justifies the expense. Routine skull radiographs are of very limited value in diagnosing brain disease, because only the skull can be imaged without invasive contrast studies. The superimposition of the structures on radiographs makes interpretation difficult. Ultrasound imaging of the brain, although useful, is only an option when an open fontanelle or craniotomy provides an acoustic window.

Computed tomography (CT) and magnetic resonance imaging (MRI) allow detection of structural changes of the brain itself (Figure 191-21).[10,11] CT is more readily available and less expensive. CT relies on traditional radiographic principles; thus the image consists of similar graded densities, with bone being white and air black. The attenuation of the x-rays will be similar to that of the gamma rays used in radiation therapy, so CT images are used to calculate dose delivery. Only cross-sectional images are acquired, although computer reconstructions can generate sagittal or dorsal planes. CT has the advantage of being able to image bone, which is useful in diseases such as osteochondrosarcomas of the skull. The ventricular system is readily appreciated on CT, but fine anatomic detail is often not visible. Edema may be visible as a reduced density of the parenchyma, whereas other processes, such as acute hemorrhage or calcification, produce an increased density. CT resolution is limited by the attenuation of the x-rays by the surrounding skull. The petrosal bones at the base of the skull are dense, thus limiting the quality of CT images of the area below the tentorium.

Figure 191-21 **A,** Computed tomography (CT) scans are more readily available and can image many intracranial diseases. Bone is readily visible as in this recurrent osteochondrosarcoma *(asterisk)* after a prior craniectomy *(arrows)*. **B,** Magnetic resonance image (MRI) provides much greater detail, especially in the caudal fossa. This proton density image of normal brain clearly delineates gray and white matter.



MRI uses magnetic resonance of charged particles to generate radio waves that can then be detected and reconstructed into an image in any plane desired. The MRI unit generates a large magnetic field through the brain, which aligns charged particles with the field. It then conducts a sequence of radio wave pulses through the brain while a radio frequency detector listens for the echo from the interaction of those pulses with the charged particles and the magnetic field. The hydrogen ion (proton) generates a large portion of the radio wave signal in most MRI sequences, and because water contains a high proportion of free protons, the MRI can be thought of as imaging free water content. This is particularly useful in the nervous system, where marked differences exist in water density between gray matter, white matter, edema, and the ventricular system. In contrast, bone generates little signal. By altering the sequence used, different weight is given to the signals producing different contrasts between the tissues. In a T1-weighted image, water in the ventricular system is black and white matter is light, whereas in a T2-weighted image, the ventricles appear white and the white matter dark. Edema is readily apparent as an increase signal on T2 images. An in-between sequence (proton density) decreases the contrast between the ventricles and the brain, but increases contrast between gray and white matter, revealing fine anatomic detail. More advanced techniques such as FLAIR (fluid attenuated inversion recovery), MRI spectroscopy, and MRI angiography can also be useful for special applications. One disadvantage of MRI is that it cannot be used when metal implants are present.

For both CT and MRI, the initial evaluation is for differences in density and signal in the brain parenchyma, which may be readily apparent as asymmetry. Even without clear differences within the parenchyma, a mass effect may produce a shift of the midline structures or distortion of the ventricles. Contrast agents are available for both imaging modalities. After IV injection, the blood-brain barrier would normally exclude such agents from the brain. Breakdown of this barrier by neoplasia or inflammation will result in accumulation and contrast enhancement of the lesion. Contrast enhancement is most apparent on the T1-weighted MRI.

819

820

Although advanced imaging may provide an unprecedented view of the nervous system, it still may not provide a definitive diagnosis. Brain biopsy is not commonly used as a diagnostic procedure in veterinary medicine, except when accompanying tumor resection. Imaging-guided biopsy techniques will decrease the morbidity associated with biopsy and increase the availability.

Because a mass lesion producing increased intracranial pressure significantly increases the risk of complications of a spinal tap, imaging should be recommended before performing the tap. The CSF is most useful in inflammatory disease but can provide clues to other diseases such as an increased protein with neoplasia. In some cases, such as cryptococcosis, the organism may be found in the CSF. More commonly, the CSF simply confirms inflammation in the central nervous system (CNS). Then auxiliary tests are necessary to make the definitive diagnosis. Cultures of the CSF are rarely positive, but the importance of ruling out a treatable condition warrants the expense if the CSF analysis, and signs are compatible with bacterial meningoencephalitis. Most infectious diseases will be identified by titers on the serum, CSF, or both. Although some titers such as the antigen titer for cryptococcosis are highly reliable, most are highly subjective. It is hoped that the increasing availability of PCR testing for infectious agents will relieve the problems clinicians have interpreting titers.

Electrodiagnostic tests allow functional testing of the nervous system. The electroencephalogram (EEG) is used primarily to confirm epileptic activity in the brain in suspected seizure cases. It is particularly useful in cases of status epilepticus to confirm that seizure activity has been stopped. The brainstem auditory evoke response (BAER) is used primarily to assess cochlear function, but can also assess brain stem conduction. Somatosensory and visual evoked potentials can assess function of these systems.

Response to therapy can be an important diagnostic tool, particularly when financial or other factors limit the diagnostic tests pursued. Therapy for the most likely treatable condition can be instituted and the response

monitored. For example, dramatic improvement with doxycycline would support a presumption of rickettsial disease. Although corticosteroids play an important role in treating brain disease, the risks of side effects, including exacerbation of an infectious disease, need to be weighed carefully. Dramatic improvement with corticosteroids would be consistent with a neoplasia or infectious and inflammatory disease. Improvement with neoplasia is usually short-lived because it relieves the peritumoral edema but does nothing about the neoplasia. Some inflammatory disease may be kept in remission with prolonged treatment. Infectious diseases will also often respond dramatically to corticosteroids, only to worsen if appropriate antibiotics are not also instituted. Response to anticonvulsant drugs helps to confirm a seizure disorder but does not rule out an underlying cause to the seizures.

191.4 PRIMARY BRAIN DISEASES

The brain is the most metabolically demanding organ in the body. A large portion of the body's energy supply goes toward maintaining resting membrane potentials and neurotransmission. The nervous system has more limited energy metabolism pathways than other tissues; thus it is more sensitive to disturbances of glucose or oxygen supply. The brain is also quite sensitive to exogenous or endogenous toxins. The higher the level of function of a portion of the nervous system, the more sensitive it tends to be to metabolic insults. Thus forebrain signs are a common manifestation of systemic diseases. The brain can also be affected in disease processes such as infections, most of which are multifocal in nature (discussed in Chapter 192). This chapter will focus on diseases that primarily affect the brain and are not covered in other chapters. They are organized roughly by typical age of onset.

191.4.1 Congenital and Hereditary Diseases

Congenital refers to any disease or malformation present at birth. It encompasses both genetic conditions and the results of external influences during gestation such as toxins, malnutrition, birth trauma, or infections. If more than one individual in a family is affected, then the condition is familial. However, a familial disease does not necessarily have to be genetic, because families may share some things (e.g., diet, environment, infection exposure). Breed predilection for a disease suggests a genetic contribution, but again, could reflect other factors such as the typical use of a particular breed or supplements in vogue with those breeders. Multiple litters must be evaluated before any estimate of genetic contribution to a disease can be formulated. Many hereditary neurologic diseases will be congenital or at least apparent at an early age, but notable exceptions exist. Some lysosomal storage diseases require time for accumulation of byproducts. Animals with hereditary cerebellar ataxia (abiotrophy) may be normal clinically and histologically for a variable period of time and then develop clinical signs as the Purkinje cells undergo premature cell death. Finally some, like idiopathic epilepsy or ceroid lipofuscinosis (CL) will not show signs until early or even late adulthood.

Most hereditary disease will be due to autosomal recessive traits or have a complex inheritance, because dominant traits can be eliminated from a breed by simply not breeding affected dogs. The nervous system is especially sensitive to genetic disease. Many genes are expressed for brief periods to appropriately direct the complex development of the nervous system. Because few neurons are capable of reproducing after maturity, defective neurons cannot be replaced. Mutations that interfere with the ability of the cell to deal with insults such as oxidative stress can lead to accumulated damage and early onset of degeneration.

191.4.1.1 Congenital Malformations

Congenital malformations of the brain would typically be present from birth and be nonprogressive. A few exceptions, such as congenital hydrocephalus, can manifest later in life with progressive signs. The nervous

system originates from a plate on the dorsal surface of the embryo, which folds in to form the neural tube. This infolding begins in the thoracic area and extends rostrally and caudally. Genetic defects and in utero infection, toxins, or malnutrition may cause failure of normal closure of the neural tube, which is typically manifested at rostral or caudal end of the developing nervous system. These malformations can range in severity from complete failure of cerebral development (anencephaly) to clinically unapparent malformations such as agenesis of the corpus callosum. Typically the effects are most apparent in the midline structures. In some cases, concurrent malformation of overlying tissues allows protrusion of meningeal or brain tissue through the defect.[12] Severe malformations will be apparent on physical exam, whereas brain imaging or postmortem examination may be necessary to detect more subtle deficits. Brain anomalies may accompany other defects such as cleft palate or cardiac anomalies.

Once the neural tube has formed, differentiation of the various parts of the brain occurs and can be disrupted by similar genetic or environmental influences. Migration of neurons within the cerebral cortex leads to the characteristic sulci and gyri and the normal laminar arrangement of neurons within the cortex. In lissencephaly, this normal migration is disrupted (Figure 191-22). Some, or all, of the surface of the cortex is smooth and abnormally thickened (pachygyria), which can be visualized on MRI. In humans a variety of mutations have been associated with lissencephaly, and a genetic cause is suspected in dogs because it has been recognized primarily in Lhasa apsos.[12–14] Affected dogs showed behavioral changes, vision deficits, and seizures.[13,14] Excessive production of small gyri (polymicrogyria) has also been reported.[12] In other conditions the gross structure of the brain is normal, but the laminar arrangement of neurons and white matter within the cortex is disrupted, leading to abnormally placed nests or rows of neurons. Such dysplasia has been observed in the cerebellar cortex but was associated with severe motor problems, suggesting that more than cerebellar function was disrupted even though dysplasia was not apparent in other areas.[15]

820
821

Figure 191-22 The lack of normal gyri in lissencephaly could be visualized with magnetic resonance imaging (MRI). Like most congenital anomalies, signs are present from birth and are static.

Cerebellar hypoplasia is seen most commonly in cats after in utero or early neonatal infection with the feline panleukopenia virus. The rapidly multiplying granule cells of the cerebellum are sensitive to damage by the virus at this stage of development.[12] Although apparently much less common, evidence indicates that canine parvovirus infection can produce similar damage to the developing cerebellum of dogs.[16] Cerebellar hypoplasia can also occur as isolated malformation without evidence of infection or as part of a more generalized brain development abnormality. The Dandy-Walker syndrome of humans is characterized by agenesis of the cerebellar vermis. A similar malformation has been described in dogs and cats.[12]

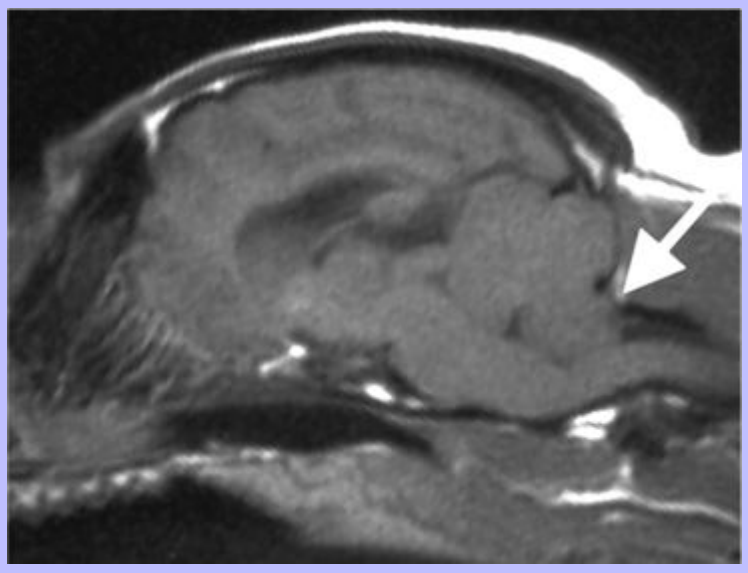
For most congenital malformations, treatment is symptomatic and the prognosis will depend upon the severity of the neurologic deficits. History and serology can rule out toxic or infectious causes that may potentially be treatable. Genetic and nutritional counseling may help prevent future occurrences in breeding kennels.

191.4.1.2 Chiari-like Malformations

Signs associated with abnormal conformation of the foramen magnum and cerebellar vermis were described as early as 1965 but were initially attributed to an enlargement of the dorsal aspect of the foramen (occipital dysplasia).[17,18] Subsequently it was demonstrated that a great deal of variation exists in the dorsal extent of the foramen magnum in normal dogs.[19] With the advent of MRI it became easier to image this area of the brain and spinal cord, and a malformation of the cerebellum similar to the Chiari type I malformation of humans was identified in the Cavalier King Charles spaniel, other dog breeds, and a cat.[20-22,22A] The Chiari type I malformation consists of an elongation of the caudal, ventral cerebellum through the foramen magnum, and in humans it is thought to be the result of small caudal fossa (the area caudal to the tentorium) crowding the enclosed structures. In addition to compressing the medulla, the herniated cerebellum obstructs normal outflow of CSF from the calvarium that can lead to secondary hydrocephalus. As the brain expands with each heart beat, the herniated cerebellum is forced caudally, generating pulsatile compression of the cervical spine. This leads to syringomyelia of the cervical spinal cord.[23] In addition to those referable to hydrocephalus and cerebellar compression, clinical signs include cervical myelopathy signs: ataxia, proprioception deficits, weakness, and cervical pain. The malformations appear to create paraesthesias, and excessive scratching of the ear, neck, or shoulder may be the major presenting complaint.[22]

The Chiari-like malformation also referred to as caudal occipital malformation syndrome,[22A] is readily diagnosed on a midsagittal MRI on which the herniation of the cerebellum and any concurrent hydrocephalus or syringomyelia can be visualized (Figure 191-23). Although some improvement can be achieved with antiinflammatory drugs and rest, definitive treatment consists of enlarging the foramen magnum via a suboccipital craniectomy and resecting any dural bands that are constricting the cerebellum. Sometimes the herniated portion of the cerebellum should be removed as well. With the improved CSF dynamics after such decompressive surgery, the hydrocephalus and syringomyelia may resolve.

Figure 191-23 Midsagittal magnetic resonance image (MRI) of a Cavalier King Charles spaniel showing protrusion of the cerebellar vermis through the foramen magnum *(arrow)* similar to the Chiari type I malformation in humans.



821

822

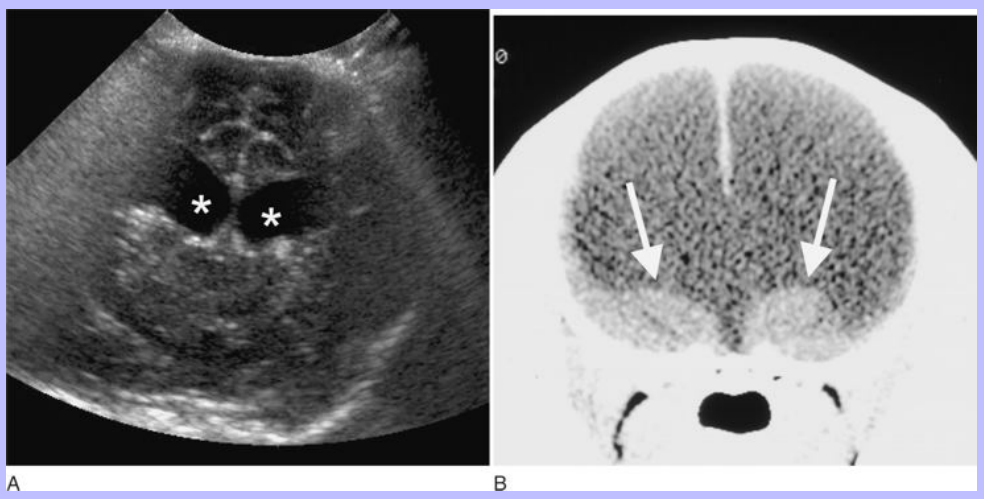
191.4.1.3 Hydrocephalus

Hydrocephalus can be either congenital or acquired. It can also be categorized as either obstructive or communicating. Obstructive hydrocephalus occurs when a blockage occurs in the flow of CSF through the ventricular system. The obstruction typically occurs at the bottlenecks of CSF flow, the connection between the lateral ventricle and the third ventricle (the intraventricular foramen), or the connection between the third and fourth ventricle (the mesencephalic aqueduct). Obstruction of one intraventricular foramen will result in unilateral dilation of the lateral ventricle. With obstruction of the mesencephalic aqueduct, both lateral ventricles and the third ventricle will dilate. Obstructive hydrocephalus is acquired when a disease process such as neoplasia, hemorrhage, or inflammation occludes the pathway. In communicating hydrocephalus, no obstruction to flow is seen and all of the ventricular system dilates. Such diffuse dilation can be seen when absorption of CSF from the subarachnoid space into the venous drainage is impeded (e.g., by inflammation or neoplastic infiltrates in the meninges). The ventricles will also dilate in response to atrophy of surrounding brain tissue and is called *compensatory hydrocephalus* or *hydrocephalus ex vacuo*.

In spite of the fact that congenital hydrocephalus is common in some breeds, little published research exists on the condition in animals. It is occasionally seen in conjunction with other congenital problems such as Chiari-like malformations[22] or cerebellar ataxia in bull mastiffs,[24] but it most commonly occurs as an isolated finding. Toy and brachycephalic breeds appear to be at highest risk for the disease.[25] In some cases a congenital stenosis or aplasia of the mesencephalic aqueduct exists.[12] Neonatal infections, such as parainfluenza virus in dogs, can result in stenosis without leaving any indications of the cause once the initial

ependymitis has resolved.[26] The strong breed predilection, however, suggests a hereditary basis in many of these dogs. Congenital hydrocephalus can lead to an enlarged calvarium and failure of normal closure of the suture lines of the skull. A small open fontanel is common in many toy breeds and does not necessarily indicate hydrocephalus.

Figure 191-24 **A,** Ultrasound can be used to image dilated ventricles *(asterisks)* if an open fontanel provides an acoustic window. **B,** Otherwise magnetic resonance imaging (MRI) or computed tomography (CT) scan is necessary. Some severe hydrocephalics may show minimal signs. The dog in **B** had minimal forebrain tissue left on CT scan *(arrows)*, yet the only complaint of the owners was irritability and polydipsia and polyuria. After a fall the dog developed adipsia and hypernatremia, which prompted referral.



Clinical signs of hydrocephalus include behavioral changes, ataxia, and seizures. A ventrolateral strabismus is common in congenital hydrocephalus, but it is not clear whether this is due to cranial nerve compromise or malformation of the skull. Lateralized signs such as circling will be evident with obstruction of the intraventricular foramen causing dilation of one lateral ventricle. Even in congenital cases, the disease may follow a waxing and waning course. Sometimes dramatic hydrocephalus may be present, and the owners report few clinical signs other than slowness to learn. Increased intracranial pressure can lead to tentorial herniation, particularly in acute, obstructive hydrocephalus.

The EEG may show a characteristic pattern of high-voltage synchronous activity, but imaging the dilated ventricles is necessary to confirm the diagnosis. If a large fontanel is present, the ventricles can often be adequately imaged with ultrasound. If not, then CT or MRI will be necessary to image the dilated ventricles and rule out obstructive disease (Figure 191-24). Normal ventricle size is 1.5 mm; anything exceeding 3.5 mm is considered to be characteristic of hydrocephalus.

The ideal treatment for hydrocephalus is to place a shunt into the dilated ventricle and drain the excess CSF into the peritoneal cavity. This may be indicated to relieve pressure even if a treatable condition is causing the hydrocephalus. A special valve is necessary to prevent excessive drainage of CSF (which could lead to collapse of the overlying cerebrum and subarachnoid hemorrhage) and to prevent pressure in the abdomen during coughing or exertion from being transmitted to the ventricles. Complications such as infection or occlusion of the shunt are common, and only a few centers perform this operation. Another mode of surgery is to enter the skull from above, open the third ventricle, and then fenestrate the floor of the third ventricle. 822
This procedure allows drainage of CSF directly into the subarachnoid space and is less invasive. It is 823
considered the treatment of choice for humans in most situations.

Medical management of hydrocephalus is largely symptomatic. Anticonvulsant drugs may be used to control seizures. Furosemide, corticosteroids, or both may help decrease intracranial pressure. Mannitol can be used in cases of acute decompensation, but the benefits are transient. Carbonic anhydrase inhibitors have been used to decrease CSF production but the side effect of acidosis limits their usefulness. Although medical therapy may ameliorate the signs, hydrocephalus tends to be a progressive disease.

191.4.2 Inborn Errors of Metabolism

Although some congenital diseases cause structural malformations of the nervous system, others interfere with function at a biochemical level or lead to premature death of neurons. Ultimately the hereditary disorders will be classified based on the gene or its product that is altered. Most such cases in veterinary medicine are classified according to the clinical presentation, pathologic changes, or both. For many, however, the clinical signs are relatively nonspecific. The clinician should have a high index of suspicion in young, purebred animals with diffuse, symmetrical signs of brain disease when toxic, routine metabolic and infectious causes have been ruled out. Breed tables can be consulted for specific diseases that have been reported.[6,7]

Some inborn errors of metabolism may be apparent on routine clinical pathology tests. Deficiencies in urea cycle enzymes will result in elevated blood ammonia, whereas ketonuria or acidosis, without a clear underlying cause like diabetes mellitus, may reflect errors in mitochondrial metabolism. If the error leads to the accumulation of an abnormal metabolite, that product can often be detected. Urine is the ideal sample to assay because the metabolite may be excreted into the urine in high concentrations, and sufficient volume of urine can be collected even in neonates. Simple urine screening tests are available for some inborn errors of metabolism, but most require testing at specialized labs. Serum or spinal fluid may need to be assayed for metabolites that are not excreted in the urine in detectable amounts. Others may require culturing fibroblasts and measuring specific enzyme activity.

Many inborn errors of metabolism will affect other organs that can be evaluated more readily than the brain. If peripheral nerve is involved, a nerve biopsy may yield clues such as the presence of vacuolated macrophages in globoid cell leukodystrophy (Figure 191-25). Occasionally such vacuolated cells may be visible on routine blood smears or CSF analysis. Because muscle also has a high metabolic demand, diseases affecting energy metabolism may show changes on muscle biopsy. If hepatomegaly or lymphadenopathy accompany neurologic signs, a biopsy of one of these more accessible organs may reveal storage products.[27,28]

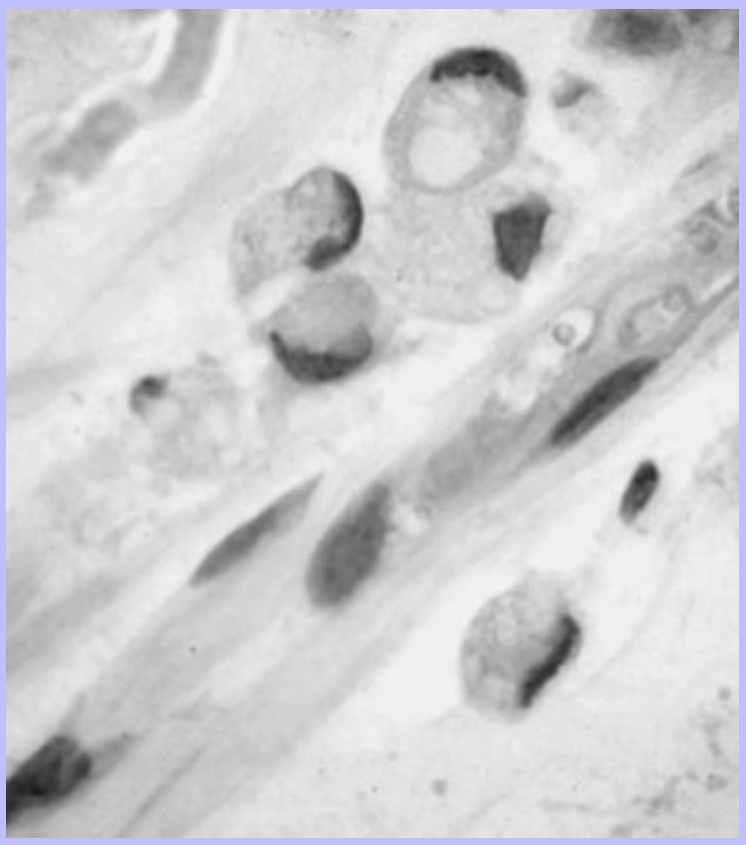
191.4.2.1 Organic Acidurias

These diseases are characterized by the presence of abnormal organic acids as the result of an error in the metabolic pathway. Although relatively few have been described in veterinary medicine, as a whole they are

common diseases in humans and probably occur in purebred dogs with greater frequency than has been recognized. They can be diagnosed by urine organic acid screens and have the potential for therapeutic intervention if the deficient pathway can be bypassed.

Malonic acid levels in a cell regulate the switch between carbohydrates and fatty acids as an energy source in the fed versus fasted state respectively. A Maltese dog from a family with malonic aciduria developed seizures, stupor, hypoglycemia, acidosis, and ketonuria when it experienced a brief period of anorexia. Altering the diet to frequent feedings of a high-carbohydrate, low-fat diet eliminated the need to rely on fatty acids as an energy source and ameliorated the clinical signs.[29]

Figure 191-25 Evidence of inborn errors of metabolism can sometimes be found in more accessible tissues such as white blood cells (WBCs), liver, or peripheral nerve. Macrophages with lysosomal storage product in vacuoles (globoid cells) were found in this peripheral nerve of a Cairn terrier with globoid cell leukodystrophy.



Cobalamin (vitamin B_{12}) is a necessary cofactor in the conversion of methylmalonyl-CoA to succinyl CoA, a significant step in gluconeogenesis. Cobalamin deficiency has been associated with elevated methylmalonic

acid and ammonia, as well as hypoglycemia in a cat (presumably due to a deficiency of intrinsic factor necessary for absorption of B_{12}).[30] Dogs with congenital cobalamin deficiency present primarily with anemia and failure to thrive, although one case presented with seizures.[30A]

Abnormal increases of methylmalonic and malonic acid (and other intermediary metabolites) were found in the urine of a 12-week-old Labrador retriever pup with progressive neurologic signs. The pup was not ketoacidotic or hyperammonemic, and cobalamin levels were normal. Diffuse atrophy of the CNS was found at necropsy, but no specific metabolic defect was identified.[31]

Staffordshire terriers with L-2-hydroxyglutaric aciduria develop seizures, ataxia, and altered behavior between 6 months and 7 years of age. On T2-weighted MRI, dramatic hyperintensity was seen in the cerebral, cerebellar, thalamic, and brain stem gray matter.[32]

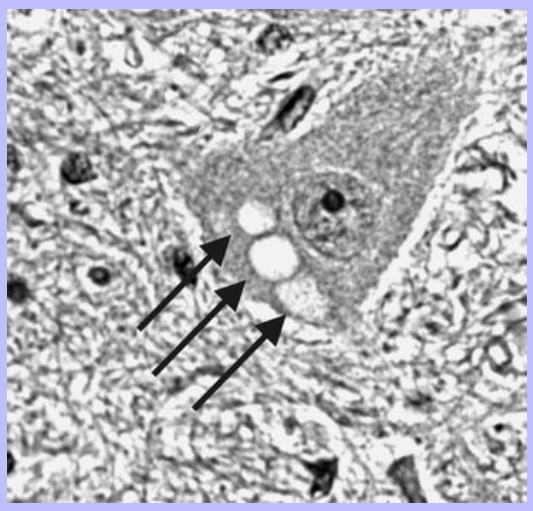
191.4.2.2 Spongiform Encephalopathies

The spongiform encephalopathies compromise a heterogenous group of diseases that have in common spongiform change within the brain at necropsy.[33] Some lysosomal storage diseases (see following) may also be characterized by vacuolation of neurons, but in those cases the vacuoles are lysosomes distended with storage products. In the spongiform encephalopathies, vacuoles appear empty and, if intraneuronal, they are not membrane bound. They can be subdivided depending on whether the vacuolation occurs within the myelin sheaths in the white matter (discussed in Leukoencephalopathies) or in the gray matter within neurons or their process (Figure 191-26). The gray matter spongiform encephalopathies include both hereditary and acquired (transmissible) diseases.

823

824

Figure 191-26 Spongiform change in the gray matter should arose suspicion of a transmissible spongiform encephalopathy (TSE), but such vacuolation *(arrows)* of neurons and their processes can be seen in hereditary diseases, such as hereditary spongiform encephalopathy in this rottweiler dog.



Most researchers believe an enigmatic agent, the prion, causes transmissible spongiform encephalopathy (TSE). Scrapie was the first TSE to be described and, for a long time, these diseases were of little concern to small animal practitioners. The outbreak of the TSE bovine spongiform encephalopathy (BSE) in England, and the subsequent recognition that this disease may be spread to cats and humans by ingestion of meat products from affected cows, has made these diseases of more general interest.[34,35] The prion is unique in that it is not a nuclei acid-based organism but rather a rogue isoform of a protein (the prion protein). An alpha-helical isoform of the prion protein is found in normal neurons. The disease isoform (usually referred to as the *scrapie isoform*) of the protein forms a beta-sheetlike amyloid, which renders it resistant to degradation by proteases. These abnormal prions then accumulate in the neurons as scrapie-associated fibrils, interfere with cell function, and produce intraneuronal vacuolation. The scrapie isoform apparently propagates by inducing the normal cellular isoform to convert to the beta-sheet conformation. Exactly how this process occurs is still a matter of much research.[36] A long latency period characterizes the TSEs.

Cats affected with feline spongiform encephalopathy (FSE) show signs reminiscent of BSE: ataxia, behavioral changes, and hyperesthesia to touch or sound. At necropsy, the TSEs are characterized by vacuolation of nerve processes and to a lesser extent their cell bodies. In cats such lesions occur throughout the gray matter of the brain.[35] Although it is hoped that the control of BSE will mean that TSEs are no longer an issue for the small animal clinician, the potential exists for a similar outbreak in the future. Maintaining an index of suspicion will permit early recognition of the disease should it occur in dogs or cats.

Spongiform change in the gray matter also occurs in other diseases including rabies and hereditary disease. A hereditary spongiform encephalopathy has been recognized in rottweiler dogs. Beginning at 6 to 8 weeks of age, affected dogs develop progressive laryngeal paralysis, tetraparesis, and proprioception deficits most prominent in the pelvic limbs and cerebellar ataxia.[37] No abnormal prion proteins were detected in these dogs,[37] and no mutations were found in the gene for the prion protein.[37A]

A hereditary polioencephalomyelopathy of Australian cattle dogs appears to be an autosomal recessive trait. The first signs recognized in affected dogs were seizures beginning at less than 1 year of age. After a variable period of time, progressive ataxia, vestibular signs, and thoracic limb atrophy and muscle rigidity developed, ultimately resulting in recumbancy.[38,39] Symmetrical increased signal was apparent on T2-weighted MRI in the cerebellar, vestibular, and other brain stem nuclei.[39] At necropsy, degeneration of the ventral horn of the spinal cord and in the cerebellar and brain stem nuclei is seen. Within these areas, vacuolar degeneration occurs in the neuropil, astrocytes, and myelin. A mitochondrial defect in astrocytes is suspected.[38]

A litter of Malinois shepherd crosses with congenital generalized tremors has been reported with diffuse vacuolation of the gray matter,[40] and the bull mastiffs with hydrocephalus and cerebellar ataxia have spongiform change in the cerebellar nuclei.[24] Although such diseases are rare, it is important to differentiate them from the TSEs, which carry significant public health implications.

191.4.2.3 Polioencephalopathies

Other conditions affect the gray matter without producing vacuolation. The selective involvement of gray matter suggests a metabolic deficit that creates a dysfunction in neurons or in some cases glia. The clinical signs of polioencephalopathies vary widely, but because neurons of the cerebral cortex are often affected,

seizures and behavior changes are common, as are cerebellar ataxia and sensory or motor deficits. The hereditary movement disorders typically affect neurons of the cerebellum and motor nuclei but will be considered as a separate class of diseases because of the limited distribution of the lesions and hence clinical signs.

Because neurons have a high metabolic demand, they are particularly susceptible to disturbances of energy metabolism. Disorders of mitochondrial metabolism can thus produce polioencephalopathies. In human medicine, such encephalopathies can also be associated with pathology in the muscles, another cell with high-energy demands. Such an association has not been shown in any of the veterinary diseases to date. Two mitochondrial polioencephalopathies have been described in dogs. One English springer spaniel, at 16 months of age, had progressive ataxia, mild behavior changes, visual deficits, and vestibular signs. At necropsy, abnormal mitochondrial changes were associated with degeneration in the cerebellar and cerebral cortex, brain stem nuclei, and optic nerves (a nerve selectively affected in the human mitochondrial encephalopathy: Leber's optic neuropathy).[41] A suspected mitochondrial encephalopathy similar to Leigh's syndrome of humans was recognized in a family of Alaskan huskies that typically are less than 1 year of age when they exhibit an acute onset of ataxia, seizures, behavior changes, blindness, and facial sensation deficits. Dramatic cavitation was seen symmetrically in the gray matter of the thalamus that extended to a variable degree into the brain stem.[42] These lesions are clearly visible on MRI as high T2 signal.[43] The lesions are similar to those seen in acquired energy metabolism problems such as a deficiency of thiamine, a vital cofactor in the Krebs cycle.[44] The sudden onset of signs in huskies could reflect an incident where metabolic demand outpaced supply or susceptibility to an outside insult such as a low thiamine level. One severely affected dog improved dramatically with supportive care that would support this hypothesis.[43] A similar condition has been reported in Yorkshire terriers.[45]

824

825

Chromatolysis refers to loss of Nissl bodies, the dense staining aggregates of ribosomes that give neurons their characteristic granular cytoplasm. Chromatolysis is most commonly seen in wallerian degeneration after destruction of an axon, but also occurs in hereditary diseases such as spinal muscular atrophy. A more diffuse multisystemic chromatolysis has been reported in Cairn terriers and Swedish Lapland pups. Affected pups develop progressive weakness, ataxia, head tremors, and cataleptic episodes.[12,46]

191.4.2.4 Neuroaxonal Dystrophy

Swellings within the axons, called *spheroids*, characterize neuroaxonal dystrophies. They are thought to represent disorders of trafficking of cytoskeletal elements, which then accumulate in axons or synaptic terminals. Because longer axons have further to transport these elements, changes are often most prominent in the termination of the long proprioception tracts in brain stem nuclei. If peripheral nerve is involved, the disease can be diagnosed by nerve biopsy.

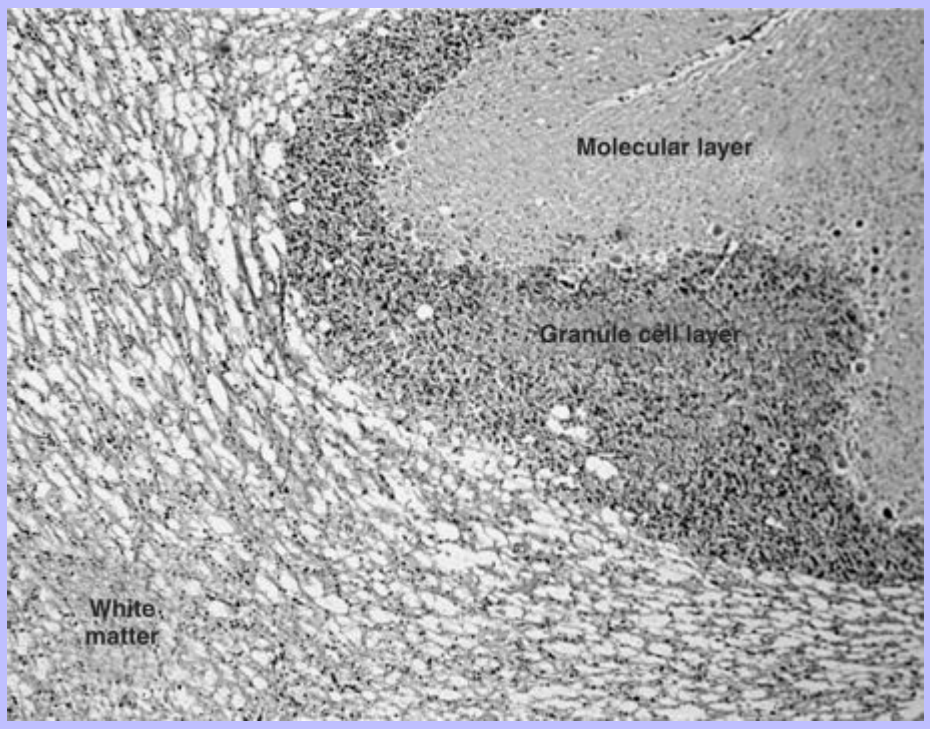
Neuroaxonal dystrophy has been reported in a variety of breeds including Chihuahua, collie, Jack Russell terrier, Papillon, and Siamese,[12,47–49] but it has been best characterized in a family of rottweilers. Affected dogs begin showing signs of hypermetria of the thoracic limbs at 1 year of age. Signs progressed over the next few years to include more pronounced dysmetria, truncal ataxia, intention tremors, menace deficits, nystagmus,[47,50] and laryngeal paralysis.[51] In a family of Scottish terriers, pups developed progressive tremors, ataxia, and paraparesis beginning at a much younger age (10 to 12 weeks). They differed from the neuroaxonal dystrophies previously described in that the axons were diffusely swollen rather than

concentrated in spheroids.[52] Similar diffuse swelling of axons in the CNS is seen in giant axonal neuropathy where peripheral nerve signs predominate.

191.4.2.5 Leukoencephalopathies

Leukoencephalopathies are diseases of myelin and thus affect predominantly the white matter. Such conditions typically produce cerebellar or long tract signs, although many variations exist. The spongiform encephalopathies that affect the white matter are often referred to as *spongy degenerations of the white matter* or *spongy leukodystrophies* to clearly differentiate them from the TSEs that affect primarily gray matter. In spongy degeneration of white matter, splitting of the myelin sheaths causes the vacuolation.[33] Other leukoencephalopathies disrupt myelin or axons without producing vacuolation and would be referred to as *leukodystrophies. Hypomyelinogenesis* refers to the conditions where myelin never forms normally. In dysmyelinogenesis, myelin formation is present but delayed or abnormal.[12] Many of the myelin diseases, such as the leukoencephalomyelopathy of rottweilers, are predominantly spinal cord diseases.[12]

Figure 191-27 In spongy degeneration of white matter, the myelin lamellae are separated, producing vacuolation primarily within the white matter, such as in this section of the cerebellum.



Congenital disorders of myelin formation most commonly begin with generalized tremors and dysmetria noticeable from the first attempts at walking. In some breeds, such as the chow chow, improvement occurs with time, whereas others, such as the Springer spaniel, are permanently disabled. Typically, myelin

throughout the CNS is affected; however, peripheral nerves are spared, so reflexes are normal or exaggerated. Both X-linked and autosomal recessive forms have been described, and mutations of one of the myelin proteins has been identified in the Springer spaniels.[12,53,54] Diagnosis is based on the typical clinical signs in a breed at risk and, if necessary, confirmed at necropsy.

Later age onset leukodystrophies have also been described in dogs. Alexander's disease (fibrinoid leukodystrophy)[12] has been reported as a sporadic occurrence in several breeds. They presented for progressive ataxia, weakness, and, in one case, seizures between 3 and 6 months of age. Perivascular accumulations of characteristic eosinophilic (Rosenthal's) fibers at necropsy permitted the definitive diagnosis.[12]

Spongy degeneration of the white matter similar to Canavan's disease of humans has been reported sporadically in a variety of breeds of dogs and cats.[12] Affected Labrador retrievers began showing signs at 4 to 6 months of age. Initial signs were episodes of extensor rigidity and dorsiflexion of the neck with retained consciousness. These were followed by progressive dysmetria, intention tremors, tetraparesis, hyperreflexia, and spasticity. Behavior, autonomic, and sensory functions remained normal. At necropsy, splitting of the myelin resulted in vacuolation of the whiter matter throughout the brain and to lesser extent the spinal cord (Figure 191-27).[55,56] In the familial spongiform leukodystrophy described in Shetland sheepdogs, the clinical signs began at less than 3 weeks of age and included progressive seizures, weakness, lethargy, and dysphagia. Spongiform degeneration was most prominent in the cerebellum and corona radiata. Biochemical screening tests in the sheepdogs failed to identify any of the abnormal organic acids or amino acids associated with spongy degeneration in people or cattle.[57]

825 826

191.4.2.6 Lysosomal Storage Disease

Storage diseases are characterized by an accumulation of metabolic byproducts within lysosomes. Lysosomes are cellular organelles responsible for breaking down complex macromolecules. This compartmentalization allows for a more acidic pH within the lysosome and protects the rest of the cell from digestion. The substrates for catabolism within lysosomes include sphingolipids (a major component of myelin), oligosaccharides, mucopolysaccharides, glycoproteins, and proteins. The storage diseases are typically caused by a deficiency in a key enzyme in the breakdown of one of these molecules, and without the enzyme the substrate accumulates within the lysosome. The syndromes are usually named for the accumulated product. Proteases are less substrate specific, thus a deficiency in a single enzyme is less likely to produce problems. As a result, disorders of protein catabolism are uncommon, although CL may represent such a defect.[27,28,58] Alternatively the defect can interfere with cell's ability to use a normal enzyme. In I-cell disease (mucolipidosis) of cats, for example, the disorder appears to be one of trafficking of the enzymes into the lysosome. As a result, multiple enzymes are affected.[59] Recent reviews of the storage diseases in animals have been published and should be consulted for details on the individual syndromes in different breeds.[27,28,58] Some drugs and toxins, such as locoweed, can interfere with the activity of these enzymes, producing similar clinical signs and histologic lesions; however, this has not been documented in small animals.[27]

Accumulation of the storage product takes time; thus most storage diseases have a delayed onset of signs even though the enzyme has been deficient from birth. The age of onset and severity can depend upon how much residual function is left in the altered enzyme. Many of the storage diseases affect multiple organs, whereas others, such as those affecting degradation of myelin, only affect the nervous system. How the

accumulated storage product produces neurologic disease is not always clear. In globoid cell leukodystrophy, one of the storage products is clearly toxic to oligodendroglia. In others, spheroid formation may be related to neuronal death.[27,28,60]

Cerebellar signs of dysmetria, truncal ataxia, and nystagmus are often the first signs of storage diseases.[28] The cerebellum is dependant on fast conduction to get sensory feedback during execution of a movement, and complex integration of sensory and motor information is necessary. Thus the cerebellum is sensitive to disorders affecting myelin or information processing. In addition, even subtle cerebellar deficits may be recognized, whereas more profound learning or mentation deficits may be necessary to reach a threshold of recognition. Signs often progress to weakness, behavior abnormalities, and seizures.[28] In some diseases, such as CL (see following), forebrain signs will be the earliest signs.[61] Peripheral nerves are involved in some conditions such as globoid cell leukodystrophy. Few imaging studies have been performed on the brains of animals with storage disease. In dogs with globoid cell leukodystrophy, increased signal intensity in white matter has been shown on T2-weighted MRI.[62] Cats with alpha-mannosidosis also show white matter changes on MRI.[63]

In some lysosomal storage diseases, signs of other organ involvement may be apparent. Ocular abnormalities can include visible changes in the retina or cataract formation. Skeletal or facial malformations are especially prominent in the mucopolysaccharidoses and may be apparent on radiographs. Cardiac, hepatic, splenic, or lymph node enlargement may accompany the neurologic signs.

Storage vacuoles may be apparent in white cells on a peripheral blood smear or, in the case of globoid cell leukodystrophy or fucosidosis, on CSF analysis. Alternatively, lymphoid tissue can be examined via biopsy of the spleen or lymph node. If the liver is enlarged, aspirate or biopsy may also reveal storage vacuoles. When peripheral nerve is involved, biopsy of the nerve may reveal vacuolated mononuclear cells. Muscle biopsy will be most useful when glycogen storage disease is suspected. Necropsy may be necessary to demonstrate storage product when only the nervous system is involved. Electron microscopy can demonstrate that the storage material is contained within lysosomes. Abnormal metabolites may be detectable in urine with some of the storage diseases. Definitive diagnosis depends upon demonstration of deficient enzyme activity in serum, leukocytes, or cultured fibroblasts.

191.4.2.7 Ceroid Lipofuscinosis

Although a lysosomal storage disease, CL differs from the other diseases in that the storage products are proteins. These products have a characteristic autofluorescence similar to ceroid and lipofuscin, pigments that accumulate normally with aging. Although named for this similarity, ceroid and lipofuscin are not found in any appreciable amounts in these diseases. Among the known storage products in CL are subunit c of mitochondrial adenosine triphosphate (ATP) synthase and sphingolipid activator proteins (saposins) A and D.[64] The enzymes responsible (saposin A and D) have been identified in humans and sheep, respectively.[65] In addition to lysosomes, evidence exists that these enzymes may be involved in mitochondrial and synaptic functions, which may explain some of the neuropathology seen.[65,66]

The original classification of CL was based on age of onset and rapidity of progression. As discussed previously, this is probably more of a reflection of the degree of residual enzyme activity than differences in enzymes responsible. Nonetheless, because purebred dogs usually have a single mutation responsible for a genetic disease, there will be consistency between individuals within a breed, making such classifications useful. The earliest reported onset of signs in CL (<6 months of age) has been reported in a cat and in

dalmatians, but affected dogs can live up to 7 to 8 years.[61,67] English setters, border collies, and other breeds have an early adult onset (about 1 year of age), acute disease, and die by 2 years of age.[61] The Tibetan terrier is the best characterized breed with adult onset, slowly progressive disease. Signs of visual impairment begin at 2 to 3 years of age, and behavior changes do not become apparent until 4 to 6 years of age.[61]

Diminished vision is usually the first sign of CL. This can be especially noticeable in dim-light situations. Behavior changes are prominent in the disease and include timidness, hyperesthesia, confusion, and unprovoked aggression. Seizures, jaw chomping, bruxism, and myoclonus are also reported. Ataxia and hypermetria are also reported but tend to be later manifestations in many breeds.[61] Brain atrophy and dilation of the ventricles can be seen on CT scan in later stages of the disease,[68,69] but definitive diagnosis relies upon identification of the characteristic autofluorescent material in the brain or other tissues.

Currently no effective therapy exists for any of the storage diseases. Gene therapy holds the promise of restoring function to affected individuals, but cost will limit its application to veterinary medicine. DNA testing is already available for some diseases and will become more readily available in the future. This will permit breeders to make informed decisions that are likely to decrease the incidence of some diseases in the future. Symptomatic therapy such as anticonvulsants and behavior-altering drugs can help ameliorate some of the symptoms.

827

191.4.3 Movement Disorders

Most of the movement disorders that are recognized in veterinary medicine are hereditary diseases, although acquired conditions are beginning to be characterized. The hereditary ataxias encompass a heterogeneous group of diseases. As with other hereditary diseases, these will ultimately be classified based on the gene responsible and its product. However, even then, signalment and clinical signs will be the initial clues that direct clinicians toward those answers. The most common movement disorders in animals are the cerebellar disorders, although in some breeds other motor systems are affected.[12,70]

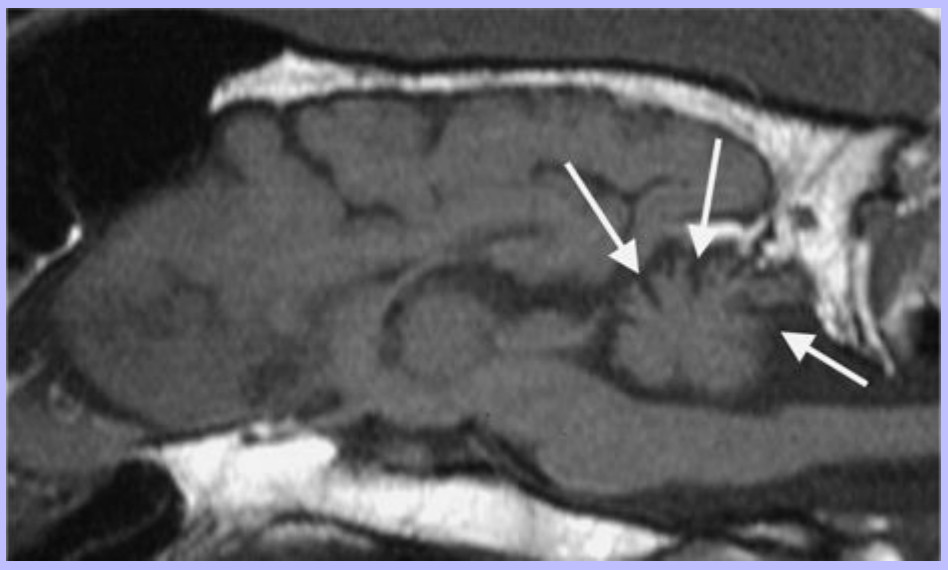
191.4.3.1 Hereditary Cerebellar Ataxia

The cerebellar ataxias can be divided into neonatal, early, and delayed onset.[70] Many neonatal conditions are associated with gross malformations of the cerebellum (discussed previously). In certain breeds with neonatal onset ataxia, such as beagles and Samoyeds, the loss of Purkinje cells is similar to that seen in later age onset conditions.[12] Others, such as neonatal ataxia in Coton de Tulear dogs, show minimal histologic changes and are presumably a biochemical dysfunction.[71]

Other hereditary ataxias are characterized by a variable period of normal development followed by progressive cerebellar ataxia as specific populations of neurons die prematurely. The age of onset of signs can vary from weaning age (e.g., English pointers, Kerry blue terriers)[72,73] to adulthood (e.g., Gordon setters, Old English sheepdogs)[74,75] to later life (e.g., Brittany spaniels).[76] This process is sometimes referred to as *abiotrophy*, based on the original hypothesis that lack of a trophic substance was responsible for the degeneration. The term is now used to emphasize the fact that these diseases have a delayed onset of degeneration and clinical signs.[12,70] The specific genetic deficit responsible has yet to be identified in any of these diseases in dogs or cats. Most are autosomal recessive, although the ataxia in English pointers is X linked.[73]

In most of these delayed onset ataxias of dogs and cats, the Purkinje cells of the cerebellum degenerate. Because the Purkinje cell is the sole efferent from the cerebellar cortex, degeneration results in a loss of cerebellar function. In addition to the period of normal function, clinicians can tell that the Purkinje cells formed and then degenerated by the presence of "empty baskets." Basket cells are interneurons that form a dense meshwork of dendrites around the Purkinje cell body. When the Purkinje cells degenerate, these empty baskets of dendrites remain, but they would not form if the Purkinje cell body had not been there initially.

Figure 191-28 In the hereditary ataxias, atrophy of the cerebellar cortex *(arrows)* may be apparent as shrinkage and flattening of the cerebellum with an increased space between the folia.



Although Purkinje cell degeneration is the most common type of degeneration described, other parts of the cerebellum can be affected. In Jack Russell terriers, the granule cell layer is primarily affected.[76A] In beagles both cell types are affected.[77] In bull mastiffs, the cerebellar roof nuclei along with some brain stem nuclei undergo spongiform degeneration.[24]

Hereditary cerebellar ataxia should be suspected when a breed at risk or other young, purebred dog develops progressive cerebellar ataxia. Atrophy of the cerebellum may be apparent on MRI of the brain (Figure 191-28). CSF analysis may be helpful in ruling out infectious and inflammatory causes, but histologic examination may be necessary to determine the character of the lesion. The severity of signs varies a great deal. Some dogs and cats with pure cerebellar cortical degeneration have only mild to moderate ataxia and may be able to live with their disabilities. Ensuring against injury due to falls is the most pressing management concern. Feeding difficulties may require the use of a high-calorie food to maintain weight. In other cases the degree of ataxia may be severe enough to warrant euthanasia.

191.4.3.2 Multiple System Degeneration

The basal ganglia, such as the caudate nucleus and substantia nigra, are also important in movement and are affected in Huntington's and Parkinson's disease in humans. When the cerebellum and basal ganglia are involved, these conditions are referred to as *multiple systems degenerations*. The best-characterized syndrome of this type in animals is the disease of Kerry blue terriers and Chinese crested dogs called *progressive neuronal abiotrophy* (PNA) by breeders. In these breeds, cerebellar ataxia begins at 8 to 12 weeks of age, but is followed at 6 to 12 months of age by degeneration of the basal ganglia.[72,78] As the basal ganglia degenerate, affected dogs have increasing difficulty initiating movements and maintaining balance. This results in a festinating locomotion in which the dog begins to lose balance and then runs in that direction to keep from falling (Figure 191-29). The degeneration of the basal ganglia is visible on MRI as an increased T2 signal. The severe motor difficulties associated with these conditions necessitate euthanasia by 1 to 2 years of age.

191.4.3.3 Dyskinesias and Dystonias

Dyskinesia is a general term for a disorder of movement usually characterized by involuntary, stereotyped movements caused by disease affecting the basal ganglia (extrapyramidal) motor systems or their neurotransmitters. In human medicine, dyskinesias are classified based on the character of the movements. 827
Chorea refers to arrhythmic, rapid, jerky movements, which are more sustained than the brief jerks of 828
myoclonus. The rhythmic jerking associated with canine distemper has been called *chorea* in the past but is actually a myoclonus. When chorea affects proximal muscles producing flinging movements of the limbs, they are called *ballismus*. *Athetosis* describes slower, flowing movements. *Dyskinesias* can involve the entire body or be limited to one side or to the face. *Dystonia* refers to a sustained abnormal contraction often producing abnormal posturing or torticollis.

Figure 191-29 As Chinese crested dogs with multiple system degeneration progress from cerebellar ataxia to basal ganglia degeneration, they develop difficulty initiating movements. They may shift weight forward until they begin to fall, and then they are able to move forward.

Such movement disorders have not been well documented in animals. In part, this may reflect a difference in the rolls of the cortical (pyramidal) and basal ganglia (extrapyramidal) motor systems in primates versus quadrupeds. More likely it is simply a failure to recognize movement disorders. Some idiopathic head tremors (see following discussion) may well represent basal ganglia disease. Oral-facial dyskinesias in animals have been observed that undoubtedly represent movement disorders. Increased availability of MRI will allow recognition of structural lesions of the basal ganglia. For example, infarcts of the basal ganglia have been identified in dogs with acute torticollis.[79]

191.4.3.4 Paroxysmal Dyskinesias

Seizures are by far the most common neurologic disorder that occurs as discrete episodes of involuntary movement, and they are discussed in detail (see Chapter 48). Reports exist of paroxysmal abnormal movements in dogs that do not appear to be seizures. Episodic ataxia and paroxysmal dyskinesia are two examples of human diseases that occur in episodes but do not have the EEG changes that define seizure disorders. Generalized seizures are distinguished by a loss of consciousness, but in focal motor seizures, consciousness may not be impaired. Thus distinguishing between a focal seizure and a paroxysmal dyskinesia can be difficult without an EEG recording during an episode. The character of the movement in paroxysmal dyskinesias tends to be different from that observed with seizures. Focal motor seizures frequently produce an erratic twitching of one side of the face and may progress to affect the limbs on the same side. This reflects the origin of the seizure in the area with largest representation in the motor cortex of the dog followed by spread of seizure activity in that hemisphere. The movements in paroxysmal dyskinesias are more of the character of a dyskinesia or dystonia. In addition, the episodes may last much longer than the 2 minutes typical of most seizures and may be precipitated by excitement or exercise.

Scotty cramp is a condition of Scottish terriers characterized by episodes of rigidity with excitement or exercise. Affected dogs develop limb rigidity, which can result in recumbency in severely affected dogs.[80] The cause of the muscle hypertonicity is not clear, but a central motor problem is suspected. Serotonin antagonists will worsen the attacks, whereas alpha noradrenergic blocking drugs and benzodiazepines are reported to help alleviate the episodes. An autosomal recessive inheritance is suspected. Similar signs have been reported in dalmatians and a Shetland sheepdog.

A movement disorder characterized by episodes of flexion of the limbs has been described in adult Bichon frises. Affected dogs develop a kyphotic stance and alternately flex various limbs. This flexion is not limited to one side of the body and appears to affect pelvic limbs or thoracic limbs randomly rather than in set progression. These episodes resemble root signature seen with intervertebral disk disease. The dogs are not in pain, however, and herniated disks are not found on myelography. Facial grimacing also occurs.[81] Similar episodes have been described in two litters of young boxers.[82] Chinook dogs have a familial disorder characterized by prolonged episodes of inability to stand with dystonic posturing and sometimes rhythmic limb or tongue movements. Whether these episodes are focal seizures, a paroxysmal dyskinesia, or some other disorder is still not clear. Dancing Doberman disease is characterized by alternating flexion and extension of the pelvic limbs, resulting in the dog “dancing” from one foot to the other. It is thought to be a peripheral neuropathy, however, rather than a central movement disorder.[83]

191.4.3.5 Tremors

Fine, fast tremors (enhanced physiologic tremors) are common with a wide variety of conditions such as weakness, fatigue, fear, pain, hypoglycemia, pheochromocytoma, hyperthyroidism, and certain drugs or toxins such as pyrethrins or caffeine. Benign tremors are common in older animals, particularly in the hind limbs. Beta-blocking drugs can ameliorate physiologic tremor, but usually the tremor does not interfere with the animal's function. The major concern is ruling out treatable underlying causes of the tremor.

An idiopathic tremor syndrome was first reported in Maltese and West Highland white terriers and called *little white shakers* syndrome.[84–86] Although these breeds appear to have a predilection of the disease, a wide variety of breeds have been reported with the disease[84,87]; *idiopathic tremors* is a more appropriate name for the condition. Most affected dogs are young adults (6 months to 5 years of age) with an acute onset of tremors. The tremors affect the entire body, including the eye, and vary from mild to severe enough to interfere with the dog's ability to stand or walk. They are exacerbated by excitement or movement and disappear at rest (intention tremors). Other signs such as absent menace response, ataxia, head tilt, or paresis may accompany the tremors. CSF analysis typically includes mild lymphocytic and monocytic pleocytosis, and a few dogs that have been necropsied have shown mild inflammatory changes on histopathology.[12,86,87] Most dogs respond very well to immunosuppressive doses of corticosteroids for 1 to 3 weeks, though relapses can occur. Benzodiazepines or propranolol may help relieve the tremors.[85–87]

A syndrome of head tremors is seen in some breeds. Doberman pinschers sometimes develop a head tremor after administration of droperidol when that drug was used in an injectable neuroleptic and analgesic combination that is no longer marketed. Because droperidol is a dopamine antagonist, the assumption was that the head tremor was akin to the tremors in human patients with Parkinson's disease. Occasionally, isolated head tremors are seen without any history of intoxication in Doberman pinschers, boxers, bulldogs, and Shetland sheepdogs. The exact cause of the tremors is not known. Often they are discrete episodes, which could represent a focal motor seizure, but response to the anticonvulsant drugs has been variable. Generally they appear to be benign.

828

829

191.4.4 Encephalitis

Encephalitis refers to an inflammation of the brain. Most infectious or inflammatory diseases of the nervous system involve the spinal cord and the brain, producing multifocal disease (discussed in Chapter 192). Potential causes include viral, bacterial, rickettsial, protozoal, fungal, and parasitic. A few diseases affect the brain almost exclusively. Encephalitis is typically an acute disease, but in some cases, such as canine distemper or FIV, can be chronic and insidious. Some infections can be quite focal, and signs will reflect the area of the brain affected; however, others will produce more diffuse signs. Altered mentation with focal facial muscle twitching, seizures, or both is a typical presentation. If the meninges are involved, pain may be a prominent feature. Signs of systemic illness may or may not be present. CSF analysis can confirm inflammation, but prior treatment with corticosteroids may mask any CSF changes. With a few exceptions such as cryptococcosis, organisms are rarely seen or cultured in CSF and titers or PCR testing is necessary to identify the cause.

Because results of culture or titers may be delayed, symptomatic therapy is usually instituted when encephalitis is suspected based on signs or CSF results. Corticosteroids are usually indicated in acute encephalitis to decrease inflammation and the attendant morbidity. Immunosuppression can lead to subsequent worsening of the condition, however, if the underlying cause is not identified and treated appropriately. CSF analysis should

be completed before corticosteroids are administered, but the pet should not be sacrificed for the sake of a definitive diagnosis.

Appropriate antibiotics are instituted based on the most probable organism. The choice of antibiotics is influenced by disease prevalence in an area, evidence from physical exam or clinical pathology, and ability to penetrate the blood brain barrier in significant concentrations. During tick season in endemic areas, doxycycline can be administered to treat rickettsial disease, especially if other signs, such as thrombocytopenia or polyarthritis, are present. Clindamycin or potentiated sulfonamides can be used if protozoal infection is suspected. Trimethoprim-sulfonamide and enrofloxacin are bactericidal, broad-spectrum antibiotics that have good to fair blood-brain barrier penetration respectively. They can be used if bacterial infection, such as spread from an otitis media or septicemia, is suspected. If better activity against anaerobes were needed, metronidazole and clindamycin would be logical choices. In areas where coccidiomycosis is endemic or if cryptococcosis is suspected, antifungals may be necessary.

191.4.4.1 Viral Encephalitis

Though rabies is uncommon in dogs and cats, the public health risk requires that it always be considered in the differentials for unvaccinated animals with brain disease. If the virus gains entry through a wound on the limbs, rabies may affect the spinal cord, producing an ascending LMN paralysis prior to brain signs. Commonly, however, the bite occurs on the face, and the signs will reflect cranial nerve and forebrain involvement. For the first few days after infection there may be a fever, pruritus of the bite site, and anxious or irritable behavior. Progression and signs of the disease are quite variable, with considerable overlap between the two general forms of the disease. In the paralytic or dumb form of rabies, LMN paralysis of cranial nerves can produce a dropped jaw, dysphagia, laryngeal paralysis, and voice change. Signs progress over days to coma and respiratory arrest. The furious form consists of the classic behavior changes of rabies. Animals become hyperesthetic, irritable, and restless. They may be photophobic and hide or avoid contact with people. They may attack inanimate objects such as their cage and pica is common. As signs progress, ataxia, disorientation, and generalized seizures develop. The animal may develop a brief paralytic stage before death.[88]

A herpes virus causes pseudorabies (Aujeszky's disease). Dogs and cats typically acquire the infection from eating tissue from infected pigs. It produces a fulminate encephalitis characterized by dementia, seizures, and intense pruritus, often to the point of self-mutilation. No effective treatment is available; affected animals typically die within 48 hours, although cats may be more resistant to the infection.[88]

Increasing evidence suggests that feline immunodeficiency virus (FIV) infection can cause an encephalopathy not related to secondary infection. Affected cats develop progressive, symmetrical forebrain signs including depression, restlessness, learning and memory deficits, and mild coordination difficulties.[89] Diagnosis is based on serology and compatible clinical signs. Encephalitis due to a secondary infection such as toxoplasmosis needs to be ruled out or treated appropriately. Drugs used in treating acquired immunodeficiency syndrome (AIDS) in humans may prove useful in FIV infected cats, but currently the prognosis is poor.

191.4.4.2 Encephalitis of Unknown Cause

Pug encephalitis is a necrotizing meningoencephalitis that affects young adult pug dogs.[90] Affected dogs typically develop an acute onset of seizures and other forebrain signs. Maltese and Yorkshire terriers develop

a similar encephalitis, although brain stem involvement is more common in the Yorkshires. CSF analysis shows a lymphocytic pleocytosis. Histologically, asymmetrical necrosis and inflammation exists that affects both gray and white matter.[12] The cause is unknown. Immunosuppressive therapy may slow the course of the disease. Many affected dogs die within days of the onset of signs, though some may survive for months.

Granulomatous meningoencephalomyelitis (GME) can affect the spinal cord, but primarily causes encephalitis. Affected dogs tend to be young adults but any age may be affected. Onset of signs is typically acute. CSF typically shows a marked elevation in white cells (lymphocytes and monocytes) and protein, but may be unremarkable, especially after corticosteroid therapy. Imaging may reveal multifocal areas of contrast enhancement or a single mass. Histologically, GME shows perivascular cuffs of inflammatory cells often with epithelioid differentiation. Lesions are most prominent in the white matter.[12,91,92] Unless confirmed by brain biopsy, GME is a diagnosis of elimination once other causes of meningoencephalitis are ruled out. Immunosuppressive doses of corticosteroids will often achieve remission of signs for a variable period of time. When the disease becomes refractory to corticosteroids, radiation therapy or chemotherapeutic agents such as lomustine or cytosine arabinoside have been used with some success, but the prognosis is poor.

191.4.5 Vascular Disease

Stroke is uncommon in animals compared with humans because of the lower incidence of atherosclerosis and primary hypertension. With advanced imaging, however, vascular disease is being recognized with increasing frequency in veterinary medicine. Cerebrovascular disease can be subdivided into infarction and hemorrhage, although the two categories overlap in the case of hemorrhagic infarcts.

829

Infarction can occur due to thrombosis or embolism of the arterial supply or due to thrombosis of venous drainage. Thrombosis typically occurs when a clot forms in vessels compromised by atherosclerosis. In dogs, atherosclerosis is seen in hypothyroidism and idiopathic hyperlipidemia, and stroke can occur in these patients. Embolism will be secondary to some systemic disease such as sepsis, cardiac disease, neoplasia, or coagulopathy. Venous occlusion can occur secondarily to thrombosis or compression of the vein. Although a rich collateral drainage usually prevents signs with venous thrombosis, a severe occlusion may result in impaired blood flow to the tissues drained.

830

Intracranial hemorrhage occurs most commonly secondary to head trauma. When venous thrombosis occurs, the arterial supply is still intact and hemorrhage into the area of infarction may occur. Primary intraparenchymal hemorrhage can occur with hypertension. Hypertension in animals is most commonly secondary to hyperthyroidism, renal disease, pheochromocytoma, or hyperadrenocorticism.

Feline ischemic encephalopathy is a cerebral infarction syndrome in cats. Some cases have been associated with aberrant migration of *Cuterebra* larvae into the brain. Not all cases have obvious vascular lesions, leading to the hypothesis that the larvae induce vasospasm.[12]

Vascular disease is characterized by a peracute onset of signs. Unilateral forebrain signs of circling, hemiparesis, seizures, and personality changes would be most common, though any part of the brain could be affected. Some progression of signs could be expected from increased intracranial pressure. CT is good at detecting acute hemorrhage, whereas MRI is more sensitive for infarction. The signal changes with time, allowing estimation of the chronicity of the lesion (Figure 191-30).[93] Because infarction is rarely due to thrombosis in animals and the therapeutic window is a matter of hours, the thrombolytic drugs used in human stroke patients hold little promise in veterinary medicine. Thus treatment will be largely symptomatic,

controlling seizures and intracranial pressure and treating any underlying cause such as vasculitis or hypertension.

191.4.6 Brain Tumors

Brain tumors in dogs are more properly classified as intracranial neoplasms, because not all tumors that arise inside the cranium originate from brain tissue (Table 191-1). Regardless of the tissue origin, intracranial neoplasms result in a characteristic milieu of clinical signs in dogs. Signs typically develop as a result of a focal tumor and can be due to the disturbance of surrounding normal brain tissue from expansive growth of the tumor or the result of the peritumoral effects, such as edema and compromised blood flow. As the disease progresses the clinical signs may change to reflect further damage within the cranial vault. This is especially true when intracranial pressure rises and causes a shift in the intracranial contents. Additional damage and clinical signs can result from expansion of the tumor into non-neural tissues, such as the nasal cavity, periorbita, or the surrounding cranial bones. Rarely, primary intracranial neoplasms can disseminate throughout the CNS either by hematogenous or CSF routes. Intracranial neoplasms rarely spread systemically, although metastasis is not unprecedented. When this occurs it generally spreads to the lungs, most likely through venous drainage from the venous sinus plexuses in the cranial vault.

Although intracranial tumors in the dog and cat have been well described, the prevalence is largely unknown due to the lack of a comprehensive screening system. The incidence for primary CNS tumors in the dog have been reported as 14.5 in 100,000 dogs and 3.5 in 100,000 cats.[94,95] The tumor incidence in dogs is virtually identical to that in humans (11.8 per 100,000).[96] Interestingly, primary CNS tumors in humans, specifically malignant gliomas and CNS lymphomas, are becoming recognized at a higher rate in some studies.[97] However, as is probably the case in small animals, this data may only be reflecting an increased availability of imaging modalities that are necessary to identify the tumors.

Figure 191-30 T1-weighted magnetic resonance imaging (MRI) with contrast enhancement from a dog with two suspected strokes of the cerebellum 1 year apart. The older infarct on the right *(black arrow)* shows the atrophy of a wedge-shaped portion of the cerebellum replaced with cerebrospinal fluid (CSF). The left side shows an area contrast enhancement *(white arrow)* 4 days after an acute recurrence of cerebellar signs.

Clear risk factors for the development of intracranial neoplasms in the dog have not been identified. In humans, much press has been devoted to the role of cellular phones, exposure to high-tension wires, the use of hair dyes, head trauma, and exposure to N-nitrosourea compounds and other nutritional factors. To date, none of these have been definitively linked to the development of a brain tumor. Ionizing radiation, however, has been identified as an unequivocal risk factor for the development of glial and meningeal neoplasms. Exposure of the cranium to even low doses of radiation can increase the incidence of glial tumors in humans by a factor of 3 to 7, with a latency period of 10 years or more after exposure.[98] It is unknown whether small animals respond similarly to ionization radiation.

This section will focus on the diagnosis of the most common intracranial neoplasms and general treatment guidelines. It is important to note that an in-depth analysis of tumor behavior and of specific treatment regimes for intracranial neoplasms is difficult to perform in companion animals, because this information has not been comprehensively gathered and disseminated. To compensate for the relative paucity of information, data derived from the diagnosis and treatment of human tumors will be provided when appropriate.

191.4.6.1 Diagnostic Procedures

An intracranial mass can be confirmed on brain imaging with MRI or a CT scan. A CT scan, though adequate for identifying tumors in the majority of the cerebral cortex, is more prone to artifact production when imaging the caudal fossa because of interference from the surrounding petrous temporal bone. An MRI is the preferred diagnostic modality, because it provides images with superb soft tissue detail and is not interfered by the surrounding bony structures. It is important to remember that any ferrous substance locating in the magnetic field will dramatically alter the image, resulting in poor tissue detail. As such, it is a good practice to perform a radiograph of the target area prior to performing an MRI to ensure a clean field. An MRI should be performed both with and without the addition of gadolinium, an intravenous contrast agent. Although it is not a definitive test, the degree of contrast enhancement and specific tumor location will aid the clinician in making a presumptive tumor diagnoses. This will be discussed in more detail with each individual tumor. The quality of images with an MRI has reached the point that a normal gadolinium-enhanced MRI of the brain essentially rules out the possibility of a brain tumor in both small animals and humans.

830 832

Table • 191-1 World Health Organization Classification System for Intracranial Neoplasia[93A]

TYPE	EXAMPLES
Astrocytic tumors	Astrocytoma
	Anaplastic (malignant) astrocytoma
	Glioblastoma multiforme
	Pilocytic astrocytoma
	Subependymal giant cell astrocytoma
	Pleomorphic xanthoastrocytoma
Oligodendroglial tumors	Oligodendroglioma
	Anaplastic (malignant) oligodendroglioma
Ependymal cell tumors	Ependymoma
	Anaplastic ependymoma
	Myxopapillary ependymoma
	Subependymoma
Mixed gliomas	Mixed oligoastrocytoma
	Anaplastic (malignant) oligoastrocytoma
	Others (e.g., ependymoastrocytomas)
Neuroepithelial tumors of uncertain origin	Polar spongioblastoma
	Astroblastoma
	Gliomatosis cerebri
Tumors of the choroid plexus	Choroid plexus papilloma
	Choroid plexus carcinoma (anaplastic choroid plexus papilloma)
Neuronal and mixed neuronal-glial tumors	Gangliocytoma
	Dysplastic gangliocytoma of cerebellum (Lhermitte-Duclos)
	Ganglioglioma
	Anaplastic (malignant) ganglioglioma
	Desmoplastic infantile ganglioglioma
	Central neurocytoma
	Dysembryoplastic neuroepithelial tumor
	Olfactory neuroblastoma (esthesioneuroblastoma)
Pineal parenchyma tumors	Pineocytoma
	Pineoblastoma
	Mixed pineocytoma/pineoblastoma
Tumors with neuroblastic or glioblastic elements (embryonal tumors)	Medulloepithelioma
	Primitive neuroectodermal tumors with multipotent differentiation
	Medulloblastoma
	Cerebral primitive neuroectodermal tumor
	Neuroblastoma
	Variant: ganglioneuroblastoma
	Retinoblastoma
	Ependymoblastoma
Tumors of the sellar region	Pituitary adenoma
	Pituitary carcinoma
	Craniopharyngioma
Hematopoietic tumors	Primary malignant lymphomas
	Plasmacytoma
	Granulocytic sarcoma
Germ cell tumors	Germinoma
	Embryonal carcinoma
	Yolk sac tumor (endodermal sinus tumor)
	Choriocarcinoma
	Teratoma

	Mixed germ cell tumors
Tumors of the meninges	Meningioma: variants include meningothelial, fibrous (fibroblastic), transitional (mixed), psammomatous, angiomatous, microcystic, secretory, clear-cell, chordoid, lymphoplasmacyte-rich, and metaplastic subtypes Atypical meningioma Anaplastic (malignant) meningioma

Other diagnostic modalities, including CSF analysis, EEG, and brain stem–evoked responses may provide evidence of an intracranial neoplasm or other CNS disease process. In a recent clinical study of 115 dogs with seizures, 36 of 37 dogs (97%) with an abnormal neurologic examination and abnormal CSF analysis (protein >25 mg/dL or nucleated cell count >5 cells/μL) were found to have MRI abnormalities.[99] Statistical analysis of the data indicated that a CSF protein concentration greater than 25 mg/dL was associated with a 76% sensitivity and 70% specificity for prediction of MRI abnormalities, whereas a CSF protein greater than 35 mg/dL resulted in 52% sensitivity and 96% specificity. Although this does show some value to CSF analysis as a screening test, disadvantages still exist. Prediction of MRI abnormalities is not the same as diagnosis of a brain neoplasm (non-neoplastic diseases may also result in MRI abnormalities). Even if a neoplasm is suspected based upon the CSF, the cytology is usually nonspecific for tumor type and tumor location.[100] Although CSF collection generally carries a low-level of risk for the patient, if a brain neoplasm is suspected, it is recommended to perform MRI before CSF tap (due to the risk of tentorial herniation with CSF tap under conditions of increased intracranial pressure).

EEG has been used in humans as a useful aid to imaging studies in the localization of structural and functional brain lesions. An EEG is not as useful for lesion localization in companion animals as it is in humans because dogs and cats have a relatively small brain that is extremely well protected by a thick calvarium and masticatory muscle mass. In addition, EEG abnormalities are not specific for different types of intracranial neoplasia, so the value in the diagnosis of neoplasia is limited to screening at best.

The BAER test reflects audiologic and neurologic function at the level of the brain stem, and is used in human beings to aid in the diagnosis and localization of lesions of the cochlea, the vestibulocochlear nerve, and brain stem auditory pathways. In a prospective study of 26 dogs with naturally occurring brain tumors, BAER was abnormal in 13 of 15 dogs with tumors of the brain stem but only in 1 of 11 dogs with forebrain lesions.[101] Although this type of information may be useful in localizing a lesion, it is nonspecific as to lesion type, and like an EEG, is useful only as a screening tool.

Functional brain imaging, combined with structural data gleaned from either MRI or CT, is becoming more integrated in the identification and management of intracranial neoplasms and other CNS diseases. Specifically, flourodeoxyglucose (FDG) positron emission tomography (PET) and functional MRI are gaining widespread use in the human field for diagnosing and staging neurologic diseases. These imaging modalities are limited to few veterinary institutions, but they may be used more frequently in the future as the technology becomes widely accepted.

Once an intracranial structural lesion (tumor suspect) is identified, it is necessary to specifically identify the type of tumor present to tailor a specific treatment regime. The primary method of obtaining tissue for histopathologic diagnosis is by surgical exploration and excisional biopsy. This is most often accomplished when the lesion is located in the superficial aspect of the cerebral or cerebellar cortex. The surgeon is often able to remove or debulk these tumors at the time of surgery, thereby affecting not only a diagnosis but also substantial cytoreduction and potential cure. Disadvantages include cost, morbidity, and mortality associated with the surgery itself; tumor seeding of the surgical site; and the potential of enhancing the biologic activity

of the tumor itself. Additionally, the possibility exists of the tumor being responsive to chemotherapy, in which case the risks of surgery would not be warranted.

Less invasive biopsy techniques are available. Fine needle aspiration and needle core biopsy using stereotaxic CT or ultrasonographic guidance are routinely available at some institutions and have proved invaluable in diagnosing tumors that are located in surgically inaccessible areas of the brain. The inherent advantages and disadvantages of fine needle and needle core biopsies relate to the small sample that is obtained. Small needle diameter limits the amount of damage to nontarget tissues, but also limits the amount of tissue available for examination. Fine needle aspiration limits the method of examination to cytology. This offers the advantages of superior assessment of individual cell morphology and rapid turnaround for intraoperative use. The disadvantages of cytology are poor ability to assess histologic architecture and limited ability to apply special staining techniques. The accuracy of fine needle aspiration for diagnosis of intracranial neoplasia has been compared with histopathology in a number of studies, both human and veterinary. In a recent study of 10 clinical cases with necropsy confirmation of the diagnosis, fine needle aspiration had an exact agreement with the histopathologic diagnosis in 60% of the cases and made the correct diagnosis with regard to neoplasia and degree of malignancy in 100% of the cases.[102] In these cases, fine needle aspiration was performed after the brains had been removed en bloc from the cranium and the lesions were located with MRI. Whether similar results can be obtained antemortem in clinical cases remains to be evaluated.

191.4.6.2 Meningioma

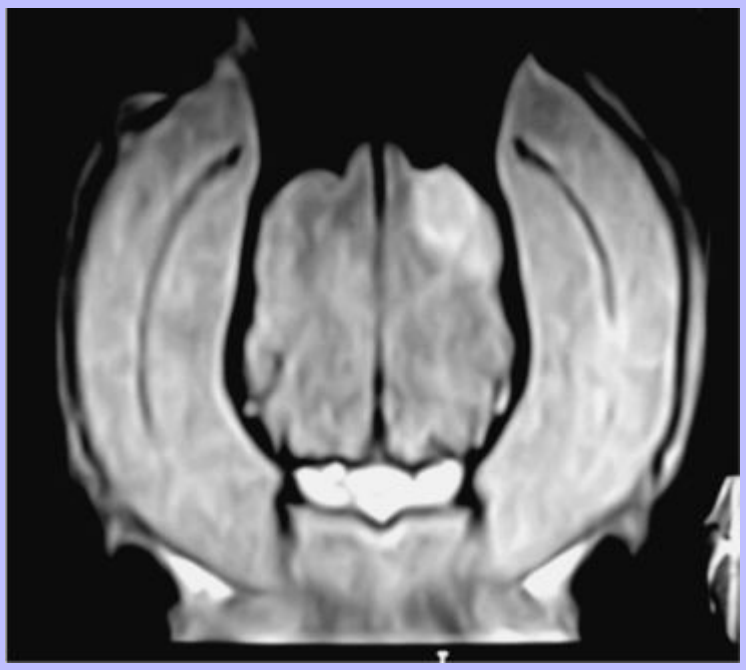
Meningiomas are the most common intracranial neoplasm in dogs and cats. They are mesenchymal tumors that arise from the cells of the three layers of the meninges: (1) the dura mater, (2) the arachnoid, and (3) the pia mater.[93,103,104] However, most commonly from the meningiocytes of the arachnoid layer. These neoplasms are in most cases benign, solitary tumors that grow slowly, often adhering to the dura mater or leptomeninges. Intracranial and extracranial metastases have been reported but are extremely rare. Meningiomas can also occur within spinal cord and intraorbital locations, although greater than 80% are reported to be intracranial.[105]

There does not appear to be a particular breed or sex of dog predisposed to meningiomas; however, it has been suggested that dolichocephalic breeds may be at increased risk.[106] Meningiomas are characteristically a neoplasm of older dogs, with 95% occurring in dogs over 7 years of age.[107]

Clinical signs in dogs with meningioma depend on the location of the tumor.[108] The majority of canine meningiomas are located in the cerebrum and often arise from over the convexities of the cerebral cortex or the falx cerebri.[104,106,109] The most common clinical signs in these dogs are seizures and changes in behavior or attitude. Cerebellar meningiomas may cause dysmetria, circling, ataxia, or intention tremors, and meningiomas that arise from the brain stem can potentially result in cranial nerve deficits or paresis.[108]

Although definitive diagnosis of an intracranial meningioma can only be made by histopathologic tissue examination, CT images and MRI are often highly suggestive of this tumor type. Meningiomas are usually visualized as a solitary, contrastenhancing, broad-based mass (Figure 191-31).[110] Typically, the tumor is homogenous in appearance with a low-intensity capsule separating the mass from adjacent brain parenchyma. In some cases, meningiomas are cystic in appearance.[111]

Figure 191-31 Meningiomas appear as a solitary, contrast-enhancing mass with a broad base on the dural surface. They are found most commonly over the convexity of the cerebrum.



The three major treatments that are used in veterinary medicine today for treatment of canine meningiomas are (1) surgery, (2) radiation therapy, or (3) a combination of the two.[112] Gene therapy has also been attempted in a limited number of studies, and some reduction in tumor size has been achieved; however, this practice has not yet gained wide acceptance.[112,113] Efficacy of chemotherapeutic compounds for the treatment of meningioma has not been demonstrated.[114] In humans the role of chemotherapy for the treatment of meningiomas is unclear and is usually reserved as a rescue protocol in nonresponders.[115] Studies in the past have reported extended survival times in dogs with brain tumors that received radiation therapy with or without surgery.[116–118] Cobalt-60 has been the most common source of radiation therapy used for treatment of canine brain tumors in the past and has been used successfully for several years to treat intracranial meningiomas.[103,119] Orthovoltage radiation has also been used successfully, although it is not considered ideal due to poor beam penetration, profile, and limited field configuration. Linear accelerators are becoming increasingly available for animal treatment at large referral institutions, and external beam megavoltage irradiation is the current recommendation for brain tumors in dogs and cats.[120]

Past radiation treatment protocols have varied from total doses of 30 to 36 Gy in 5 to 6 fractions over 14 to 19 days to the more recent total doses of 45 to 48 Gy in 12 fractions over 26 days.[116] Acute effects have been minimal and usually remain limited to the temporary disruption of normal epithelial tissue within the radiation field. Early delayed effects due to transient demyelination can cause recurrence of presenting signs or mental depression and usually occur within a few weeks to a few months after treatment. These changes

are typically steroid responsive and transient. Late delayed effects can occur more than 6 months after treatment, are not responsive to therapy, and are usually associated with brain necrosis.[121] In the human literature, daily fractions of 3 Gy or less given over 4 weeks with a total normal tissue dose of 50 to 55 Gy appears to induce fewer late effects, and this approach has been advocated by some in veterinary medicine.[122] The use of stereotaxic delivery of radiation may be of benefit because it decreases the dose of ionizing radiation to the surrounding healthy tissue. This method has been used recently to treat canine meningiomas with encouraging results.[123]

The prognosis for dogs with intracranial meningiomas that receive no treatment is poor. One study found that untreated dogs had a median survival time (MST) of 75 days after CT diagnosis.[124] Dogs receiving only palliative therapy (corticosteroids and anticonvulsants) after diagnosis by CT or MRI have shown average survival times ranging from 59 to 81 days.[118,121] However, extended survival times of greater than 16 months have been noted when surgical resection of the meningiomas is followed by radiation treatment.[117,125]

191.4.6.3 Neuroepithelial Tumors

Neuroepithelial tumors or gliomas are comprised of both astrocytic and oligodendroglial cell lines, as well as other neuroepithelial tissues (see Table 191-1). Although the true incidence in dogs is unknown, these tumors are second only to meningiomas when an intracranial neoplasm is histopathologically diagnosed. Astrocytomas are the most common human intracranial neoplasm; much effort has been devoted to the identification of imaging and histopathologic findings associated with rapidly growing, aggressive tumors. The World Health Organization (WHO) classification scheme characterizes astrocytomas based upon aggressiveness and allows for treatment planning and prognostication. High-grade (malignant) astrocytomas may arise alone or from a preexisting low-grade tumor. Low-grade astrocytomas (secondary) are much less invasive and carry an improved prognosis. Regardless, astrocytomas are usually fatal in both dogs and humans, although the survival time is unpredictable. In humans, the MST of patients with low-grade astrocytomas is 5 years. Interestingly, death usually results from malignant transformation into a high-grade tumor.

The characteristic appearance of an astrocytoma or oligodendroglioma on an MRI is that of a diffuse, nonenhancing or variably enhancing mass (Figure 191-32) that is hypointense on T1-weighted images and best seen on T2-weighted images. Typically the lesion exhibits a local mass effect. The borders of the tumor often appear distinct on MRI but histologically these tumors are usually invasive. Occasional evidence of invasion can be imaged if a powerful MRI is used.

Treatment of gliomas, whether an undifferentiated tumor, oligodendroglioma, or astrocytoma, is similar to that of a meningiomas: surgery and radiation therapy. These tumors, depending on the classification, tend to be invasive. As such, surgery would be expected to be less curative than it would for meningiomas. Chemotherapy may play a larger role in the adjunctive treatment of malignant gliomas compared with meningiomas. Although still controversial, sole-drug and multidrug chemotherapy has been shown to increase the proportion of long-term survivors in humans from less than 5% to approximately 15% to 20%.[126] The most commonly used drugs are procarbazine, lomustine, and vincristine. The role of these drugs and others has yet to be defined in dogs.

Choroid plexus tumors typically display homogenous contrast enhancement with discrete borders and appear hyperintense on (postcontrast) T1-weighted images. They can occur in the lateral, third, or fourth ventricle,

because these locations are where the choroids plexus resides (Figure 191-33). The most common location, however, is in the lateral aspect of the fourth ventricle.[127] Choroid plexus tumors are well vascularized, leading to good contrast enhancement and increased bleeding if the tumors are excised. These tumors often cause obstructive hydrocephalus due to their location in the ventricular system. This will be evident on imaging studies and may contribute to the overall morbidity of the animal. Embryologically the choroid plexus and ependymal cells are derived from similar tissues. As such, the MRI appearance and tumor distribution for choroid plexus papillomas and ependymomas are similar. However, ependymomas appear to be more uncommon and have a predilection for brachycephalic breeds of dogs.[128] Treatment for choroids plexus and ependymal tumors is largely conjectural, because no study has clearly defined the role of surgery, radiation therapy, or chemotherapy. When accessible, surgery is probably the treatment of choice. However, the high vascularity of these tumors, combined with the relative inaccessibility, indicate that chemotherapy or radiation therapy may play a vital role in effective management.

833
834

Figure 191-32 Gliomas appear as intraparenchymal masses with variable enhancement.

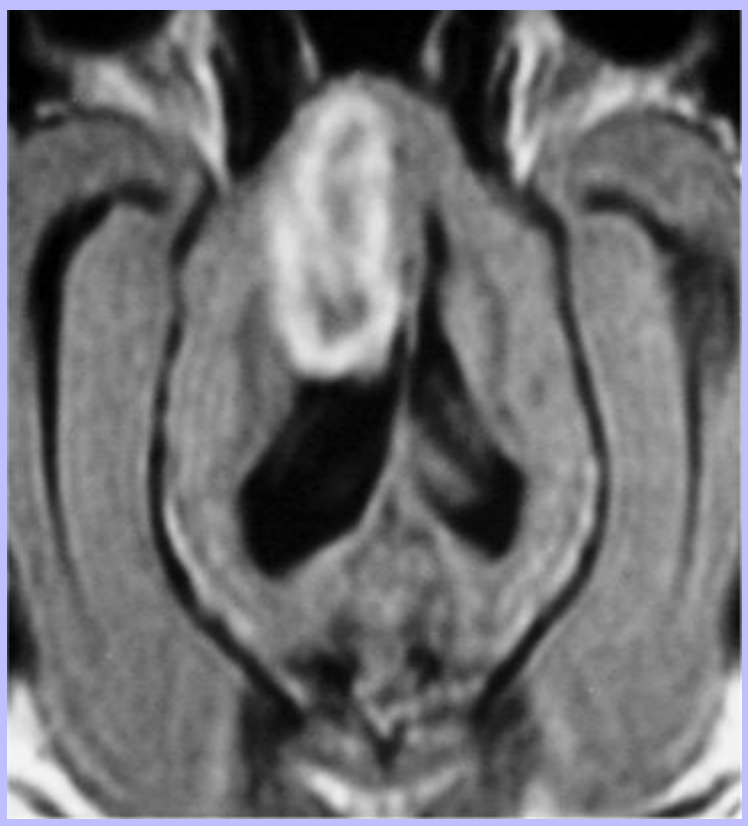


Figure 191-33 Choroid plexus papillomas arise within the ventricular system and have discrete borders. They usually are more uniformly enhancing than this example.

191.4.6.4 Central Nervous System Lymphoma

Primary CNS lymphoma is a result of neoplastic transformation of native lymphocytes within the CNS, whereas secondary CNS lymphoma results from spread of systemic disease. Regardless, involvement of the CNS provides the clinician with a challenge in both disease diagnosis and treatment. The blood-brain barrier effectively excludes many common drugs that are used to treat systemic disease and can hide involvement of the brain, making it difficult to confirm the presence of a neoplastic process within the brain. Diagnosis of CNS lymphoma is made by CSF analysis and, in cases of systemic disease, the presence of atypical lymphocytes in other body systems. In one study, 7 out of 7 dogs with CNS lymphoma had atypical lymphocytes noted in the CSF.[129] The clonal expansion of lymphocytes in lymphoma will all express identical unique DNA sequence in the variable region of the antigen receptor gene. A PCR assay that detects clonal rearrangement of these genes has been developed for dogs and hold promise as a means of diagnosing CNS lymphoma from CSF.[129a] Localized radiation therapy of the brain may be effective in cases of primary CNS lymphoma. Intrathecal administration of cytosine arabinoside at 20 mg/m^2, diluted in 2 to 4 mL of lactated Ringer's solution, given twice weekly for a total of 6 treatments, has been advocated by one author.[129] Another treatment method uses 100 mg/m^2 of cytosine arabinoside (intrathecal) given weekly 1

week beyond the point at which the CSF is devoid of all atypical lymphocytes. Lomustine (CCNU), an alkylating nitrosourea chemotherapeutic, is effective at crossing the blood-brain barrier and has gained support for the treatment of resistant systemic lymphoma in dogs.[130] CCNU and other chemotherapeutics that cross the blood-brain barrier (e.g., hydroxyurea, methotrexate) may also be considered a good choice for systemic treatment of lymphoma when the CNS is involved.

Intravascular lymphoma, a type of systemic lymphoma that is limited to the lumen and walls of blood vessels, has also been reported in the dog. This disease has a propensity for the brain and lungs in both dogs and humans and ultimately results in the occlusion of blood vessels.[131] Diagnosis is difficult, because both the CSF and peripheral blood analysis are not diagnostic for this disease. Imaging of the brain with MRI could yield evidence of multifocal abnormalities. In one case report, an MRI revealed diffuse postcontrast enhancement of the brain parenchyma and multifocal areas of hyperintensity.[132] Definitive diagnosis is made by histopathologic examination of a biopsy specimen. Treatment for intravascular lymphoma is similar to that for systemic disease: chemotherapy. However, specific treatment regimes and survival data for a large case series is not available.

191.4.6.5 Metastatic Neoplasms of the Central Nervous System

Metastatic neoplasms of the CNS are common in both humans and dogs. Generally, systemic tumors spread to the brain; spread to other parts of the CNS occurs with less frequency. Although the exact incidence of CNS metastasis in veterinary patients is unknown, it is known that in humans metastasis occurs in 20% to 30% of cases of systemic neoplasia. It has been noted in some studies that the rate of CNS metastasis has increased over the last 2 to 3 decades.[133] However, this finding may only reflect an increased ability to detect antemortem evidence of metastasis with advanced imaging procedures or increased longevity of animals with systemic neoplasia as a result of better treatment regimes. Regardless, CNS metastasis has become a real concern for veterinarians and, like treatment of CNS lymphoma, presents a unique challenge in both the diagnosis and treatment of these tumors.

834
835

Although it is true that any form of neoplasia has an inherent ability to spread, certain tumor types have been found to metastasize to the CNS with some regularity. Involvement of the CNS can be accomplished by direct invasion from the surrounding structures or systemic spread through the vascular system. Nasal adenocarcinomas tend to be locally invasive, and systemic tumors such as melanomas, hemangiosarcomas, and lymphosarcomas tend to spread hematogenously.

Recognizing CNS metastasis in an animal with systemic disease requires paying careful attention to the neurologic examination and questioning of the animal's caregiver. Because neurodiagnostic procedures are expensive and require anesthesia, reasonable suspicion is necessary to justify the search for CNS metastasis. CSF analysis may be beneficial as a screening test. Although CSF cytology rarely yields abnormal cells, it can provide other clues to CNS involvement. Albuminocytologic disassociation, or increased protein without an increased cell count, is a common finding in cases of tumors within the CNS. In other cases the CSF may have increased white cells. To confirm a diagnosis, however, advance imaging with MRI or CT should be performed. Metastatic tumors will lack a defined blood-brain barrier; therefore they commonly exhibit well-defined contrast enhancement (Figure 191-34) and are best visualized on MRI that is T1-weighted. Biopsy would be necessary to confirm a diagnosis.

In some instances an animal with systemic neoplasia may have signs limited to the CNS. In these cases a tumor may be diagnosed on MRI and treatment begun prior to diagnosis of a systemic tumor. Therefore it is

good practice to perform a thorough systemic workup, including thoracic and abdominal radiographs and, potentially, abdominal ultrasonography on every animal that is diagnosed with a brain tumor.

191.4.6.6 Pituitary Tumors

Pituitary tumors can be considered one of the most common intracranial neoplasms in dogs. Cushing's disease, or pituitary-dependent hyperadrenocorticism (PDH), comprises 80% to 85% of dogs with naturally occurring Cushing's syndrome. Virtually 100% of dogs with PDH have a functional tumor of either the pars distalis (80%) or pars intermedia (20%) of the anterior pituitary. These tumors are generally less than 1 cm in diameter and cause little damage to surrounding neural tissue. However, these tumors may continue to grow throughout the animal's life, ultimately resulting in both neurologic deterioration and death. Pituitary macrotumors—tumors greater than 1 cm in diameter—are also fairly common in dogs. These tumors are generally nonfunctional and cause clinical signs related to a space-occupying mass in the cranium. Most animals with expansive pituitary tumors exhibit signs related to hypothalamic disturbance (diencephalic syndrome), such as propulsive and constant pacing, behavior changes, endocrine disturbances, loss of vision, and potentially proprioceptive deficits.

Figure 191-34 Because they lack a blood-brain barrier, metastatic tumors such as this hemangiosarcoma of the diencephalon show well-defined contrast enhancement.

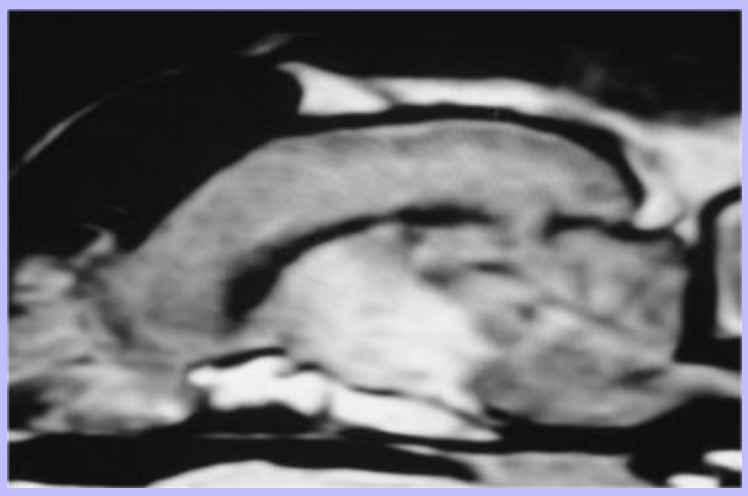

Figure 191-35 Pituitary macrotumors arise from the sella and invade the hypothalamus. They typically show marked contrast enhancement.

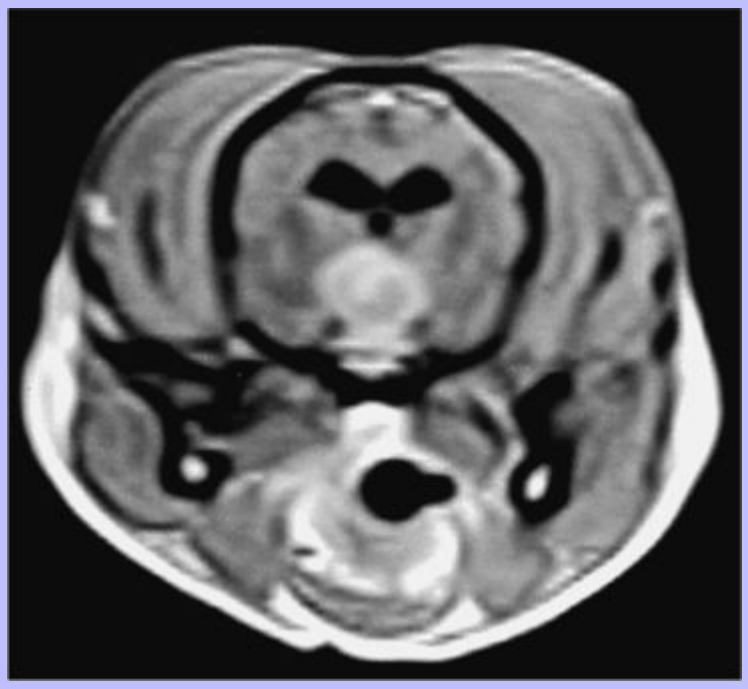

Diagnosis of a pituitary tumor is made with an MRI or CT (Figure 191-35). These tumors exhibit bright homogenous contrast enhancement with distinct borders. Peritumoral edema can be extensive in animals with large pituitary tumors. It is important to note that the anterior pituitary lacks a functional blood-brain barrier, because this tissue embryologically is derived from Rathke's pouch of the oral ectoderm. As such the tissue will normally enhance with the addition of a contrast agent. However, a pituitary microtumor can generally be visualized as an asymmetrical enhancement of the anterior pituitary.

Some pituitary tumors in humans are responsive to chemotherapy, but the treatment of choice is surgical excision. The cure rate is high, and perioperative morbidity and mortality is low. In dogs, pituitary surgery is rarely performed. Where it is performed in dogs with pituitary microtumors and PDH, a remission time of up to 39.4 months has been noted. The 1-year estimated survival rate was 84%, the 2-year survival was 80%, and the overall success rates of hypophysectomy around 73.1%.[134] The growth rate of pituitary tumors in dogs with PDH is unknown, but in one study 36% of dogs that had a tumor greater than or equal to 4 mm exhibited continued tumor growth and developed CNS signs within 1 year.[135] This finding may indicate that surgical removal of the tumor should be performed early in the disease process, prior to expansive tumor growth and CNS dysfunction.

Surgery for pituitary macrotumors is rarely performed, because the size of the tumor and location make complete excision improbable. In these cases, radiation therapy is generally recommended.

192 CHAPTER • 192 Multifocal Neurologic Disease

Rodney S. Bagley

Many diseases occur primarily or exclusively in specific areas within the nervous system. These conditions cause clinical signs that allow clinicians to localize lesions to discrete areas within the nervous system. Some diseases, however, affect the nervous system in a number of anatomically and functionally distinct areas (Box 192-1). In these instances, a constellation of clinical signs result from dysfunction of these differing neuroanatomic areas. It is also possible that, when clinical signs reflect more than a single level of neuroanatomic involvement, more than one disease is present within the nervous system in the same animal (e.g., a brain tumor and a cervical disk extrusion). Therefore it is reasonable to expect that signs of neurologic dysfunction will be found in multiple areas within the nervous system in animals with more than a single disease process. Diseases that primarily affect specific areas of the nervous system, such as the spinal cord or brain, are discussed in those chapters pertaining to those discrete neurologic regions. In this chapter the more clinically important diseases that often result in multifocal or diffuse clinical signs are reviewed. If the neurologic signs present in an animal cannot be localized to one functional area within the nervous system, consideration should be given to these diseases.

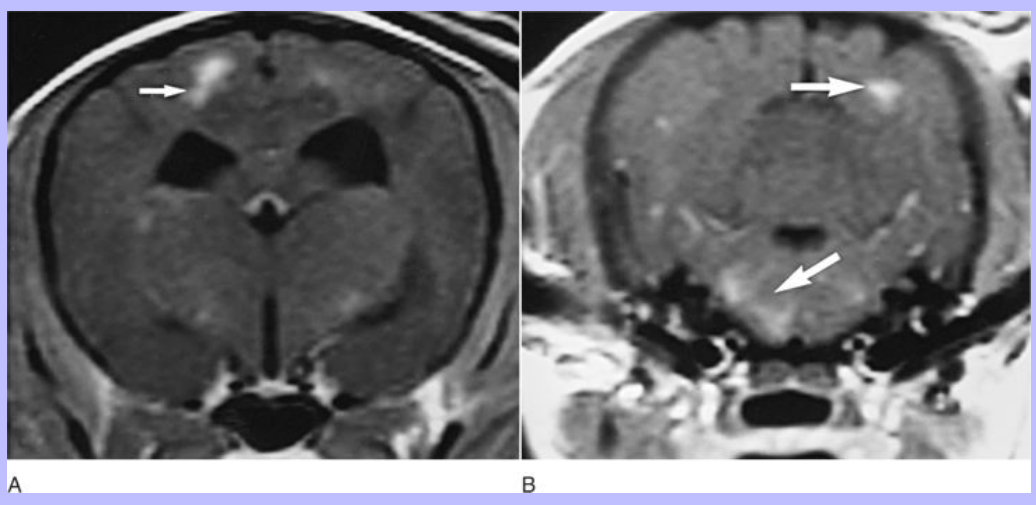
192.2 INFLAMMATORY DISEASES

Encephalitis and meningitis often exist concurrently in dogs and cats and are the most common group of diseases that result in multifocal nervous system signs.[1–3] Causes include both infectious and noninfectious causes. Infectious agents associated with encephalitis and meningitis include viral (distemper, parvovirus, parainfluenza, herpes, feline infectious peritonitis [FIP], pseudorabies, rabies), bacterial, rickettsial (Rocky Mountain spotted fever [RMSF], *Ehrlichia*), spirochete (Lyme disease, leptospirosis), fungal (blastomycosis, histoplasmosis, cryptococcosis, coccidiomycosis, aspergillosis), protozoal (toxoplasmosis, neosporosis), parasitic, and unclassified organisms (protothecosis). Incidence of infectious agents causing meningitis varies with geographic location. Additionally, infectious causes of encephalitis and meningitis exist that have not been identified or well-clarified as causes of inflammatory central nervous system (CNS) disease in small animals.

Encephalitis and meningitis may affect the nervous system at multiple levels. Intracranial signs (behavior changes, mental status abnormalities, visual deficits) including cranial nerve dysfunction and spinal cord signs (paresis, ataxia) are commonly seen. Neck pain is a prominent clinical feature of meningitis but may be less obvious with pure parenchymal involvement (e.g., myelitis). Pain may be assessed by vocalization during direct palpation or by reluctance to move the head and neck freely or with manipulation (decreased range of motion). Diffuse spinal pain is also possible. Because these diseases are often polysystemic, diffuse pain may also result from an associated articular facet polyarthritis or myositis. Some animals will react as if painful to minimal palpation (hyperesthestic) anywhere on the body, especially of the limbs and face. Many animals become irritable and uncharacteristically aggressive. Because chorioretinitis is often concurrent, fundic examination may yield important clues to the polysystemic nature of the problem.

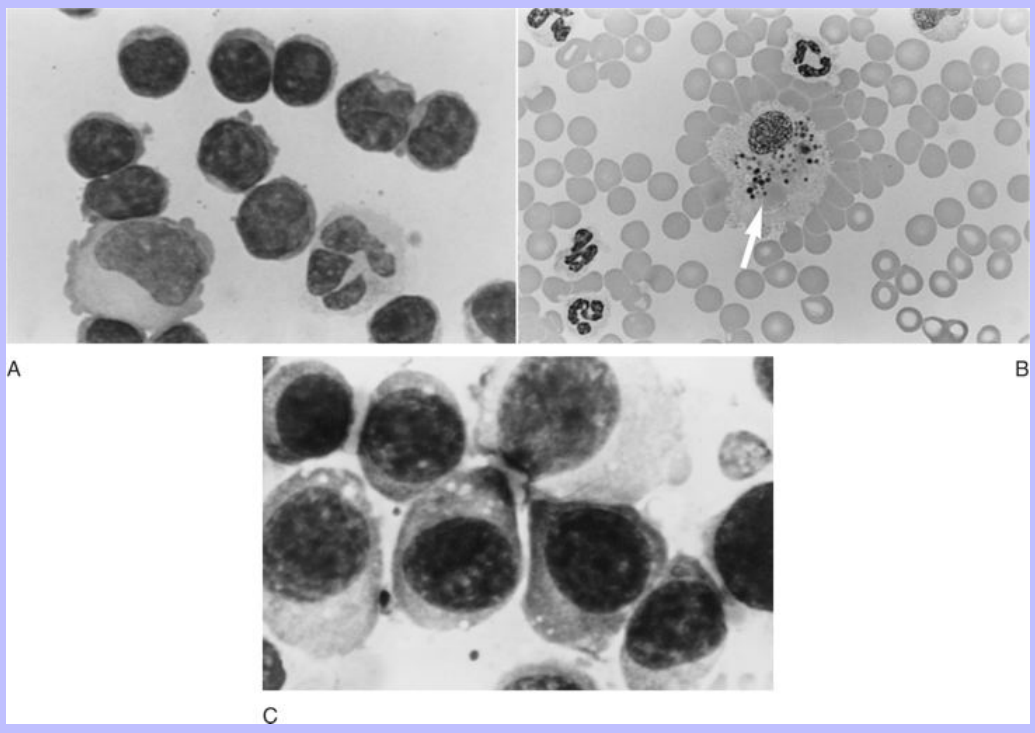
Figure 192-1 Transaxial, T1-weighted, contrast-enhanced (Magnevist [gadolinium DTPA], Berlex Laboratories, Inc., Cedar Knolls, NJ) magnetic resonance image (MRI) at the level of the thalamus **(A)** and brain stem **(B)** from a dog with multifocal clinical signs. Multifocal lesions are present in the cortex and brain stem *(arrows)*. Diagnosis was granulomatous meningoencephalitis (GME).



In many animals with encephalitis and meningitis, the cardinal signs of systemic inflammatory processes, such as the presence of a fever and increases in white blood cells (WBCs) in the leukograms, may not be found as localized inflammatory disease in the CNS and may not elicit a systemic inflammatory response. For ultimate diagnosis, imaging studies such as magnetic resonance imaging (MRI) and computed tomography (CT) are helpful in defining structural lesions (Figure 192-1).[4] Multifocal, discrete, anatomic lesions are often present within the nervous system and may be especially conspicuous after intravenous contrast medium administration, suggesting alterations in the blood-brain barrier to the cerebral vasculature. Cerebrospinal fluid (CSF) analysis is often important in diagnosis of an inflammatory CNS disease. CSF results alone, however, rarely yield a definitive causative diagnosis and are most helpful when evaluated concurrently with CNS anatomic imaging. Increased numbers of nucleated cells and increased protein concentrations commonly present in CSF from animals with inflammatory CNS disease may also be present with a variety of CNS diseases that result in secondary inflammation (i.e., tumors, trauma, vascular disease) (Figure 192-2). Nucleated cell numbers and types are variable depending upon the cause. In most primary inflammatory CNS conditions, however, mononuclear cells and neutrophils are the predominant cell types present. Eosinophils may indicate a parasitic or allergic response but have also been seen with certain infection conditions, such as *Cryptococcus* in cats and protothecosis in dogs. If prior CNS hemorrhage has occurred, erythrophagocytosis may be noted (see Figure 192-2). Primary CNS hemorrhage may also secondarily result in inflammation.

Unfortunately, evidence of inflammation on CSF evaluation alone is not specific for primary encephalitis because other CNS diseases (e.g., neoplasia, trauma, infarction) may result in a CSF pleocytosis and protein elevations. Therefore evaluation of serum or CSF titers for the aforementioned infectious diseases is often necessary to establish associated infectious diseases. It is recommended to assess several titers in animals with inflammatory CNS disease in an effort to establish an infectious cause. Common infectious causes for dogs include toxoplasmosis, neospora, distemper, and some fungi. Common infectious causes in cats include toxoplasmosis, FIP, *Cryptococcus*, and other as yet unclassified but suspected viral agents. In up to 60% or more of cases of encephalitis, however, an infectious cause is not identified.

Figure 192-2 Cerebrospinal fluid (CSF) cytology from various dogs with multifocal clinical signs. **A,** Predominantly small mononuclear cells with some neutrophils and monocytes are seen, consistent with a lymphoid pleocytosis (×100). **B,** Numerous red blood cells (RBCs), some neutrophils, and erythrophagocytosis *(arrow)* are seen (×50). **C,** The predominant cell is a large blast-type cell, consistent with lymphosarcoma (×100).



Occasionally, CSF from an animal with inflammatory CNS disease will be normal at a single sampling. This is especially true when the disease is primarily intraparenchymal and sometimes after previous corticosteroid administration.

Treatment of meningitis is ideally directed at a specific causative organism. However, treatment often needs to be initiated prior to establishing the exact cause of inflammation because results of serologic testing may delay diagnosis. More aggressive treatment is warranted in animals with severe to rapidly deteriorating clinical signs prior to a definitive diagnosis being rendered.

In this situation, multiple drug therapies are recommended and treatment should begin earlier rather than later in the disease course. Trimethoprim-sulfadiazine (30 mg/kg every 12 hours), clindamycin (20 to 25 mg/kg every 12 hours), doxycycline (10 mg/kg orally every 24 hours), and corticosteroids (prednisone 1 to 4 mg/kg every 12 hours) can be used in combination. Although corticosteroids may seem to be contraindicated with infectious diseases, they are often beneficial in the acute treatment of brain inflammation and edema and have proven

beneficial even with bacterial meningitis in children. It is often the associated inflammatory reaction in the CNS that is more detrimental to CNS function than the primary pathophysiologic effects of the organism itself. If rickettsial diseases are suspected, chloramphenicol (15 to 25 mg/kg orally every 8 hours) can be substituted or added to the regime; however, this drug is becoming infrequently used in veterinary medicine in general. If the animal is receiving phenobarbital, the clinician should not use chloramphenicol, because this drug will decrease the metabolism of the barbiturate and the animal could become comatose and die. Therefore in animals with encephalitis and seizures, it is probably wise to avoid chloramphenicol in case barbiturates are needed for seizure control.

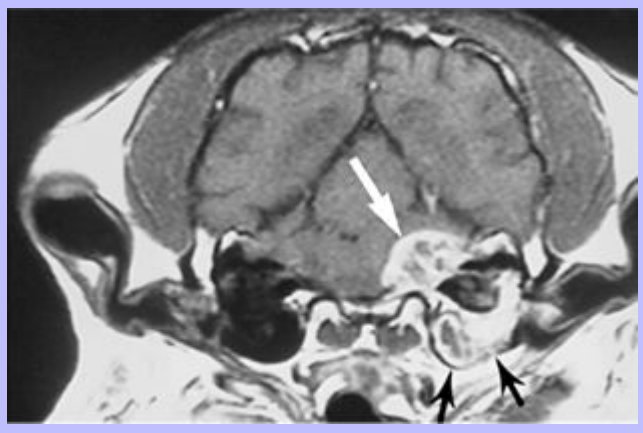
192.3 SPECIFIC INFLAMMATORY DISEASES

192.3.1 Bacterial Diseases

Bacterial meningitis is rare in dogs and cats.[1] Often, a concurrent disease that results in persistent bacteremia is present. Notable examples in dogs are endocarditis and pyometra. Extension of a local bacterial disease process, most commonly from the nasal passages or middle ear, is also possible (Figure 192-3). Dogs and cats with bacterial meningitis usually have rapidly progressing clinical signs, and the disease is often fatal. Abscesses may form, resulting in focal clinical signs.[5] A variety of causative bacteria may be present.

Diagnosis is aided by CSF analysis. CSF collection should be performed with caution, however, because the associated intracranial alterations associated with fulminant bacterial encephalitis may result in an increased intracranial pressure and resultant brain herniation. Although attempts have been made to classify CSF changes commonly associated with septic inflammatory CNS diseases, the degree of crossover in CSF nucleated cell counts and types makes it difficult to presumptively diagnose a specific inflammatory disease from the CSF results alone. One clue to the presence of bacterial component is a decreased glucose concentration in CSF as compared with plasma, presumably due to consumption of glucose by the organisms. If bacterial encephalitis is suspected, additional CSF should be collected in a sterile container without fixative or other chemicals for culture and sensitivity. Glass tubes containing ethylenediamine tetra-acetic acid (EDTA), commonly used for submission of CSF for cytologic analysis, are not appropriate for culture because the EDTA is bacteriostatic and may hinder organism growth. Because the number of organisms in CSF can be small, the greater amount of CSF cultured the more likely an organism will be isolated.

Figure 192-3 Transaxial, T1-weighted, contrast enhanced (Magnevist [gadolinium DTPA], Berlex Laboratories, Inc., Cedar Knolls, NJ) magnetic resonance image (MRI) at the level of the vestibular area from a snow leopard with seizures and a head tilt. A brain abscess is present, extending from the middle and inner ear to the brain stem *(arrows)*. A surgical biopsy and culture found both fungal and bacterial organisms were present.



Because identification of the organism may take a few days and the clinical signs are often rapidly progressive, treatment is often initiated prior to culture analysis. As stated previously, prior to a specific cause being identified, trimethoprimsulfadiazine, clindamycin, doxycycline, and corticosteroids can be used in combination for treatment of CNS inflammation and infection. Methylprednisolone sodium succinate (30 mg/kg) can be administered intravenously initially if the animal is severely impaired, rapidly deteriorating, or unable to swallow. If the animal is more mildly affected and can swallow effectively, prednisone or prednisolone can then be initiated at anti-inflammatory doses. In some instances, the infection will form a discrete abscess. Because this abscess and its associated inflammation can rapidly increase intracranial pressure, surgical decompression of a focal abscess should take place as soon as possible. Similarly, penetrating intracranial wounds may require débridement to avoid infectious complications.

Although not associated with meningitis per se, tetanus can result in both confusing and diffuse clinical signs. Tetanus is due to a neurotoxin secreted by the organism *Clostridium tetani*. This toxin binds to interneurons and inhibits the release of inhibitory neurotransmitter (glycine) in inhibitory interneurons (Renshaw cells). The organism gains access to the body through a wound, which often cannot be seen in dogs. Cats, which are more resistant to the disease than dogs, usually have a visible wound.

Clinical signs include extensor rigidity, inability to open the mouth, salivation, prolapsed nictitating membrane, inability to urinate, and seizures. Bradycardia, megaesophagus, and hiatal hernia may be seen.[6,7] Tetanus localized to one part of the body is occasionally found. Diagnosis is based upon clinical signs. Anaerobic culturing of a wound may reveal the organism. A serum test for antibodies has occasionally been useful but is not readily available. Treatment includes wound débridement, antitoxin (administered once intravenously),

penicillin, muscle relaxants, enteral or parenteral nutrition support, a quiet environment, and good supportive care. Anticonvulsants are given if seizures occur.

192.3.2 Viral Diseases

Canine distemper remains a surprisingly common cause of neurologic dysfunction in dogs. This disease is caused by a paramyxovirus. Clinical signs can occur at any age, regardless of vaccination status. Most commonly, young dogs with inadequate vaccinations are affected with the polysystemic signs (i.e., gastrointestinal [GI], respiratory) and the neurologic signs of infection. However, in the modern era of prophylactic vaccination for distemper, distemper infection may only result in nervous system signs. Nervous system disease associated with distemper is characterized pathologically by two main forms: (1) neuronal and glial cell death (polioencephalopathy) and (2) demyelination (leukoencephalopathy).[3,8–10] It has been suggested that those animals with a poorer antibody response to the virus tend to have the former form and those with an adequate immune response to the virus tend to have the latter—immune-mediated demyelination. Any region of the nervous system can be involved. Myoclonus, a rhythmic, shocklike contraction of a muscle or group of muscles, is usually the result of previous or concurrent distemper infection and lends a clue to the virus' presence. Muscles of the limbs are commonly involved, but other muscles, including the tongue, may be affected.[11]

Clinical signs of a prior or concurrent systemic illness (respiratory, GI) are not always found in dogs with distemper. Diagnosis is suggested by finding inclusion bodies in pathologic specimens. Elevated CSF antibody titer (immunoglobulin G [IgG] and immunoglobulin M [IgM]) against distemper virus is supportive of a diagnosis, especially if concurrent serum distemper titers are not elevated or if a CSF electrophoresis suggests intrathecal antibody production. Occasionally, dogs with CNS distemper do not have positive CSF distemper titers.[12] No specific treatment is effective against the distemper virus. Corticosteroids, although seemingly contraindicated, may decrease inflammation and improve clinical signs in some dogs.

Other viruses of dogs that result in encephalitis and meningitis do so primarily in very young animals. Examples include herpes virus, parvovirus, and parainfluenza virus. Occasionally, these viruses will cause encephalitis and meningitis in adult dogs. Parainfluenza virus has a propensity for causing hydrocephalus.

FIP results from a coronavirus-induced vasculitis. This disease can involve various areas of the nervous system, primarily the intracranial structures and spinal cord. Very young and, conversely, very old cats seem predisposed.[13] Of the two forms of FIP that exist in cats, the “dry” form commonly affects the nervous system. This viral infection results in an immune complex vasculitis that is responsible for most of the pathologic effects. CSF analysis may show a pleocytosis, with either mononuclear cells or neutrophils as the predominant cell type and elevated protein concentration, often greater than 1 g/L (0.1 g/dL). No specific treatment is effective. Immunosuppressive therapy may result in short-term improvement of clinical signs.

Feline immunodeficiency virus has been associated with nervous system signs including behavior changes, seizures, anisocoria, and muscle twitching.[3] As the clinical spectrum of this disease evolves, it may represent an important CNS pathogen of cats. Feline leukemia virus (FeLV) has also been associated with a myelopathy independent of the presence of lymphoma.[14]

839

840

Toxoplasma gondii and *Neospora caninum* are protozoal organisms that can affect any area of the nervous system resulting in encephalitis, myelitis, peripheral neuropathy, or myositis in dogs.[15] These organisms are the most common cause of infectious encephalitis and myelitis in the Pacific Northwest. A classic sign of the

infection in young animals is a hyperextended pelvic limb or limbs. Other systemic signs such as chorioretinitis may also be present. Cats also commonly have toxoplasmosis within the nervous system; however, neosporosis has only been established experimentally in this species. CSF analysis often contains a pleocytosis and increased protein concentration. In some instances, discrete granulomas may be found within the CNS and peripheral nerves. Diagnosis of toxoplasmosis is based on the presence of IgM or rising IgG titers to the organism (toxoplasmosis), on visualization of the protozoan in biopsy specimens, or on both.[16] Clinical distinction between the two organisms is not always possible but is increased by awareness of the later protozoal organism and special staining and electron microscopic characteristics. Although sometimes helpful in the diagnosis, CSF titers to toxoplasmosis antibodies may be negative in the presence of CNS toxoplasmosis infection. Serum titers may be more often positive compared with CSF titers with CNS toxoplasmosis. Serologic titers to the presence of Neospora are also available to support the diagnosis of this infection. As with most systemic titer results, the presence of antibodies against these organisms does not ensure the presence of active CNS infection.

Treatment for toxoplasmosis currently is clindamycin[17]; however, this drug is often used in combination with a potentiated sulfa drug in immunosuppressed humans with toxoplasmosis.[18] Trimethoprim sulfa antibiotics have also been used successfully to treat CNS toxoplasmosis. Treatment courses of antibiotics are usually administered for as long as 4 weeks. In some animals, constant treatment with antibiotics is necessary to control clinical signs. A similar treatment is used for neosporosis; however, few cases with definitive treatment success have been reported.[19]

192.3.3 Rickettsial Diseases

Infection with rickettsial organisms associated with RMSF and *Ehrlichia* commonly involve the brain stem, particularly the vestibular system.[20] With RMSF a history of systemic illness (usually with a thrombocytopenia) often exists 5 to 10 days prior to development of neurologic signs. As the animal's fever is decreasing, neurologic signs commonly appear. Diagnosis is based on lack of mass lesion with intracranial imaging studies and a pleocytosis on CSF evaluation. Occasionally, increased contrast enhancement is noted in the choroid plexus area in affected dogs. This must be differentiated from the degree of contrast enhancement normally seen in these structures. CSF usually contains mild increases in nucleated cells (<50 nucleated cells/µl; normal <5 nucleated cells/µl) and mild increases in protein concentration (<50 mg/dL; normal <25 mg/dL). Increasing serum titers to the organism supports diagnosis, but results are often available after the disease has progressed. Prognosis is dependent primarily on the severity of clinical signs prior to treatment. Dogs that are severely obtunded prior to treatment are less likely to recover. Dogs with clinical features of vestibular disease after a systemic febrile illness associated with thrombocytopenia should be treated with tetracycline or doxycycline prior to establishing a definitive diagnosis with titers.

192.3.4 Fungal Diseases

Of the fungal diseases that can affect the nervous system, *Cryptococcus*, blastomycosis, coccidiomycosis, candidiasis, and aspergillosis are most common.[2,3] Immunodeficiency may play a role in these uncommon nervous system infections. Definitive diagnosis is made through viewing the organism in CSF or biopsy samples and fungal culture of infected nervous tissues. Treatment can be attempted with antifungal agents; however, the presence of an intact blood-brain barrier may interfere with drugs reaching therapeutic concentration in CNS tissue. Fluconazole and itraconazole hold the most promise for treating fungal

encephalitis and meningitis. These drugs have historically been rather expensive and owner financial constrains often limit effective long-term therapy.

With cryptococcosis, identification of the organism from cytologic evaluation of samples such as CSF, nasal discharge, and skin lesions supports the diagnosis. A neutrophilic pleocytosis, and occasionally an eosinophilic pleocytosis, may be found on CSF analysis. Detection of the cryptoccal capsular antigen in serum is usually diagnostic. Tissue biopsy and fungal culture or fungal culture of CSF may be more definitive in establishing a diagnosis.

192.3.5 Parasites

Involvement of the intracranial nervous system can occur with parasites such as *Cuterebra* larvae, *Toxocara*, and aberrant heartworm migration. These parasitic conditions may result in inflammation with eosinophils.

192.4 NONINFECTIOUS DISEASES

Most meningitis syndromes (~60%) in dogs do not have a definable infectious cause. Noninfectious disease of the supratentorial structures includes some specific diseases such as granulomatous meningoencephalitis (GME), breed-specific encephalitis and meningitis, and many nonspecific entities. GME can occur as a disseminated disease, a focal mass-lesion, or as a primary ocular disease. Unfortunately, many nonspecific encephalities are inappropriately diagnosed as GME. The cause of true GME is not known.[1] Some animals initially thought to have this disease have been shown to have lymphoma. CSF usually shows a mononuclear pleocytosis but is rarely pathognomonic for the disease. Occasionally the CSF will be normal or contain only increases in protein. CT or MRI may show diffuse inflammatory changes or a mass lesion.[4] Biopsy is needed for definitive diagnosis. Treatment options include immunosuppression (corticosteroids, azathioprine), surgery (if a focal mass), or radiation therapy. The latter has shown the most promise recently for definitive treatment of this disease.[21] Most dogs with GME die within 6 months to 1 year after diagnosis unless radiation therapy is used. Newer medical treatments under investigation that show promise in treatment of GME include cytosine arabinoside and procarbazine.[22]

192.4.1 Breed-Associated Encephalitis, Meningitis, and Vasculitis

Multiple primary CNS inflammatory and CNS vasculitis diseases are inherent in specific breeds of dogs. Pug encephalitis is an example of a breed-associated inflammatory brain disease[23]; it usually occurs in young pugs but has been reported in dogs up to 7 years of age. The disease is characterized histologically by forebrain inflammation and necrosis, primarily of the cerebral hemispheres.[23] It is not unusual, however, that initial clinical signs include neck pain, and that the disease is misinterpreted as a primary spinal cord disease such as intervertebral disk disease. Usually this disease has been fatal, and therapy (corticosteroids) has not altered the course of the disease; however, the prognosis with this disease is debatable. A similar disease has been described in Maltese terriers, Yorkshire terriers, and some other breeds.[24–26]

Other inflammatory diseases that do not have a definitive cause are also often grouped together under the heading of "steroid-responsive meningitis."[2,3] Almost assuredly, multiple diseases exist within this group. Younger, large breed dogs such as retrievers are often affected. Clinical signs often include cervical pain as a prominent feature. Additionally, there exists a syndrome of spinal cord vasculitis that occurs in beagles and Bernese mountain dogs. Other dogs such as German shorthaired pointers and Nova Scotia duck trolling

840

841

retrievers have an apparent breed-associated meningitis syndrome.[2,3] Clinical signs are similar to other meningitis syndromes. CSF from affected dogs often contains a preponderance of neutrophils. In some cases associated hemorrhage will make the CSF bloody upon collection. This is often misinterpreted as iatrogenic at time of collection; however, the presence of erythrophagocytosis is helpful in establishing previous CNS hemorrhage. Some of these animals will have positive LE (Lupus erythematous) cell tests, suggesting a possible immune-mediated component to the disease, although LE is quite nonspecific in dogs. Corticosteroid therapy often is rapidly beneficial in these dogs.

192.4.2 Generalized Tremors

Adult animals that have generalized tremors often have associated encephalitis. Many of these dogs also have additional clinical signs that reflect dysfunction of multiple regions with the nervous system. Generalized tremor syndrome occurs in numerous dog breeds.[27–29] Diffuse, low-amplitude tremors are the norm. Many dogs are initially thought to be hypothermic or apprehensive. Historically, dogs with white haircoats were more often affected, thus the term *white shakers*. However, dogs with a variety of haircoat colors, like the miniature pinscher, can be affected.[29] Clinical signs usually occur in young (1 to 4 years of age) dogs and include generalized tremor, ocular muscle tremor, vestibular signs (head tilt, ataxia), cerebellar signs, and seizures. The disease is often associated with a mild encephalitis. CSF from affected animals usually contains mild increases in nucleated cell counts and mild to normal protein content. No obvious cause of the encephalitis has been found. Clinical signs usually respond to immunosuppressive doses of corticosteroids. After the clinical signs have initially resolved, the corticosteroid dose can be slowly decreased (over weeks to months) to prevent recurrence. The disease, in some dogs, will only remain in remission with continual corticosteroid administration.

192.4.3 Dysautonomia

Dysautonomia is a disease that seems to have regional prevalence in the United States with primary concentration in the Midwest (Kansas, Missouri).[30–35] Animals with this disease can have numerous clinical signs reflective of both a diffuse neurologic and systemic process. Clinical signs may include vomiting, diarrhea, ileus, decreased GI motility, dry mucous membranes, dry eyes (keratoconjunctivitis sicca [KCS]), dramatic loss of body mass, pupillary changes with decreased pupillary light reflex (PLR) (mydriasis), dilated anal sphincter, dysuria, and bradycardia. In some instances, decreased to absent spinal reflexes suggest lower motor neuron (LMN) involvement. A regional infectious or toxin cause is suspected. Diagnosis is suspected based on the presence of the aforementioned constellation of clinical signs. Some pharmacologic manipulations may also be helpful, such as assessment of response to 0.1% pilocarpine instillation in the eyes and assessment of wheal and flare reaction subsequent to intradermal histamine administration. Radiographic assessments may show evidence of ileus, distended intra-abdominal organs, decreased intestinal motility after barium administration, megaesophagus (with or without aspiration pneumonia), and distention of the bladder. Treatment is directed at supporting body functions; however, the overall prognosis is poor because clinical signs are persistent.

192.4.4 Central Nervous System Hemorrhage

Hemorrhage in or around the CNS may also result in a multifocal clinical picture.[36,37] Hemorrhage may be associated with systemic bleeding disorders, thrombosis and other vascular occlusive disease, vasculitis, and hypertension. Vascular and other hemorrhagic diseases involving the nervous system are uncommonly reported

in animals, as compared with human beings. With the advent of the increased use of advanced imaging studies such as MRI, vascular disease and CNS hemorrhagic phenomenon are increasingly recognized. Thrombosis, infarction, and hemorrhage can occur spontaneously—secondary to drug therapy (L-asparaginase, anticoagulants)—with thrombocytopenia and other bleeding disorders, anticoagulant rodenticide toxicity, trauma, hypertension (hyperthyroidism, hyperadrenocorticism), atherosclerosis from hypothyroidism, infection (septic emboli), and diseases that result in hypercoagulability such as glomerulonephritis. Of special note, many dogs with idiopathic thrombocytopenia have CNS bleeding complications. Greyhounds appear predisposed to cerebrovascular problems. Clinical signs are usually acute in onset and may be initially progressive because the vascular event results in secondary ischemia, inflammation, and edema. Hemorrhage and infarction may be seen with CT and MRI. Acutely, the associated mass effect and edema can mimic other intracranial structural diseases such as tumor. Diagnosis is supported by cerebral angiography; however, this is uncommonly performed in dogs and cats. Treatment is directed at any underlying cause of thrombosis or hemorrhage. If the hemorrhage results in mass effect, acute surgical decompression may be necessary to avoid severe brain or spinal cord dysfunction. Blood product support, procoagulant, or anticoagulant drugs (as necessary) may be needed during the perioperative and postoperative time.

192.5 METABOLIC DISEASES

Many metabolic diseases may affect the nervous system at multiple levels and result in diffuse or multifocal clinical signs.[38] Hypoglycemia secondary to insulinoma can result in clinical signs of CNS (depression, seizures, tremors) and peripheral (weakness, decreased spinal reflexes, muscle atrophy) dysfunction.[39–44] The dichotomy of seizures (a supratentorial sign) and decreased to absent reflexes (an LMN sign) may initially result in confusion during neuroanatomic localization. Clinical signs of weakness with insulinomas are often attributed to the hypoglycemia, and the concurrent neuropathy is often overlooked.

Hyperthyroidism of cats has been associated with both central and peripheral nervous system abnormalities.[45] CNS signs include restlessness, hyperexcitability, irritability, aggression, wandering, pacing, circling, insomnia, and seizures. Apathy, lethargy, and depression occur infrequently. Focal neurologic deficits may result from associated cerebrovascular accidents, most likely secondary to hypertension. Clinical signs of peripheral nervous system involvement include generalized weakness, neck ventroflexion, muscle tremors, gait abnormalities, and muscle atrophy. Muscle weakness often manifests as a decrease or inability to jump. Neck ventroflexion may occur with other diseases, including myasthenia gravis (MG), polymyopathy (including hyperkalemic polymyopathy), and organophosphate toxicity.

Conversely, hypothyroidism has been associated with various nervous system abnormalities in dogs.[46] Whether these signs reflect a primary metabolic disturbance or secondary structural abnormalities associated with underlying vascular disease is not always determined. Cranial (vestibular, facial, trigeminal) and appendicular peripheral nerves may be abnormal. Morphologic changes in nerves included demyelination, remyelination, and axonal necrosis. These changes, however, are not specific for hypothyroid neuropathy.

Hyperadrenocorticism may result in abnormalities of the muscle and peripheral nervous system.[47] Affected dogs usually are weak, but an extremely small percentage of dogs (<1%) have a stiff gait, most obvious in the pelvic limbs. An associated pseudomyotonic state has been described. In some instances, myotonia may predominate. Whether this secondary consequence of hyperadrenocorticism is primarily a myopathy or neuropathy has not been determined. If hyperadrenocorticism is the result of a pituitary tumor, clinical signs of intracranial disease are also possible. Macroadenomas may enlarge dorsally from the sella and compress the diencephalon. The most common

abnormalities are listlessness, decreased appetite, and, less commonly, disorientation. Seizures and blindness are extremely rare.

192.5.1 Neoplasia

Tumors of the nervous system include primary and secondary (metastasis) neoplasms.[48] Often tumors of the nervous system result in focal clinical signs. Some tumors, however, are diffuse and therefore result in diffuse clinical signs. Prominent examples include lymphosarcoma and carcinomatosis. Multiple cranial nerves (III, IV, V, VI, VII) may be involved with hematogenous neoplasia (leukemias) due to direct involvement with the tumor cells.[49] Choroid plexus tumors, which often arise within the ventricles of the brain, may metastasize within the neural axis by metastasis through the CSF.[48] If the spinal cord is affected, clinical signs of spinal dysfunction may occur concurrent with intracranial signs from the primary tumor. Diagnosis is aided by advanced imaging and CSF analysis.

Neoplasia secondarily involves the brain via metastasis or via direct extension from extraneural sites.[50–52] Clinical signs may be localized or multifocal depending upon the number and location of metastasis and associated pathophysiologic sequelae such as hemorrhage and edema.[51]

192.6 OTHER DISEASES

Many degenerative neurologic diseases of dogs and cats are inherited or congenital; therefore they are seen primarily in young animals.[1] Storage diseases are prominent examples. Diseases that involve the neuronal cell body are more likely to have cerebral, cranial nerve, or peripheral nerve signs, whereas diseases that primarily involve myelin are more likely to result in ataxia and paresis of the limbs.[1] The storage diseases and other degenerative diseases of dogs and cats have been reviewed previously.[1]

Numerous toxins can affect the nervous system, often at multiple sites.[53,54] Examples of primary toxins include organophosphates, metaldehyde, lead, and bromethalin. Diagnosis can be difficult if exposure has not been documented historically. Treatment is directed toward the specific toxin.

193 CHAPTER • 193 Diseases of the Spinal Cord

Richard A. LeCouteur

Jacqueline L. Grandy

193.1 MECHANISMS OF DISEASE

Spinal cord diseases can be divided into two groups.[1] The first group comprises diseases that affect both the nervous system and other organ systems. The second group includes diseases that are unique to the nervous system, such as disorders of myelin, neurons, or supporting cells (glial cells and the like). Categories of disease that may be included in either of these two groups are congenital and familial disorders, toxicities, nutritional disorders, degenerative diseases, neoplasia, and idiopathic disorders.

The localization of specific functions in the nervous system has important effects on the clinical presentation and progression of spinal cord diseases. Localization of function in the spinal cord causes a pathologic process to result in many different clinical presentations, depending on the part or parts of the spinal cord it affects. For example, a spinal cord neoplasm at the level of the C3 vertebra may result in tetraparesis, whereas the identical neoplasm at the level of the T13 vertebra may result in paraparesis, leaving the thoracic limbs unaffected. Furthermore, localization of function in the spinal cord renders the cord inherently vulnerable to focal lesions that in other organs, where function is more uniformly distributed, might not result in detectable clinical signs. For example, a small infarction of the cervical spinal cord may result in tetraplegia, whereas a similar lesion in the hepatic parenchyma probably would not compromise liver function.[1]

The unique susceptibility of the nervous system to a localized lesion is compounded by its strictly limited capacity to restore function in damaged tissue. Because the pathologic reactions of the spinal cord to disease are to a degree nonspecific, various disorders may induce a somewhat similar histologic appearance.[2,3]

Clinical syndromes that affect the spinal cord may be characterized by a single focal lesion (transverse myelopathy) or by several focal lesions (multifocal disorders). Myelopathies may be *extrinsic,* meaning that spinal cord dysfunction occurs secondary to diseases of the vertebrae, meninges, or epidural space, or it may be *intrinsic,* which means the disease begins as an intramedullary lesion. Extrinsic myelopathies are almost always transverse myelopathies.

Because the nervous system can respond in only a limited number of ways to the numerous causes of myelopathies, a systematic diagnostic approach must be taken for an animal with a spinal cord disorder.

193.2 APPROACH TO A SPINAL CORD PROBLEM

193.2.1 Diagnosis

193.2.1.1 Signalment

Accurate diagnosis of a spinal cord disorder must include consideration of the animal's age, breed, and gender. Diseases may be specific to certain species and breeds.[4–8]

193.2.1.2 History

An accurate and complete history constitutes the initial step in the diagnosis of all neurologic problems. Important aspects of the history include the rapidity of onset of the problem and the nature of its progression. This information may be helpful for determining the cause of a problem. For example, neoplastic diseases that affect the spinal cord often result in focal signs that have an insidious onset and a gradual progression. In contrast, vascular disorders, such as infarction or hemorrhage, may manifest an acute onset of focal signs without evidence of progression. Inflammatory, degenerative, or metabolic disorders generally cause a diffuse distribution of signs with an insidious onset and gradual progression. Traumatic and congenital diseases may result in either a focal or multifocal distribution of signs, most often with an acute onset and without progression, although such diseases may have a progressive course.

Although careful consideration of these factors is helpful in determining the cause of a spinal cord problem, so many exceptions to general statements exist that such information must be used with caution. For example, an acute onset of signs does not rule out neoplasia as a possible cause of myelopathy, because a neoplasm may be associated with rapid decompensation of neural tissue, particularly if vascular factors, such as infarction or hemorrhage, are involved.

193.2.1.3 Physical Examination

The physical examination consists of a series of observations that provide information about the general health of all body systems. The results of this examination supplement the information collected in the history and may implicate involvement of body systems other than the nervous system. For example, an animal suspected of having spinal pain may in fact have abdominal pain. A thorough orthopedic examination should be performed for any dog or cat suspected of having a spinal cord disorder. Particular attention should be paid to examination of the joints. Rupture of anterior cruciate ligaments bilaterally or bilateral patellar luxations may mimic paraparesis caused by a neural disorder.

193.2.1.4 Neurologic Examination

The neurologic examination is an extension of the physical examination. When spinal cord disease is suspected, it is essential to complete a thorough, comprehensive, and unbiased examination of the nervous system. Errors in diagnosis commonly occur when the examiner focuses on only the region of an obvious neurologic deficit and overlooks more subtle alterations in other parts of the nervous system. The objectives of the neurologic examination are to detect any disorder of the nervous system and to determine its location and extent.[4–8]

193.2.1.5 Problem List and Differential Diagnosis

A comprehensive list of problems should be compiled after the physical and neurologic examinations have been completed. All identified problems should be included, even though some may not appear to be directly related to the presenting complaint. A list of the possible causes of each problem should be compiled, with the most probable causes listed first. Ranking of the differential diagnoses is based on the information collected in the history (e.g., signalment, nature of onset and progression of signs) and on the results of the physical and neurologic examinations.

193.2.1.6 Minimum Database

Initial clinicopathologic tests include a complete blood count, blood chemistry profile, and urinalysis. The results of the initial blood and urine tests may support a diagnosis of an infectious or a metabolic or toxic disorder that is either producing or complicating signs of spinal cord dysfunction. Additional diagnostic tests may be required for investigation of disorders suspected on the basis of the results of the initial screening tests. For example, hyperglobulinemia detected in a cat with signs of myelopathy may support completion of a serum feline infectious peritonitis (FIP) virus titer.

Thoracic radiographs should be obtained as part of the minimum database in dogs or cats with a spinal cord disorder. This is especially necessary in older animals, in animals in which abnormalities of cardiovascular or respiratory function are suspected, and in animals in which neoplasia is included on a list of differential diagnoses. Abdominal radiography or ultrasonography should also be performed.

193.2.1.7 Ancillary Diagnostic Investigations

The recommended essential procedures for diagnosis of a myelopathy, in advised order of completion, are noncontrast vertebral radiography, cerebrospinal fluid (CSF) analysis, and myelography. Other procedures, such as electrophysiologic testing or advanced imaging (computed tomography [CT] or magnetic resonance imaging [MRI]), may be added to this list, depending on the nature of the problem investigated.

193.2.1.7.1 Noncontrast vertebral radiography

Noncontrast vertebral radiography is essential to the accurate diagnosis of a disorder affecting the spinal cord.[4–8] Owing to the limitations of a neurologic examination in outlining multiple lesions of the spinal cord and for the purpose of comparison if problems related to other regions of the vertebral column occur in the future, the entire vertebral column must be radiographed. Correct technique, exact positioning, and use of appropriate projections are essential.[9–12] Further diagnostic investigations may be indicated based on the initial interpretation of the noncontrast vertebral radiographs. For example, a finding of discospondylitis may be followed by culture and sensitivity testing of the blood, urine, or an aspirate from an infected disk or by serologic testing for *Brucella canis*. Differentiation of an infectious lesion from a vertebral neoplasm may be difficult on the basis of noncontrast vertebral radiography alone. In such cases, a biopsy, by means of needle aspiration or surgical excision, may be indicated.

193.2.1.7.2 Cerebrospinal fluid analysis

Collection and analysis of the CSF are essential when noncontrast vertebral radiographs do not completely define the location, nature, and extent of a spinal cord disorder.[13] CSF may be collected by means of a cisternal or a lumbar subarachnoid puncture. It has been recommended that CSF be collected from a cisternal site if cervical spinal cord disease is suspected and from a lumbar location if a thoracolumbar disorder is involved. However, a lumbar collection site (most often between the L4 and L5 or L5 and L6 vertebrae) may be used for most dogs or cats with a spinal cord disorder regardless of the suspected location of the problem. Precautions must be taken in the collection of CSF from animals suspected of having increased intracranial pressure.

Analysis of CSF collected from a dog or cat suspected of having a spinal cord disorder should always include a total red blood cell count, total and differential white blood cell (WBC) count, and quantitative estimation of protein content. The results for CSF from normal dogs and cats have been published.[14–17] It should be noted that normal values for CSF collected from lumbar sites differ from those for CSF collected from cisternal sites.[17,18]

843

844

The results of CSF analysis may support further examination of the cerebrospinal fluid, such as bacterial or fungal culture and sensitivity testing, completion of titers, or CSF protein electrophoresis and determination of the immunoglobulin G (IgG) index.[19–21]

193.2.1.7.3

Myelography

Myelography is the radiographic examination of the spinal cord and emerging nerve roots after injection of contrast material into the subarachnoid space. Myelography should be done when the results of noncontrast vertebral radiography and CSF analysis do not fully define a disorder affecting the spinal cord or when spinal surgery is contemplated.[11,12] Patterns of myelographic alteration may be used to differentiate intramedullary, intradural-extramedullary, and extradural space-occupying lesions.[11,12]

Myelography should be considered only if positive findings are essential for diagnosis and prognosis, or to determine a precise site for surgery, because it is a difficult procedure to complete and may have undesirable consequences.[22–24] A lumbar injection site is preferred for dogs or cats with spinal cord disease at any level of the vertebral column. Dynamic radiographic techniques and oblique projections may augment the diagnostic information gained from a myelographic study.

193.2.1.7.4

Electrophysiology

The role of electrophysiologic testing in the diagnosis of spinal cord disease is limited. Abnormal findings on electromyographic (EMG) examination are seen only when the lower motor neurons in the ventral horn of the spinal cord, or their axons in the ventral root are affected by a pathologic process. EMG examination may be performed to define the extent of a lesion affecting the brachial or lumbar enlargement of the spinal cord; the examination maps the distribution of EMG abnormalities caused by denervation and correlates this information with the spinal nerve root origins of the nerves supplying the affected muscles.[1] Electrophysiologic findings may be valuable for defining precisely the location and extent of a spinal cord lesion, because EMG may help distinguish between disuse atrophy and atrophy secondary to denervation.[25,26]

Determination of the sensory or motor nerve conduction velocities of the thoracic or pelvic limbs may aid in the identification of the nerve roots affected by a spinal cord disorder. Spinal cord potentials (cord dorsum potentials) evoked by stimulation of a peripheral sensory nerve may be used, along with the sensory nerve conduction velocities, to determine involvement of sensory nerve roots proximal to the dorsal root ganglia. However, in animals with spinal cord disorders, evoked spinal cord potentials are of limited usefulness for localizing lesions, determining the disease's severity and prognosis, or evaluating the response to therapy.[25,26]

A variety of pressure, flow, and electrophysiologic techniques have been developed to assess the function of the lower urinary tract.[5] Cystometry, profile recording of the urethral closure pressure, electromyography of the urethral sphincter, uroflowmetry, and evoked spinal cord potential measurements after pudendal nerve stimulation have all been investigated in dogs or cats.[5] Combinations of these electrophysiologic tests may provide the information needed about the functional status of spinal cord segments involved in micturition.

193.3 CLINICAL SIGNS OF SPINAL CORD DISEASES

Assessment of an animal's gait and posture, postural reactions, spinal reflexes, cranial nerve function, and state of consciousness is essential in determining whether a spinal cord disease exists, the most likely location or locations of a spinal cord lesion, and whether a focal, multifocal, or disseminated disease process is present that involves the spinal cord and/or other parts of the nervous system.[1]

Five groups of clinical signs are seen to a varying degree in all animals with disease that affects the spinal cord: depression or loss of voluntary movement, alteration of spinal reflexes, changes in muscle tone, muscle atrophy, and sensory dysfunction. Careful assessment of these groups of clinical signs in an animal suspected of having a disease affecting the spinal cord facilitates localization of the lesion and diagnosis. Neurologic disorders that result in either loss of voluntary movement alone or sensory dysfunction alone are unlikely to be spinal cord disorders, because most spinal cord diseases do not affect selected tracts while sparing anatomically adjacent pathways.

Diseases of the spinal cord may also result in dysfunction of the bladder, urethral sphincter, and anal sphincter and in loss of voluntary control of urination and defecation. This may be due to interruption of spinal cord pathways connecting the brain stem and cerebrum to the bladder and rectum that are important in normal detrusor reflex function and voluntary control of micturition and defecation, or it may be due to interruption of the parasympathetic nerve supply to the bladder and urinary and anal sphincters (L7 to S3 spinal cord segments and spinal nerves). Spinal cord diseases also indirectly interferes with excretory functions by impairing the animal's ability to assume the posture necessary for normal defecation or urination.

193.3.1 Voluntary Movement

Loss of voluntary movement as a result of interruption of motor pathways at any point from the cerebrum to the muscle fibers is referred to as *paralysis (plegia)*. Lesser degrees of motor loss are referred to as *paresis*. The terms *tetraplegia* (or *quadriplegia*) and *tetraparesis* (or *quadriparesis*) refer to an absence of voluntary movement in the thoracic and pelvic limbs and to depression of movement in the thoracic and pelvic limbs, respectively. The terms *paraplegia* and *paraparesis* describe the absence of voluntary movement and depression of voluntary movement in only the pelvic limbs. *Hemiplegia* and *hemiparesis* refer to paralysis or motor dysfunction, respectively, of a pelvic limb and a thoracic limb on the same side.

Voluntary movement must be differentiated from reflex movement by means of neurologic examination findings and general observation.

Ataxia (incoordination) is seen in association with paresis and probably occurs as a result of interference with both the ascending and descending spinal cord pathways. Many ascending spinal cord tracts contribute to the transmission of sensory information to the cerebrum for coordination of voluntary movements; however, interference with the spinocerebellar tracts probably causes a large part of the ataxia seen in association with

spinal cord disease in animals. Observation of gait is the only clinical testing technique for assessing these pathways.

193.3.2 Spinal Reflexes

Spinal reflexes are stereotyped involuntary actions that occur independent of brain input and that may be elicited consistently by specific stimuli. The central nervous system (CNS) components of spinal reflex arcs are located entirely in the spinal cord. Disturbance of spinal reflexes occurs in almost all animals with spinal cord disease. A spinal reflex may be normal, depressed *(hyporeflexia)*, absent *(areflexia)*, or exaggerated *(hyper-reflexia)*. Classification of spinal reflexes into one of these categories is helpful for localizing a spinal cord lesion.

Depression of a spinal reflex in association with spinal cord disease most frequently occurs as a result of involvement by a pathologic process of spinal cord segments that mediate the reflex. It must be remembered that involvement of motor nerves arising from or of sensory nerves traveling to such spinal cord segments, or abnormalities of the effector organ (muscle), may also result in depression of spinal reflexes.

844

845

Exaggeration of a spinal reflex in association with spinal cord disease occurs when a lesion affects the spinal cord cranial to segments that mediate a reflex. The neural mechanisms that result in spinal reflex exaggeration are not completely understood. The concept that reflex exaggeration simply results from interruption of descending inhibitory pathways is useful for lesion localization; however, other factors are likely to be involved, such as collateral axonal sprouting or the development of denervation supersensitivity. Exaggeration of a reflex may result from a brain lesion, as well as from a spinal cord lesion.

Spinal cord lesions that affect both gray and white matter may result in depression of spinal reflexes mediated by spinal cord segments involved in a pathologic process and in exaggeration of spinal cord reflexes mediated by spinal cord segments caudal to a lesion. This is useful for lesion localization, particularly lesions that affect the cervical enlargement (C6 to T2 spinal cord segments), where thoracic limb hyporeflexia and pelvic limb hyper-reflexia may be present.

Interpretation of reflex abnormalities must be approached with the knowledge that two (or more) lesions in the same anatomic division of the spinal cord may produce reflex changes identical to those seen with a single lesion. For example, two lesions between the T3 and L3 spinal cord segments cause hyper-reflexia in the pelvic limbs indistinguishable from that resulting from a solitary lesion in this location. Furthermore, hyporeflexia produced by one spinal cord lesion may mask hyper-reflexia that would otherwise result from a second lesion in a more cranial location. For example, a lesion in the lumbar enlargement (L4 to S3 spinal cord segments) causes hyporeflexia in the pelvic limbs that masks the hyper-reflexia that otherwise would result from a second lesion cranial to the L4 spinal cord segment.

Depression of spinal reflexes caudal to a lesion may be seen for several days after spinal cord injury in humans or primates and is called *spinal shock*. Spinal shock may occur in quadrupeds; however, it is too brief to be of clinical significance. Hyporeflexia observed immediately after spinal cord injury should be attributed to damage to spinal cord segments that mediate the reflexes or to other systemic complications (e.g., hypovolemic shock) that frequently accompany spinal cord trauma.

193.3.3 Muscle Tone

Maintenance of normal muscle tone is a function of spinal reflexes (tonic muscle stretch reflexes). Alterations in muscle tone therefore are interpreted in a fashion similar to that for alterations in spinal reflexes described

above. Abnormal muscle tone may be depressed *(hypotonia),* absent *(atonia),* or exaggerated *(hypertonia),* depending on the location of the spinal cord lesion.

193.3.4 Muscle Atrophy

Two types of muscle atrophy may occur in association with a spinal cord disease. *Denervation atrophy* is seen when the lower motor neurons (LMNs) innervating a muscle are damaged by a lesion that affects their spinal cord segment or segments of origin. Denervation atrophy is evident within a week of injury, usually is severe, and is associated with EMG abnormalities. *Disuse atrophy* may be seen in muscles innervated by LMNs caudal to a spinal cord lesion. Disuse atrophy commonly is slower in onset and progression than denervation atrophy, most often is less severe, and usually is not associated with EMG alterations.

193.3.5 Sensory Dysfunction

Abnormalities of sensory (ascending) pathways of the spinal cord contribute to the ataxia of spinal cord disease; however, specific clinical tests of their function do not exist. Perception in animals must be inferred from certain behavioral responses that indicate that ascending sensory signals have reached the cerebral cortex (e.g., aversive response to a noxious stimulus). Interruption of sensory signals at any point between (and including) sensory receptors in the periphery and cerebral cortex may depress or obliterate normal sensory function. Therefore the results of a clinical examination for signs of sensory dysfunction alone may not be of value in localizing a lesion to the spinal cord. However, combined with the results of other parts of a neurologic examination, signs of sensory dysfunction may provide important diagnostic and prognostic information.

Proprioceptive positioning (perception of body position or movement) and pain perception are tested during a neurologic examination. Proprioceptive positioning is a sensitive indicator of spinal cord function, and depression or loss of proprioceptive positioning frequently is the sign first caused by a myelopathy.

Pain perception may be normal, depressed *(hypesthesia),* absent *(anesthesia),* or exaggerated *(hyperesthesia)*. Two types of pain perception may be distinguished in animals. *Cutaneous ("superficial") pain perception* is manifested by a response to pricking or pinching of the skin; *deep pain perception* is manifested by reaction to pinching of the toes or tail across bone with hemostatic forceps. Areas of decreased or absent cutaneous pain perception may aid the identification of specific nerves, nerve roots, and spinal cord segments involved in a pathologic process. This technique of cutaneous mapping is especially useful with lesions that affect the cervical or lumbar enlargements.

Deep pain perception appears to be the sensory function most resistant to a spinal cord disease, and it is the last spinal cord function to disappear in myelopathies of any type. An animal with complete bilateral loss of deep pain perception due to a transverse myelopathy is necessarily paralyzed caudal to the lesion. Loss of deep pain perception, therefore, is a grave prognostic sign.

Hyperesthesia in association with a spinal cord disease may indicate nerve root or spinal nerve involvement, or it may be consistent with meningeal irritation. A focal area of hyperesthesia over the vertebral column may indicate the location of a spinal cord lesion.

193.4 LOCALIZATION OF SPINAL CORD DISEASES

Motor, sensory, reflex, and sphincter abnormalities may help determine the location of a lesion in one of four major longitudinal divisions of the spinal cord: the cervical region (C1 to C5 spinal cord segments), the cervical

enlargement (C6 to T2), the thoracolumbar region (T3 to L3), and the lumbar enlargement (L4 to Cd5). It is essential to remember that these divisions refer to spinal cord segments, not vertebrae, and that spinal cord segments do not correspond exactly with vertebrae of the same number. Some variations may be encountered because of slight differences among animals in segments that form the cervical and lumbar enlargements. The diseases most commonly associated with neurologic signs referable to each of these four regions are listed in Boxes 193-1 to 193-4.

A disorder of any of the four regions of the spinal cord results in a combination of neurologic signs specific for that region.[6] Recognition of these clinical signs allows accurate localization of a spinal cord lesion. The presence of neurologic deficits indicative of involvement of more than one region of the spinal cord is highly suggestive of multifocal or disseminated spinal cord disease.

847

193.4.1 Box • 193-1 Diseases Affecting the Cervical Region (Spinal Cord Segments C1 to C5)*

193.4.1.1 Hereditary/Congenital Causes

Atlantoaxial subluxation

Congenital vertebral anomalies

Spina bifida

Myelodysplasia

Syringomyelia/hydromyelia

Globoid cell leukodystrophy

Hereditary ataxia

Pilonidal sinus/epidermoid cyst/dermoid cyst

Spinal stenosis

193.4.1.2 Degenerative Causes

Intervertebral disk disease

Cervical spondylomyelopathy

Leukoencephalomyelopathy of rottweilers

Neuroaxonal dystrophy of rottweilers

Spondylosis deformans

Dural ossification

Synovial cyst

193.4.1.3 Inflammatory/Infectious Causes

Discospondylitis

Corticosteroid responsive meningitis-arteritis

Granulomatous meningoencephalomyelitis

Distemper myelitis

Feline infectious peritonitis meningitis/myelitis

Bacterial/fungal/rickettsial/protothecal meningitis/myelitis

Protozoal myelitis

Feline polioencephalomyelitis

Spinal nematodiasis

193.4.1.4 Neoplastic Causes

Neoplasia

193.4.1.5 Traumatic Causes

Spinal cord trauma

193.4.1.6 Vascular Causes

Ischemic myelopathy

Progressive hemorrhagic myelomalacia

Hemorrhage

Vascular malformations and benign vascular tumors

Spinal intra-arachnoid cyst

* Common causes are in italics.

The functional differences between upper motor neurons (UMNs) and LMNs may be used to localize lesions to one of the longitudinal regions of the spinal cord. Cell bodies of spinal cord LMNs are located in the spinal cord gray matter. Their axons leave the spinal cord via the ventral nerve roots to become part of a peripheral nerve and terminate in a muscle. The cell bodies of the LMNs of the thoracic limb are in the C6 to T2 spinal cord segments,

which form the cervical enlargement, whereas the LMNs of the pelvic limb arise from the L4 through S1 spinal cord segments of the lumbar enlargement. Anal and urethral sphincter LMNs originate from the S1 through S3 spinal cord segments. Signs of LMN dysfunction, which in diseases affecting the spinal cord reflect damage to the spinal cord segment or segments from which the LMNs originate, include decreased or absent voluntary motor activity; decreased or absent muscle tone; normal, decreased, or absent segmental spinal reflexes; and rapid, severe atrophy of an affected muscle as a result of denervation.

847

848

UMNs arise from cell bodies in the brain. Their axons form the descending pathways of the spinal cord and terminate on interneurons, which in turn synapse with LMNs. Lesions that affect UMNs result in UMN signs, which are the result of an increase in the excitatory state of LMNs. UMN signs include depression or loss of voluntary motor activity, normal or exaggerated segmental spinal reflexes, appearance of abnormal spinal reflexes (e.g., crossed extensor reflex), increased muscle tone, and muscle atrophy as a result of disuse.

Unilateral signs caused by spinal cord disease are unusual; however, signs frequently are asymmetric. In most cases a lesion that results in asymmetric signs is located on the side of the greater motor and sensory deficit.

193.4.5 Cervical Region (C1 to C5 Spinal Cord Segments)

Fatal respiratory paralysis resulting from interruption of descending respiratory motor pathways or damage to motor neurons of the phrenic nerve (C5 to C7 spinal cord segments) occurs in a complete transverse myelopathy. Lesions that are less than complete may not affect respiration, but other signs may be detectable.

Ataxia and paresis of all four limbs usually are seen. Tetraplegia rarely is seen, because lesions severe enough to cause tetraplegia also cause respiratory paralysis. Hemiparesis occasionally may be present in association with a cervical lesion. Lesions of the cervical spinal cord may result in paraparesis with minimal neurologic deficits in the thoracic limbs. The reasons for this are poorly understood.

Spinal reflexes and muscle tone are intact in all limbs and may be normal or exaggerated. Muscle atrophy generally is not present; however, disuse atrophy may develop in disease that has a chronic course. Anal reflexes are intact, and anal tone usually is normal. Bladder dysfunction may occur as a result of detrusor muscle areflexia, with normal or increased urinary sphincter tone and loss of voluntary control of micturition. Reflex dyssynergia may also be seen. Although voluntary control of defecation may be lost, reflex defecation occurs when feces are present in the rectum. Horner's syndrome (ptosis, miosis, and enophthalmos) rarely may be present in an animal with a severe destructive cervical lesion. Proprioceptive positioning and other postural reactions usually are depressed or absent in all limbs. Complete loss of proprioceptive positioning may occur without detectable loss of pain perception.

Cervical hyperesthesia (“spasms,” apparent pain on palpation, cervical rigidity, and abnormal neck posture) may be seen in some animals with cervical myelopathy. It should be noted that apparent cervical pain may also be seen in association with lesions affecting the brain stem and cerebrum. Occasionally an animal may hold a thoracic limb in a partly flexed position, a posture that may be consistent with C1 to C5 nerve root or spinal nerve entrapment *(root signature),* although this posture is seen more commonly with a disorder affecting the cervical enlargement.

Disorders that affect the cervical region of the spinal cord must be differentiated from brain lesions that result in tetraparesis. This may be accomplished with a complete neurologic examination; however, occasionally the distinction may be difficult to make. In most circumstances, a cervical lesion does not result in neurologic deficits attributable to involvement of the medulla oblongata; however, there are several notable exceptions to this rule. Positional strabismus, resulting from loss of the vertebral joint proprioceptive input to the attitudinal

reflexes, may be seen in association with a cranial cervical lesion (C1 to C3 spinal cord segments). A cranial cervical lesion may also cause facial hypesthesia as a result of involvement of the spinal nucleus and tract of the trigeminal nerve. Cranial cervical trauma often results in clinical signs referable to injury of the caudal brain stem (head tilt, pharyngeal paresis, facial paresis) or cerebellum.

The Schiff-Sherrington sign (syndrome or phenomenon), which consists of hypertonicity of thoracic limb muscles and hyperextension of the neck, is seen in association with spinal cord lesions caudal to the cervical enlargement. It is essential to differentiate this sign from thoracic limb hypertonicity caused by a cervical lesion.

193.4.6 Cervical Enlargement (C6 to T2 Spinal Cord Segments)

Ataxia and paresis of all four limbs usually are present with lesions of the cervical enlargement. Occasionally paresis of the thoracic limbs and paralysis of the pelvic limbs may be seen.

Spinal reflexes and muscle tone may be normal or decreased in the thoracic limbs and normal or exaggerated in the pelvic limbs. The nature of thoracic limb reflex alterations depends on the exact craniocaudal location of a lesion in this region. Muscle atrophy often is severe in the thoracic limbs. The panniculus reflex may be depressed or absent unilaterally or bilaterally as a result of interruption of the LMNs involved in this reflex (C8 and T1 spinal cord segments). If bladder dysfunction occurs, it is similar to that observed with a lesion in the cervical region, with loss of voluntary control of urination. Anal reflexes and anal tone most often are normal, although voluntary control of defecation may be absent. Unilateral Horner's syndrome is commonly observed with a spinal cord lesion of the cervical enlargement, particularly a lesion involving the Tl to T3 spinal cord segments or nerve roots.

Proprioceptive positioning and other postural reactions usually are depressed in all four limbs. Alterations in these functions may be more pronounced in the pelvic limbs than the thoracic limbs. Occasionally, proprioceptive positioning is absent only in a thoracic and pelvic limb on the same side. Severe depression or loss of pain perception rarely is seen in association with a lesion of the cervical enlargement, except in intrinsic myelopathies (e.g., ischemic myelopathy). Hyperesthesia at the level of a lesion of the cervical enlargement, thoracic limb lameness, or apparent neck pain may be seen.

193.4.7 Thoracolumbar Region (T3 to L3 Spinal Cord Segments)

Most spinal cord lesions of dogs or cats occur in the thoracolumbar region. Typically the thoracic limb gait is normal, and paresis and ataxia, or paralysis, is seen in the pelvic limbs. The thoracic limb spinal reflexes are normal. Pelvic limb spinal reflexes and muscle tone are normal to exaggerated, depending on the severity of the lesion. Muscle atrophy is not seen in the thoracic limbs. Pelvic limb muscle atrophy, if present, is the result of disuse and is seen in animals with a severe, chronic lesion.

Anal reflexes and anal tone usually are normal or exaggerated. Voluntary control of defecation may be lost. Reflex defecation occurs when the rectum is filled with feces; however, it may not be at an appropriate time or place. The degree of bladder dysfunction varies, depending on the severity of the spinal cord lesion. There may be loss of voluntary control of urination, detrusor muscle areflexia with normal or increased urinary sphincter tone, or reflex dyssynergia, in which initiation of voiding occurs and is stopped by involuntary contraction of the urethral sphincter. The bladder can be manually expressed in some animals, but not others, as a result of increased tone of the urinary bladder sphincter; this is often referred to as a *UMN bladder*. Although “overflow” incontinence may occur with lesions of the spinal cord in this region, secondary to overfilling of the bladder,

detrusor muscle tone and urinary sphincter tone are present, which distinguishes this type of incontinence from that due to lesions of the lumbar enlargement and cauda equina (LMN bladder).

Proprioceptive positioning and other postural reactions are normal in the thoracic limbs and depressed or absent in the pelvic limbs. Pain perception is normal in the thoracic limbs and may be normal, depressed, or absent in the pelvic limbs. The panniculus reflex may be reduced or absent caudal to a lesion. In the lumbar region, the panniculus reflex may be present in lesions caudal to L3 as a result of the pattern of cutaneous innervation of lumbar spinal nerves.[1] There may be an area of hyperesthesia at the level of a lesion. The Schiff-Sherrington sign may be seen with a lesion in the thoracolumbar region. It usually is an indication of an acute, severe spinal cord lesion, although such a lesion may be reversible.

193.4.8 Lumbar Enlargement (L4 to Cd5 Spinal Cord Segments) and Cauda Equina

Involvement of the lumbar enlargement and cauda equina by a pathologic process results in varying degrees of pelvic limb paresis and ataxia, or paralysis, and is often accompanied by dysfunction of the bladder and by paresis or paralysis of the anal sphincter and tail. Thoracic limb function is normal. Pelvic limb reflexes and muscle tone are reduced or absent. Muscle atrophy often is present in the pelvic limbs. Conscious proprioception and other postural reactions may be reduced or absent in the pelvic limbs.

Anal tone and anal reflexes are reduced or absent. The rectum and colon may become distended with feces, and fecal incontinence, with continual leakage of feces, is often seen. Constipation may result from the inability to void feces. Paresis or paralysis of the urethral sphincters and detrusor muscle result in overfilling of the bladder and "overflow" incontinence. Affected animals have a large residual volume of urine in the bladder, and the bladder is easily expressed manually (LMN bladder). The Schiff-Sherrington sign occasionally may be seen with an acute lesion that affects this region of the spinal cord.

The term *cauda equina* is used to describe the lumbar, sacral, and caudal nerve roots and spinal nerves as they extend caudally from the caudal tip (conus medullaris) of the spinal cord in the vertebral canal. Lesions that affect the cauda equina result in clinical signs that are indistinguishable from those produced by lesions affecting the spinal cord segments from which the nerves of the cauda equina arise (L6 to Cd5).

193.5 ALPHABETIC LISTING OF DISEASES

193.5.1 Atlantoaxial Subluxation (Atlantoaxial Instability) and Malformations of the Odontoid Process

193.5.1.1 Etiology and Pathogenesis

Subluxation, instability, or malformation of the atlantoaxial joint that permits excessive flexion of the joint may result in compression of the spinal cord as a result of dorsal displacement of the cranial portion of the body of the axis into the vertebral canal. Such conditions may result from congenital or developmental abnormalities, trauma, or a combination of these factors.[9,10,27,28]

Agenesis or hypoplasia of the dens, nonunion of the dens with the axis, absence of the transverse ligament of the atlas, and dorsal angulation of the odontoid process with compression of the spinal cord have been associated with atlantoaxial instability in dogs.[29,30] Traumatic atlantoaxial luxation may occur in any breed of dog or cat and usually results from rupture of the atlantoaxial ligaments or fracture of the dens at its

junction with the axis. The onset of signs usually is acute and coincides with the trauma, but occasionally it is delayed.

193.5.1.2 Clinical Findings

Congenital or developmental malformations occur most frequently in small dog breeds.[31] Animals with congenital atlantoaxial joint abnormalities usually develop clinical signs during the first year of life. Occasionally a dog with a congenital atlantoaxial abnormality appears normal until trauma occurs at an older age, at which time clinical signs may occur.

Clinical signs associated with congenital atlantoaxial instability may have an acute onset, may be slowly progressive, or may be intermittent. Signs are indicative of a transverse myelopathy between C1 and C5 and vary from mild cervical pain to tetraparesis or tetraplegia and possibly death as a result of respiratory paralysis. Occasionally, signs of brain stem dysfunction may follow an atlantoaxial luxation (e.g., dysphagia, facial paralysis, or vestibular deficits).

Atlanto-occipital luxation results in trauma to the medulla oblongata and clinical signs indicative of a caudal brain stem or cranial cervical spinal cord injury. Severe injuries may result in respiratory paralysis and death.

193.5.1.3 Diagnosis

Atlantoaxial instability is best demonstrated by radiography. Radiographically, the body of the axis is displaced dorsally and cranially into the vertebral canal, and the distance between the dorsal arch of the atlas and the spinous process of the axis is increased. If lateral views are not diagnostic, slight flexion of the head may be necessary. Extreme care must be taken when manipulating an animal suspected of having atlantoaxial instability while it is under anesthesia or during radiography, because flexion of the animal's neck may result in further spinal cord compression. Splinting the animal's neck and head in extension beforehand may help prevent excessive flexion of the head during induction of anesthesia, intubation, and positioning for radiography. Abnormalities of the dens may be seen on ventrodorsal views or slightly oblique lateral views such that the wings of the atlas are not superimposed on the dens (Figure 193-1). An open mouth view may show agenesis, nonunion, or fracture of the dens; however, the degree of cervical flexion required for completion of this view may result in further spinal cord compression. Therefore obtaining an open mouth view usually is not recommended.

Animals with congenital or developmental abnormalities of C2 may have additional vertebral abnormalities, such as shortening of C1 or abnormal atlanto-occipital articulation. Agenesis or malformation of the dens may be an incidental finding and is probably not of clinical significance unless associated with radiographic findings of atlantoaxial instability. However, spinal cord compression associated with hypoplasia of the dens without radiographic evidence of atlantoaxial instability has been reported in a dog. Similarly, abnormal angulation of the dens may cause spinal cord compression. In these cases, myelography or advanced imaging (especially CT) may be necessary to demonstrate spinal cord compression (Figure 193-2).

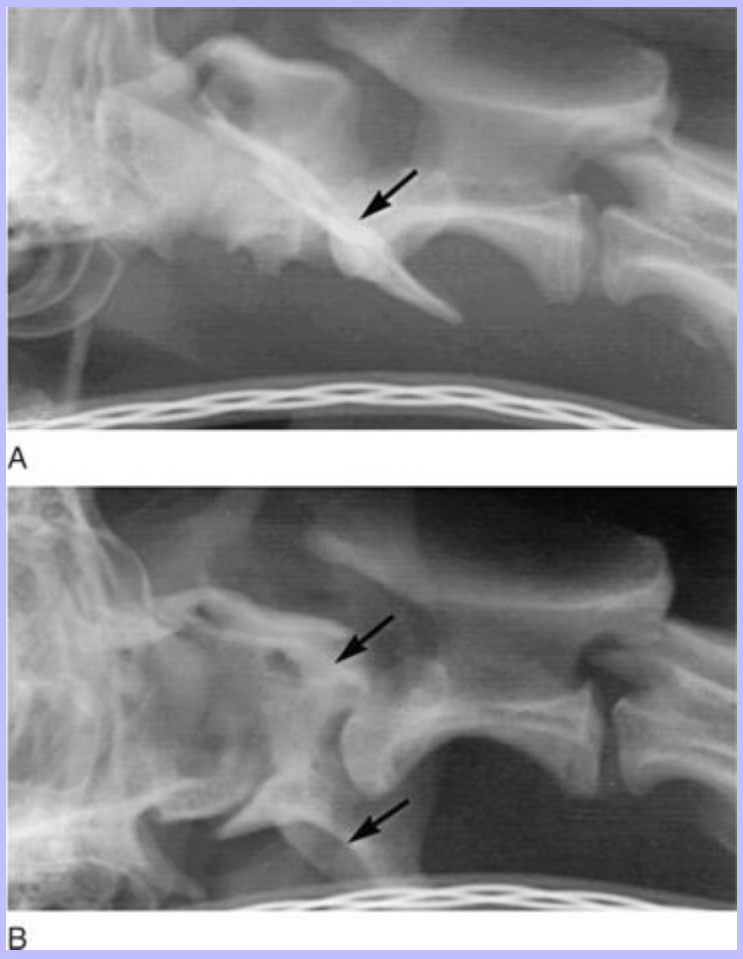
193.5.1.4 Treatment

Animals with an acute onset of neurologic deficits resulting from atlantoaxial instability or traumatic atlanto-occipital luxation should be treated medically, as described for other forms of spinal cord trauma. In addition, the head and neck should be splinted in extension. Animals with mild luxations and cervical pain only or with minimal neurologic deficits, or animals with multiple vertebral abnormalities, such as

atlantoaxial instability and shortening of the body of C1, may respond to splinting of the head and neck in extension and strict cage rest for at least 6 weeks. Casting material or a metal metacarpal splint may be used for this purpose. Care must be taken to ensure that respiration is not compromised. Splinting the head and neck may permit the formation of fibrous tissue to stabilize the atlantoaxial joint and is most successful in small dogs. However, clinical signs may recur.

849
850

Figure 193-1 Atlantoaxial subluxation and agenesis of the dens. Lateral **(A)** and oblique **(B)** radiographs of the cranial cervical vertebrae of a 10-month-old female miniature dachshund that was tetraparetic after a minor trauma. In the lateral projection **(A),** the wings of the atlas are superimposed *(arrow),* obscuring the cranial aspect of the axis. In the oblique projection **(B),** the cranial aspect of the axis is visible because the wings of the atlas *(arrows)* are rotated out of the primary area of interest, and absence of the dens is confirmed.



Surgical stabilization or decompression (or both) is indicated in animals with moderate to severe neurologic deficits or recurrent episodes of neck pain unresponsive to medical therapy or splinting and in animals in which angulation of the dens results in spinal cord compression. Various surgical techniques that use either a dorsal or a ventral approach have been described.[32–34]

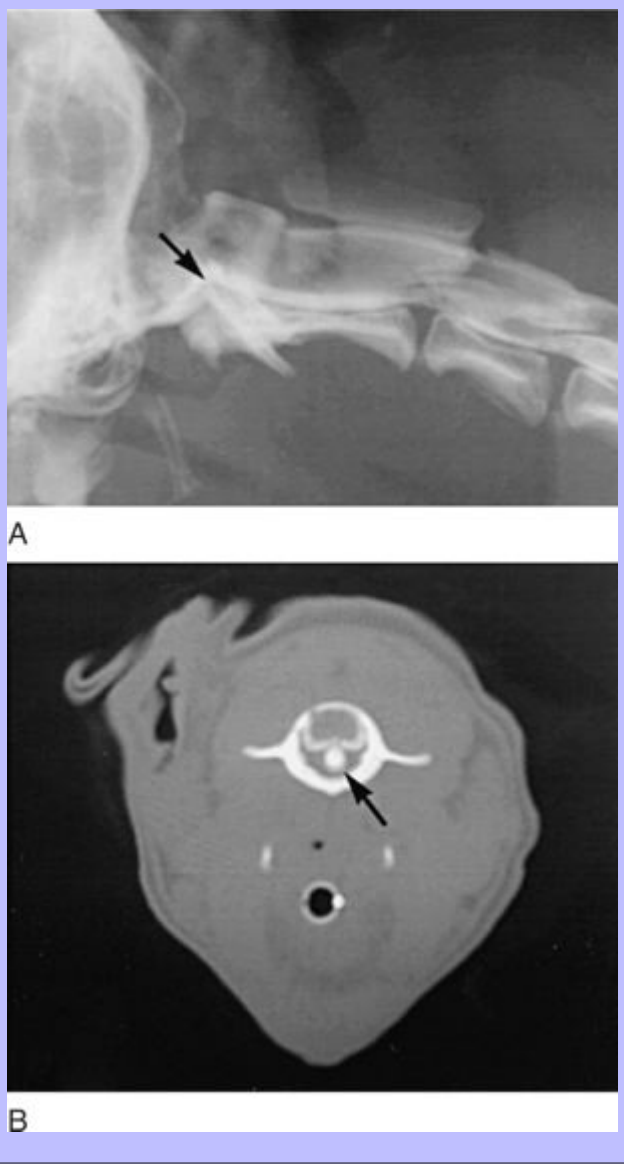
The prognosis for animals with atlantoaxial instability varies, depending on the severity of the spinal cord injury that occurs. The prognosis is fair to good for those with mild to moderate neurologic deficits and guarded for those with an acute onset of tetraplegia.

193.5.2 Bacterial, Fungal, Rickettsial, or Protothecal Meningomyelitis

193.5.2.1 Etiology and Pathogenesis

Dogs and cats are affected infrequently by bacterial or fungal meningitis and/or myelitis.[3–6,35,36] Several routes of infection exist. Direct implantation of organisms may occur with a bite wound, spinal puncture, or surgery or may accompany migration of a foreign body, such as a grass awn. Extension may occur from a focus of infection, such as a paravertebral infection, discospondylitis, or dermoid sinus, or from infection following tail docking. Infection may also result from hematogenous spread of systemic infection (e.g., endocarditis). Because clinical signs produced by bacterial or fungal agents depend more on the neural structures affected than on the agent responsible, these agents are discussed together.

Figure 193-2 Dorsal angulation of the dens. Lateral myelogram **(A)** and transverse computed tomography (CT) image **(B)** taken after myelography of the cranial cervical vertebrae of a 3-year-old male Chihuahua that had an acute onset of tetraparesis and generalized ataxia. The myelogram **(A)** confirms ventral compression of the spinal cord *(arrow)* in the region of the dens. The CT image **(B)** confirms that the dens *(arrow)* is causing compression of the overlying spinal cord.



Meningitis may be accompanied by infection of the underlying parenchyma of the spinal cord (myelitis). Meningitis and/or myelitis may be focal, multifocal, or disseminated in distribution and is frequently accompanied by meningoencephalitis. Pathologically, meningitis is characterized by infiltration of inflammatory cells into the leptomeninges. Inflammation may occur throughout the entire subarachnoid space of the brain and spinal cord. Myelitis is characterized by necrosis and infiltration of inflammatory cells into the spinal cord parenchyma.

Bacteria that have been isolated from cats or dogs with meningitis and myelitis include *Staphylococcus aureus, Staphylococcus epidermidis, Staphylococcus albus,* and *Pasteurella, Actinomyces,* and *Nocardia* spp. Fungal infections have been caused by *Cryptococcus neoformans, Blastomyces dermatitidis, Histoplasma capsulatum,* and *Coccidioides immitis. C. neoformans* is found ubiquitously and frequently causes infection in immunosuppressed animals. Cryptococcosis is more common in cats than in dogs, and infection may result from extension of nasal infection through the cribriform plate. *Blastomyces, Histoplasma,* and *Coccidioides* infections are found in certain geographic areas in the United States, and in such cases the CNS is infected by hematogenous spread.[1]

850
851

Focal epidural infections have been reported to occur, generally as a result of migrating grass awns or penetrating wounds.[37] Proliferation of inflammatory tissue may result in an extradural space-occupying lesion that causes spinal cord compression and clinical signs of a transverse myelopathy.[38] Abscessation may occur within the spinal cord and may have the radiographic appearance of an intramedullary mass.[39]

Rickettsial or protothecal infections may cause meningomyelitis similar in clinical presentation to that resulting from bacterial or fungal infection of the CNS. Ehrlichiosis (*Ehrlichia canis* infection) and Rocky Mountain spotted fever ([RMSF] caused by *Rickettsia rickettsii*) may cause meningo-encephalitis or meningomyelitis in dogs. Rocky Mountain spotted fever is transmitted primarily by two outdoor ticks (*Dermacentor variabilis* and *Dermacentor andersoni*), whereas ehrlichiosis is transmitted by a tick that is frequently found inside houses *(Rhipicephalus sanguineus)*. Acutely, both diseases may induce immune-mediated vasculitis in a variety of tissues, including the CNS. Borreliosis, caused by *Borrelia burgdorferi,* has been reported to occur in dogs and may be expected to cause meningomyelitis, as it does in humans.[40] *Prototheca wickerhamii* and *Prototheca zopfii,* species of ubiquitous, colorless, unicellular algae, have been isolated from pyogranulomatous lesions of the spinal cord and other organs. Protothecosis rarely occurs, and infection may depend on inadequate host immune response.[40]

193.5.2.2 Clinical Findings

193.5.2.2.1 Bacterial or fungal infections

Clinical signs of meningitis include apparent spinal pain, hyperesthesia, and cervical or thoracolumbar rigidity, occasionally manifested as a “sawhorse” posture.[40] Irritation of the numerous nerve endings in the meninges results in reflex muscle spasms when affected animals are stimulated. Fever is intermittent and is more likely to occur in association with concurrent bacteremia or disseminated fungal infection. Fever may occur in association with primary CNS infections as a result of leukocytic pyrogens in the CSF or hypothalamic circulation.

Neurologic deficits are indicative of associated myelitis or radiculitis, and abnormalities depend on the location and extent of infection. Focal myelitis may result in signs of transverse myelopathy.

Disseminated bacterial meningomyelitis often is associated with meningoencephalitis, and clinical signs usually are acute and rapidly progressive. Focal bacterial meningitis and/or myelitis and fungal meningomyelitis may be associated with the development of more slowly progressive clinical signs.

Paraparesis and pelvic limb ataxia are common in animals with cryptococcal meningitis and/or myelitis. Progressive paralysis of a single pelvic limb has been reported in two cats with cryptococcal infection of the lumbar spinal cord. Cats with CNS cryptococcal infections may show an acute onset of clinical signs despite chronic destruction of nervous tissue.

The clinical signs of bacterial or fungal meningitis and myelitis in animals are indistinguishable from those of other causes of meningitis and myelitis, such as granulomatous meningoencephalitis and corticosteroid-responsive meningitis; necrotizing vasculitis of the meningeal arteries and distemper virus myelitis in dogs; and CNS toxoplasmosis and FIP meningomyelitis in cats. The differential diagnosis of meningitis also includes intervertebral disk protrusion (especially in the cervical spine), spinal fracture, discospondylitis, polymyositis, and polyarthritis.

193.5.2.2.2 Rickettsial infections

Central depression is the most consistent clinical finding in dogs with rickettsial infection. Other abnormalities indicative of spinal cord and/or meningeal involvement include paraparesis, tetraparesis, ataxia, and generalized or localized hyperesthesia.[41,42] Cervical rigidity and apparent pain may occur in animals with RMSF.[1] Neurologic abnormalities indicative of cerebral involvement include vestibular disturbances, seizures, cerebellar abnormalities, and coma. Other clinical signs that occur in dogs with rickettsial infections include listlessness, depression, fever, anorexia, lymphadenopathy, dyspnea, diarrhea, vomiting, hemorrhagic diathesis, and joint pain. Dogs of all ages may be infected, and the clinical signs are often indistinguishable from those of systemic viral infections (especially canine distemper), septicemia, and immune-mediated disorders.

193.5.2.2.3 Protothecal infections

Clinical signs reported in dogs with CNS protothecosis have included ataxia, circling, and paresis or paralysis. Only the cutaneous form of this disease has been reported in cats.[40]

193.5.2.3 Diagnosis

193.5.2.3.1 Bacterial or fungal infections

A diagnosis of bacterial or fungal meningitis and/or myelitis is made on the basis of the results of CSF analysis and isolation of a causative organism by culture of CSF. Clinical signs may reflect meningeal irritation or myelopathy that may be indistinguishable from signs caused by other, noninfectious myelopathies, such as intervertebral disk disease. The presence of fever or an abnormal hemogram cannot be relied upon for diagnosis of meningitis/myelitis, because neither may be seen in affected animals.

Bacterial or fungal meningitis has been reported to result in moderate to severe CSF pleocytosis that reflects the degree of leptomeningeal or ependymal involvement.[13] A finding of more than 5000 WBCs/μL may be noted in some cases. Polymorphonuclear (PMN) cells predominate. Mixed mononuclear and PMN pleocytosis occurs with fungal meningitis, and eosinophils may be present,

especially in cases of cryptococcal meningitis. The CSF appears turbid if the cell count is greater than 500 WBCs/μL. Disseminated bacterial meningomyelitis is rarely recognized antemortem in dogs or cats. Focal bacterial epidural, meningeal, or parenchymal infections more commonly occur.

CSF protein may be moderately to markedly increased as a result of increased capillary permeability and leakage of serum proteins into the CSF and probably also owing to local production of immunoglobulins.[13,43] If the CSF protein content is high, fibrin clots may develop. The CSF pressure is usually normal but occasionally is increased, especially in animals with cryptococcal meningitis. Hemorrhage into the CSF may occur; a red or pink supernatant is indicative of recent hemorrhage. Xanthochromia develops if more than 48 hours have elapsed since the hemorrhage. The CSF glucose content (normally 60% to 80% of a simultaneously determined plasma glucose concentration) may be decreased as a result of glucose utilization by micro-organisms and possibly by PMN leukocytes. However, a low CSF glucose concentration is not a consistent finding in animals with bacterial meningitis.

Bacteria or fungal organisms may be identified by staining (i.e., Gram stain or acridine orange) of sedimented or centrifuged CSF. Cryptococcal organisms often are observed in cell preparations of CSF and can be identified with Wright's stain or Gram stain or by use of a wet mount preparation with India ink.

CSF from all animals with CSF abnormalities consistent with meningitis should be submitted for both aerobic and anaerobic bacterial culture and for antibiotic sensitivity testing of any cultured bacterial isolates. CSF fungal culture may also be performed. Negative CSF culture results are common, even in animals in which bacteria or fungal organisms have been identified in the cerebrospinal fluid. Culturing the sediment of centrifuged CSF or filtering CSF and culturing the filter may increase the likelihood of obtaining a positive CSF culture. Causative organisms may be isolated from blood cultures of animals that are bacteremic or that have a systemic fungal infection. *Histoplasma* organisms may be found in buffy coat or bone marrow neutrophils or monocytes. A large volume of CSF (preferably 2 or 3 mL) should be collected for bacterial and/or fungal culture. If a delay in processing of a CSF sample is anticipated, CSF may be aseptically inoculated into a blood culture bottle for submission to a diagnostic laboratory.

851 852

Serology may also be useful in the diagnosis of CNS fungal infections. The titer of antibody-coated latex agglutination to cryptococcal (capsular) antigen may be useful in supporting a diagnosis of cryptococcal meningitis and in assessing the response to therapy. The latex cryptococcal agglutination titer (LCAT) is more sensitive than the indirect fluorescent antibody test and may be used on CSF. However, animals with a localized CNS infection may have a negative titer.[44]

Focal epidural inflammatory lesions may appear as an extradural mass on myelography. Chronic focal meningitis may result in obstruction of CSF flow and blockage of contrast material on myelography as a result of arachnoid adhesions.

193.5.2.3.2 Rickettsial infections

The characteristic histopathologic lesions of RMSF are necrotizing vasculitis, perivascular accumulation of PMN cells, and lymphoreticular cell infiltration into most tissues of the body, including the meninges and CNS. The histopathologic lesion in canine ehrlichiosis is generalized lymphoid and plasma cell accumulation in the bone marrow, meninges, kidneys, and other organs. The results of CSF analysis of dogs with RMSF may be normal or may show a mild increase in protein (less than 60 mg/dL) and nucleated cells (fewer than 80cells/μL) with lymphocytes the predominant cell type. Currently, little

information is available on the expected CSF findings in animals with ehrlichiosis. In one reported case, the CSF protein and nucleated cell levels were increased, with lymphocytes the predominant cell type. Diagnosis of both diseases is based on serology.[45]

193.5.2.3.3 Protothecal infections

Neutrophilic or eosinophilic leukocytes often are increased in the CSF of animals with protothecosis. Culture of CSF on fungal media may result in isolation of the organism. Rectal scrapings should also be performed. Fluorescent antibody examination may demonstrate the organism in tissue sections.[40]

193.5.2.4 Treatment

193.5.2.4.1 Bacterial infections

In the treatment of bacterial meningitis and/or myelitis, it is desirable to use an antimicrobial that is specific for the causative organism and that crosses the blood-brain barrier (or the blood–spinal cord barrier) in therapeutic concentrations, so that drug concentrations may be maintained after the acute phase of inflammation has subsided[46] (Box 193-5). The blood-brain, blood-spinal cord, and blood–spinal fluid barriers are most permeable to antimicrobials with high lipid solubility, low ionization potential, and low protein-binding affinity.[41,46,47] Antibiotics may be administered to animals suspected of having bacterial meningitis before the results of culture and sensitivity testing have been obtained. The selection of antibiotic should be based on tentative organism identification (by Gram or acridine orange staining) from the CSF, the suspected source of infection, and on the drug's ability to reach effective tissue concentrations in the CNS. High-dose intravenous therapy with a bactericidal drug should be used when possible, although many bactericidal drugs penetrate the CSF poorly. Penicillin and penicillin derivatives in high doses have been recommended for the treatment of CNS infections caused by gram-positive cocci (e.g., penicillin G, 10,000 to 20,000 U/lb given intravenously every 6 hours for at least 7 days). Oxacillin may be used for the treatment of meningitis caused by penicillin-resistant *Staphylococcus* strains (Box 193-5).

Clindamycin

First-generation cephalosporins

From Gormley WB et al: Cranial and intracranial bacterial infections. *In* Youmans JR (ed): Neurological Surgery, 4th ed. Philadelphia, WB Saunders, 1996, p 3191.

Most cephalosporins penetrate the CNS poorly.[48] Several third-generation cephalosporins (e.g., cefotaxime) reach effective CNS concentrations and are considered the drugs best suited for treatment of gram-negative meningitis. First-and second-generation[48,49] cephalosporins do not reach effective CSF concentrations and should not be used in the treatment of CNS infections.

Metronidazole is useful for the treatment of most anaerobic infections, is bactericidal, and diffuses well into all tissues, including the CNS.[50] Metronidazole has played an increasingly greater role in the therapy of brain abscesses of humans and is used in combination with high doses of penicillin when aerobes are present. Toxicity (central vestibular signs and cerebellar dysfunction) has been reported in dogs treated with metronidazole.[51] Chloramphenicol reaches higher CSF concentrations than most other antibiotics; however, it is bacteriostatic, and many *Staphylococcus* strains have been shown to be resistant to this drug.[52] Most sulfonamides penetrate the CSF effectively. Sulfadiazine (which is less protein bound than other sulfonamides) penetrates the CSF and nervous tissue better than sulfamethoxazole and is effective if given orally. Data are not available on the concentration of trimethoprim in the CSF of dogs.

852
853

Intrathecal administration of antibiotics has been used in humans. Although its use is possible in dogs or cats, multiple CSF punctures, each requiring anesthesia, are needed. Some drugs are toxic when introduced directly into the CNS (e.g., penicillin may cause seizures), and drugs may not diffuse freely through the cerebrospinal fluid, especially if CSF flow is blocked.

Treatment with antibiotics should be started as soon as possible after submission of CSF for culture. After the results of culture and sensitivity are known, therapy may be altered. Treatment is continued for 4 to 6 weeks; however, treatment for longer periods often is necessary, and relapses are possible. It is also important to identify possible sources of infection outside the CNS (e.g., endocarditis, discospondylitis, and paravertebral abscess). Localized spinal cord or meningeal infections that are well encapsulated may be resistant to antibiotic therapy. Surgical exploration is indicated if focal meningeal or epidural infection refractory to medical therapy is suspected.

Use of corticosteroids in cases of bacterial meningitis and myelitis is controversial. Corticosteroids may reduce inflammation and thereby decrease the resulting spinal cord and nerve root damage; however, such treatment may also decrease host defense mechanisms, resulting in worsening of clinical signs and a higher incidence of relapse.

The prognosis in cases of bacterial meningitis and myelitis depends both on the ability to eliminate the causative organism and on the extent of neurologic deficits. Neurologic deficits that occur as a result of spinal cord or nerve root inflammation may be permanent.

193.5.2.4.2

Fungal infections

Fungal infection of the CNS of dogs or cats is extremely difficult to eliminate.[40,41] The disease is often multisystemic and is seldom recognized in the early stages of CNS involvement. Amphotericin B is frequently used to treat systemic fungal infections, although it is poorly absorbed into the CSF and nervous tissue. Intrathecal administration of amphotericin B has been recommended, especially in animals with *C. immitis* meningitis, but it may result in arachnoiditis and cranial nerve toxicity.

Combinations of drugs have been recommended. Amphotericin B, ketoconazole (poor CNS penetration), and flucytosine (good CNS penetration) are the main agents used. Rifampin has been used to enhance amphotericin B activity. Combined treatment with amphotericin B and 5-fluorocytosine (5-FU) has been recommended for use in cases of cryptococcosis. Long-term, high-dose ketoconazole therapy is reported to be effective for treatment of cryptococcosis in cats.[53] Sequential LCAT determinations may provide a quantitative indication of the clinical response to treatment of cryptococcosis.[44,54]

Because obtaining therapeutic concentrations of antifungal agents in nervous tissue is difficult, the prognosis for CNS mycotic infections is poor.[55] Newer generation azole antifungal agents (e.g., fluconazole, itraconazole) are currently under investigation for treatment of fungal infections of the CNS.[56–60]

193.5.2.4.3

Rickettsial infections

Rickettsial organisms appear to be extremely sensitive to tetracyclines (10 mg/lb given orally three times a day for 14 days).[40] Tetracyclines are bacteriostatic, and elimination of the organisms from the body

depends on the immunocompetence of the affected animal. Doxycycline has better CNS penetration than oxytetracycline or tetracycline and is used in animals with meningitis or myelitis resulting from RMSF or ehrlichiosis. Chloramphenicol, rather than tetracycline, is used to treat young dogs prior to the eruption of permanent teeth. Severely affected dogs, especially those with neurologic involvement, may die despite therapy. Neurologic deficits may be permanent in affected dogs. Recovery may be prolonged, and pancytopenia persistent, in dogs with chronic ehrlichiosis.

193.5.2.4.4 Protothecal infections

Treatment of cutaneous protothecosis in a dog with a 6-month course of oral ketoconazole has been reported.[61] Effective therapy for disseminated proto-thecosis has not been described.

193.5.3 Calcinosis Circumscripta

Calcinosis circumscripta is usually an idiopathic condition that results in circumscribed single or multiple calcium deposits, often in periarticular connective tissue.[62] It occurs mainly in young dogs of large breeds, with an apparently high incidence in German shepherds.[63–65] The clinical signs of spinal cord compression caused by these slow-growing deposits vary, depending on the location of the mass. The diagnosis is made on the basis of radiography. Myelography usually reveals a solitary, rounded, mineralized mass dorsal to the spinal cord that results in extradural spinal cord compression (Figure 193-3). Advanced imaging (CT or MRI) may further delineate the extent of mass lesions. Complete surgical removal of the mass provides long-term resolution of clinical signs.[62–64]

193.5.4 Cervical Spondylomyelopathy

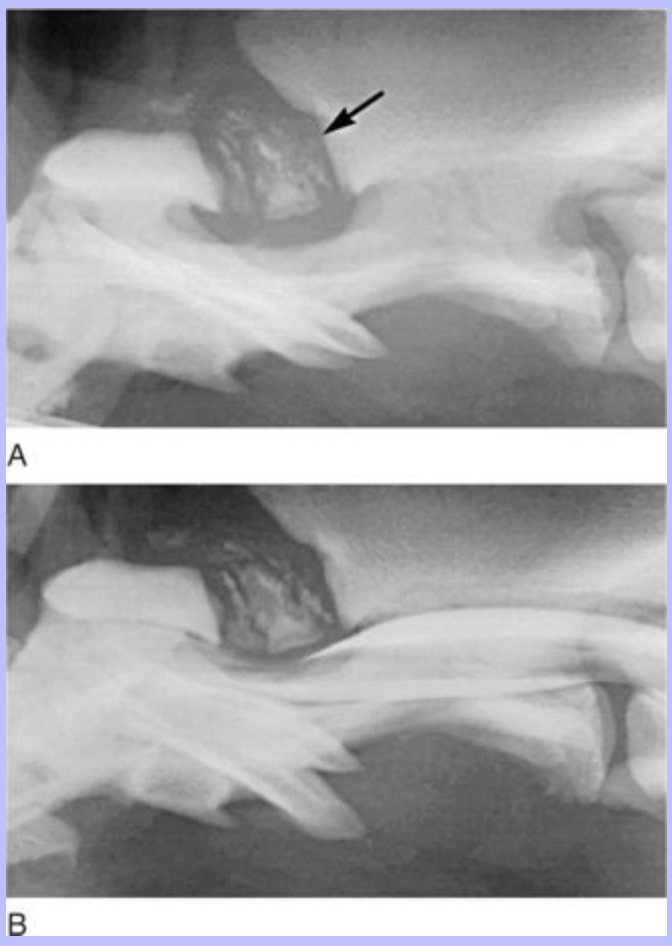
193.5.4.1 Etiology and Pathogenesis

Several terms have been used to describe this disease of the cervical vertebral column of Great Danes, Doberman pinschers, and other large breed dogs.[66–71] These terms include *wobbler syndrome, caudal cervical malformation-malarticulation, cervical spondylopathy, cervical vertebral instability,* and *cervical vertebral stenosis*. The term *wobbler* is nonspecific; it describes a dog with generalized ataxia and tetraparesis that may be seen with a variety of cervical myelopathies. The number of different terms that have been used reflects the many unanswered questions that remain regarding the etiology and pathogenesis of this condition. The term *cervical spondylomyelopathy* accurately reflects the complexity of the syndrome and therefore has become widely accepted. Although the etiology remains undetermined, the high incidence of the syndrome in certain dog breeds suggests that heredity is a contributing factor. Osteochondrosis resulting from overnutrition and rapid growth may also be a factor.[66–71] In humans, stenosis of the vertebral canal may be clinically “silent” as long as it is not complicated by other factors, such as vertebral instability or intervertebral disk protrusion.

853

854

Figure 193-3 Calcinosis circumscripta. Lateral radiograph **(A)** and myelogram **(B)** of the cranial cervical vertebrae of a 10-month-old neutered male German shepherd with signs of worsening tetraparesis and generalized ataxia. The radiograph **(A)** confirms a focal area of soft tissue mineralization between the dorsal arch of C1 and the spinous process of C2 *(arrow)*. The myelogram **(B)** shows dorsal spinal cord compression caused by this mass.



Vertebral instability, either alone or in combination with vertebral malformation and/or soft tissue stenosis, has been suggested as an initiating cause of spinal cord compression and associated neurologic abnormalities.[68] The histopathologic alterations seen in the spinal cord are characteristic of chronic compression and usually involve both white and gray matter. White matter degeneration is noted in tracts cranial and caudal to the level of focal compression. Myelin degeneration appears to predominate over axonal degeneration.

Cervical spondylomyelopathy occurs most frequently in young Great Danes (less than 2 years of age) and middle-aged or older Doberman pinschers (3 to 9 years of age).[66–71] Other breeds that have been reported to be affected are the Saint Bernard, weimaraner, Labrador retriever, German shepherd, boxer, basset hound, Rhodesian ridgeback, Dalmatian, Samoyed, Old English sheepdog, and bull mastiff. Males appear to be affected more often than females. The C5–C6 and C6–C7 vertebrae and disks appear to be affected most commonly, although alterations consistent with a diagnosis of cervical spondylomyelopathy may be seen at the level of C4–C5 and less frequently at C3–C4. Spinal cord compression may be present at more than one site in the cervical spine. Stenosis of the vertebral canal of basset hounds has been reported to occur at C2–C3. Although the lesions seen in all breeds of dogs of all age groups are similar, certain pathologic changes are more characteristic of each particular group. Younger Great Danes frequently have dorsal spinal cord compression as a result of elongation of the cranial aspect of the dorsal arch of affected vertebrae. Older Doberman pinschers frequently have severe ventral spinal cord compression centered over the anulus fibrosus of the affected intervertebral disk.

193.5.4.2 Clinical Findings

The clinical signs reflect chronic compression of the cervical spinal cord. These signs are most often gradually progressive over several months or years; however, they sometimes may develop acutely, perhaps after an apparently insignificant traumatic episode. Gait deficits are frequently noted initially in the pelvic limbs. A mild pelvic limb ataxia progresses in severity until a wide-based, crouching stance and dragging or knuckling of the toes of the pelvic limbs may be seen. Abnormalities may be more easily observed when an affected dog rises from a lying position, turns, or negotiates stairs or a curb.

Neurologic abnormalities that may be noted in the pelvic limbs include depression or loss of proprioceptive positioning reactions and exaggerated spinal reflexes. Thoracic limb abnormalities most often occur after the development of neurologic deficits in the pelvic limbs, and thoracic limb deficits seldom progress to the level of severity of the pelvic limb abnormalities. Thoracic limb deficits usually are mild and may be evident only during intensive evaluation of postural reactions, particularly thoracic limb hopping reactions. Neurogenic atrophy of the supraspinatus or infraspinatus muscles may be detected; however, widespread LMN involvement in the thoracic limbs is rarely seen. In dogs with a chronic course, a stiff, “choppy” thoracic limb gait may be seen, often in combination with a rigid flexion of the neck. Although affected dogs may resist extension of the neck, apparent neck pain, as seen frequently with an acute cervical disk protrusion, seldom is elicitable.

193.5.4.3 Diagnosis

Radiography is the most accurate means of delineating the pathologic alterations of cervical spondylomyelopathy.[72,73] A diagnosis of cervical vertebral canal stenosis has been made on the basis of noncontrast lateral radiographs of the cervical spine; however, numerous studies have emphasized that noncontrast radiographs of the cervical spine may be normal in affected dogs. Abnormalities that may be present on noncontrast radiographs include malalignment of vertebrae, remodeling of vertebrae with cranial stenosis of the vertebral canal, new bone formation (spondylosis deformans), narrowing or collapse of one or more intervertebral disk spaces, calcification of the nucleus pulposus of one or more intervertebral disks, sclerosis of vertebral endplates, and degenerative changes of vertebral articular facets. It is important to note that features such as vertebral remodeling with spondylosis deformans, narrowing of intervertebral disk spaces, and asymmetry of articular facets may not be associated with clinically significant vertebral canal

stenosis. “Tilting” of adjacent vertebrae, which may be apparent on plain spinal radiographs, may be within normal limits.

Myelography is essential for determining the location or locations, nature, and extent of spinal cord compression. Myelographic findings are essential in the consideration of treatment options and any surgical repair that is to be attempted. The importance of ventrodorsal projections in defining lateral spinal cord compression, and that of dynamic or “stressed” radiographs in outlining dorsal spinal cord compression, in combination with myelography, has been emphasized by several authors. Lateral and ventrodorsal “traction” radiographs are recommended as a method of showing the dynamic nature of a lesion.[68–71]

The myelographic abnormality most frequently recognized in Doberman pinschers is ventral spinal cord compression resulting from a hypertrophied, hyperplastic, or “redundant” dorsal anulus fibrosus. Other findings include dorsal spinal cord compression resulting from hypertrophied or hyperplastic ligamentum flavum, dorsolateral spinal cord compression resulting from malformed articular processes, and spinal cord compression resulting from malformed or malaligned vertebrae.

Dynamic or “stress” radiography, after myelography, may be of value in demonstrating instability, ventral spinal cord compression as a result of dorsally protruding intervertebral disks, or dorsal spinal cord compression as a result of ventrally protruding interarcuate ligament or joint capsule. A dorsal extended view is appropriate for demonstrating dorsal spinal cord compression due to interarcuate ligament hypertrophy/hyperplasia. It has been reported, however, that routine use of “stressed” views is not warranted because of the possibility of misinterpretation of alterations and because of the risk of further injury to a spinal cord that may already be severely compromised.

“Traction” radiography, for which firm traction is placed on the cervical spine during exposure of a lateral or ventrodorsal radiograph, may further delineate the dynamic nature of a lesion. With this technique, spinal cord compression resulting from “redundant” or protruding anulus fibrosus may be relieved by the procedure. Failure to relieve the compression with “traction” may indicate a static lesion, such as a disk protrusion. It should be noted that “traction” may relieve the compression evident on lateral radiographs, whereas the lateral compression seen on ventrodorsal radiographs may remain. “Traction” views in both the lateral and ventrodorsal projections are recommended after myelography, because they do not appear to increase spinal cord compression and they provide useful information for the selection of an appropriate surgical technique.

854
855

Advanced imaging modalities (e.g., CT or MRI) may be useful for further defining the nature and extent of spinal cord and nerve root involvement in caudal cervical spondylo-myelopathy and for differentiating this condition from other causes of caudal cervical spinal cord compression.[74]

193.5.4.4 Treatment

Numerous regimens have been recommended for the management of dogs with cervical spondylomyelopathy.[66–78] Treatment is directed toward relief of clinical signs through medical therapy and management practices or toward surgical relief of spinal cord compression. The large number of recommended treatments reflects the variety of lesions demonstrated by various diagnostic techniques, the variable results achieved by investigators, and the personal bias of individual surgeons. In most dogs the disease course is chronic and progressive, and the prognosis, in the absence of treatment, is guarded to poor.

Medical therapy consists of the use of anti-inflammatory medications and management procedures that reduce neck movement, such as close confinement or use of a neck brace.[68–71] Some affected dogs may be maintained at an acceptable level of neurologic function for months to years with corticosteroid administration. In some dogs, corticosteroid therapy may be discontinued during periods of improved neurologic function and re-established during periods of relapse of neurologic abnormalities. The adverse effects of long-term corticosteroid therapy must be considered, and it must be remembered that in most cases, this approach does not address the underlying sustained spinal cord compression.

Techniques for surgical management attempt to correct the underlying spinal cord compression.[66–82] The high potential for morbidity and postoperative complications associated with surgical management of cervical spondylomyelopathy must be considered before surgery is recommended. These considerations must be balanced against the current knowledge of the natural progression of the disease. Surgical procedures may use either a dorsal or a ventral approach to the vertebral column. The primary objective of all surgical procedures is decompression of the spinal cord or stabilization of affected vertebrae, or both.

The prognosis for dogs with cervical spondylomyelopathy is difficult to determine. In general, medical therapy may be expected to provide clinical improvement for a variable period (weeks to years). Medical therapy does not alter sustained and often progressive spinal cord compression. Surgical therapy that relieves spinal cord compression may be associated with postoperative complications; however, the following statements may be made: (1) The prognosis for dogs with a chronic history of worsening signs is not as favorable as for dogs with an acute onset of signs; (2) mildly affected dogs have a fair prognosis for recovery; (3) dogs with a single level of compression appear to have a better prognosis after surgery than those with multiple-level compressions; (4) long-term follow-up of dogs treated by fusion reveals that up to 19% of dogs develop spinal cord compression at an adjacent interspace an average of 20 months after surgery.[83]

Overall, the prognosis for long-term resolution of clinical signs must be considered guarded, regardless of the type of therapy.

193.5.5 Congenital Vertebral Anomalies

193.5.5.1 Etiology and Pathogenesis

Vertebral anomalies frequently occur in cats or dogs as a result of disturbances in embryonic development.[31,84,85] Most such anomalies are not clinically significant. If a vertebral anomaly causes instability or deformity of the vertebral canal, or spinal cord or nerve root compression, clinical signs may result. Multiple spinal anomalies may occur in a single dog or cat.

The most frequently recognized vertebral anomalies are alteration in location of the anticlinal vertebrae, anomalies of articular processes, variations in numbers of vertebrae, transitional vertebrae, butterfly vertebrae, block vertebrae, nonfusion of sacral vertebrae, or hemivertebrae. Of these anomalies, hemivertebrae are the most significant as a cause of neurologic abnormalities.[31]

193.5.5.1.1 Hemivertebrae

Hemivertebrae are wedge shaped, and the apex may be directed dorsally, ventrally, or medially across the midline.[31] Hemivertebrae may be associated with moderate to severe angulation of the spine and may be displaced dorsally during growth by pressure from adjacent vertebrae. Hemivertebrae occur most commonly in the thoracic spine of "screw-tailed" brachycephalic breeds (French and English bulldogs, pugs, and Boston terriers), but they may occur at any location in any breed of dog. Thoracic hemivertebrae are the development of caudal hemivertebrae. Kyphosis, scoliosis, and lordosis are commonly associated with hemivertebrae.

193.5.5.1.2 Block vertebrae

Block vertebrae may involve the vertebral bodies, vertebral arches, dorsal spinous processes, or entire vertebrae, at any level of the vertebral column. The sacrum is considered a "normal" block vertebra. Block vertebrae may be the same length as the number of involved vertebrae or shorter and can result in abnormal angulation of the spine. Partial "blockage" of vertebral bodies may occur, allowing partial development of an intervertebral disk.

193.5.5.1.3 Butterfly vertebrae

Butterfly vertebrae result from persistence of the notochord. In some instances, sagittal cleavage of the notochord may result in a sagittal cleft dorsoventrally through the vertebral body. On a dorsoventral radiograph, such vertebrae resemble a butterfly with wings spread. Compensatory growth of the adjacent normal vertebrae often fills in the funnel-shaped depression of the vertebral endplates. Butterfly vertebrae are most commonly seen in brachycephalic "screw-tailed" breeds.

193.5.5.1.4 Transitional vertebrae

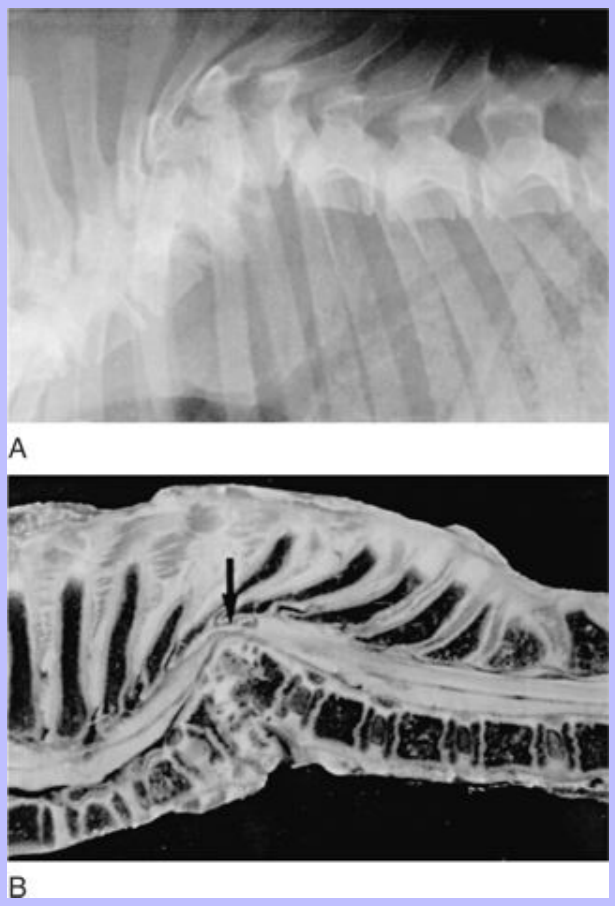
Dogs may have variations in the number of cervical, thoracic, lumbar, or sacral vertebrae. Furthermore, congenital absence or alteration in the shape of vertebral articular processes and variation in the location of the anticlinal (usually T11) and diaphragmatic (usually T10) vertebrae may occur. Vertebrae that have the characteristics of two major divisions of the vertebral column are referred to as *transitional vertebrae*. Observed alterations include transverse processes of C7 resembling a rib, a transverse process on the most caudal thoracic vertebra in place of a rib, the first sacral vertebra having a transverse process, and the last lumbar vertebra having a transverse process that has fused with the ilium. These alterations may be accompanied by an alteration in the size and shape of the vertebral body or in the plane of the vertebral body or intervertebral disk.

193.5.5.2 Clinical Findings, Diagnosis, and Treatment

Congenital vertebral anomalies frequently occur; however, clinical signs related to anomalous vertebrae are not present in most affected animals. In most animals in which clinical signs develop, trauma to the spinal cord has occurred secondary to vertebral instability or progressive deformity with growth. Diagnosis of a vertebral anomaly is made using radiographs of the vertebral column (Figure 193-4). Radiographically, hemivertebrae and adjacent vertebrae appear to be formed of normal bone, and disk spaces are usually normal or widened. Vertebral bodies appear to have a portion absent and do not appear to be compressed.

Adjacent vertebrae frequently have an altered shape that conforms to the defect found in the congenitally affected segment. Vertebral endplates are smooth and of normal thickness. Hemivertebrae should be differentiated from vertebral compression caused by a traumatic fracture, pathologic fracture as a result of vertebral neoplasia, or osteomyelitis. In most cases myelography is necessary to detect spinal cord compression resulting from a congenital anomaly. Advanced imaging (CT or MRI) may be useful in further defining the extent of vertebral and spinal cord involvement. Vertebral anomalies resulting in spinal cord compression and instability of the vertebral column may be treated through surgical decompression, vertebral realignment, and stabilization.[86]

Figure 193-4 Hemivertebrae. Lateral radiograph **(A)** of the midthoracic region of the vertebral column of a 3-month-old male malamute that had a history of inability to use the pelvic limbs since birth. Pain perception was absent in the pelvic limbs. Note the kyphosis associated with hemivertebrae affecting three midthoracic vertebrae. Severe spinal cord compression *(arrow)* is seen in a gross necropsy specimen **(B)** of the vertebral column sectioned in the midsagittal plane.



193.5.6 Corticosteroid-Responsive Meningitis-Arteritis

193.5.6.1 Etiology and Pathogenesis

Corticosteroid-responsive meningitis-arteritis, which occurs in young, medium to large breed dogs, may be the most frequently occurring form of meningitis.[87–89] The etiology is unknown; however, immunopathologic mechanisms are suspected, because IgA seems to play a central role in the pathogenesis.[21,90–92] It has been suggested that repeated vaccinations with multivalent modified live vaccines may be a cause. The clinical and clinicopathologic findings associated with this disease are similar to those seen in dogs with necrotizing vasculitis of the spinal meningeal arteries.[49,93–98]

193.5.6.2 Clinical Findings

Affected dogs are usually 7 to 16 months of age. Clinical signs include reluctance to move, arched back, stiff gait, apparent cervical and/or thoracolumbar pain, fever, muscle rigidity or spasms, apparent pain on opening the mouth and, less commonly, neurologic deficits, such as decreased proprioceptive positioning, paraparesis, or tetraparesis. Optic neuritis has been reported in an affected animal.[87] The clinical signs are indistinguishable from those of meningitis and myelitis of other causes (bacterial, fungal, viral) and from necrotizing vasculitis of spinal meningeal arteries. Clinical signs may be acute in onset and progressive, or they may follow a waxing and waning course over a period of weeks or months.

193.5.6.3 Diagnosis

The diagnosis is made on the basis of increased white blood cells in the CSF, failure to isolate an infectious agent from the CSF, and response to therapy with corticosteroids. Most affected dogs may have a mature neutrophilia in peripheral blood. The WBC count of the cerebrospinal fluid may be normal or may range from 50 to more than 3000 cells/μL, with predominantly mature neutrophils. Neither bacteria nor fungi are seen in the white blood cells. The CSF protein concentration most often is increased (40 to 350 mg/dL). Bacterial (aerobic and anaerobic) and fungal cultures of the CSF, urine, and blood are negative. It may be difficult to differentiate this disease from granulomatous meningoencephalomyelitis on the basis of CSF analysis. Examination of the IgG index and the IgM and IgA contents of the CSF may be useful in distinguishing corticosteroid-responsive meningitis from other causes of meningitis, such as chronic distemper encephalitis or granulomatous meningoencephalitis of dogs.[21]

193.5.6.4 Treatment

Early diagnosis is essential for successful treatment.[92] Initially, a corticosteroid is given at a dosage sufficient to produce remission of clinical signs (prednisone, 1 to 2 mg/lb/day). Corticosteroids are reduced slowly over several months to the lowest dose necessary to maintain remission of the clinical signs. Maintenance treatment using every other day dosing is preferred. Approximately 50% of affected animals have recurrence of clinical signs after corticosteroid therapy is discontinued. Increasing the corticosteroid dose may be necessary if clinical signs recur. Therapy for up to 6 months may be necessary to prevent recurrence of clinical signs. Ideally, CSF analysis results should be within normal limits before therapy is

stopped.[92] The prognosis for eventual resolution of clinical signs is good. Treatment with antibiotics may be indicated initially if the diagnosis is uncertain and bacterial meningitis is suspected.

193.5.7 Degenerative Myelopathy

193.5.7.1 Etiology and Pathogenesis

Degenerative myelopathy is characterized by slowly progressive ataxia and paresis of the pelvic limbs. Histologically, demyelination, axonal degeneration, and astrocytosis in the white matter of the spinal cord are seen. These changes are found throughout the spinal cord and are most severe in the thoracic spinal cord segments, especially in the dorsolateral and ventromedial funiculi.[99–101] The etiology of degenerative myelopathy is unknown in dogs.[102,103] Dural ossification, spondylosis deformans, chronic intervertebral disk protrusion, or infectious or vascular disorders may occur concurrently with degenerative myelopathy. The occurrence of degenerative myelopathy predominantly in German shepherds suggests a genetic basis for the disease, although there is no direct evidence to support this.

856

857

193.5.7.2 Clinical Findings

Degenerative myelopathy generally occurs in dogs 6 years of age or older, although a similar condition has been reported in German shepherds 6 and 7 months of age.[104] Males are affected more often than females. It has been reported most commonly in German shepherds and German shepherd–mixed breed dogs, although it does occur in other large and medium breeds.[99–101]

Affected dogs usually have a slowly progressive paraparesis and pelvic limb ataxia. The onset of clinical signs is gradual. Neurologic deficits often are more noticeable when the dog walks on a smooth surface. Affected dogs may have worn pelvic limb toenails. Although neurologic deficits are most often present bilaterally, they may be asymmetric. Paraparesis and ataxia progressively worsen, so that most affected dogs become nonambulatory within several months to 1 year after neurologic deficits are first detected. Paralysis of the pelvic limbs rarely occurs, probably because most large dogs are euthanized if they become nonambulatory.

Apparent pain or discomfort is not evident in affected dogs. Voluntary control of urination and defecation is retained, although affected dogs may not be able to urinate or defecate in an appropriate place owing to severe paraparesis or inability to assume a voiding posture. This is important, because some dogs have apparent incontinence in the house, which may suggest a lesion of the cauda equina or sacral spinal cord segments. Muscle atrophy is not severe in the initial stages of the disease but may become noticeable in later stages; it is due to disuse rather than denervation. Cutaneous and deep pain perception remain intact throughout the course of the disease.

The neurologic examination findings usually are indicative of a transverse myelopathy between T3 and L3. Abnormalities include decreased or absent conscious proprioception and placing reactions in the pelvic limbs, normal to exaggerated patellar reflexes, normal to exaggerated withdrawal reflexes in the pelvic limbs, normal anal sphincter tone and anal reflex, normal muscle tone in the tail and, in some cases, crossed extensor reflexes in the pelvic limbs. The panniculus reflex usually is normal bilaterally. It is important to note that patellar reflexes may be decreased or absent unilaterally or bilaterally in some cases, possibly as a result of degeneration of the dorsal root ganglia or dorsal gray matter of the lumbar spinal cord (i.e., an afferent rather than a LMN lesion).

193.5.7.3 Diagnosis

Diagnosis of degenerative myelopathy is based on the clinical findings, the age and breed of the dog, and the ruling out of all other causes of a transverse myelopathy in the T3 to L3 region of the spinal cord. Diseases to be considered in the differential diagnosis include discospondylitis, myelitis, spinal cord compression due to type II intervertebral disk protrusion, and spinal neoplasia. Radiographs of the vertebral column may be normal or may demonstrate degenerative changes, such as dural ossification, spondylosis deformans, or narrowed intervertebral disk spaces. An increased protein content (40 to 100 mg/dL) is often found in CSF collected from the lumbar subarachnoid space. The CSF protein level is usually normal in samples collected from the cisternal subarachnoid space. The WBC count is normal in both lumbar and cisternal CSF. Significant myelographic abnormalities are not found.

193.5.7.4 Treatment

Effective treatment has not been reported, and affected dogs usually progress to severe nonambulatory paraparesis within a year of initial diagnosis. Therapy with vitamin supplementation, epsilon-aminocaproic acid (EACA), N-acetylcysteine, and exercise has been recommended by one author.[99–101] However, to date no controlled studies have shown that this therapeutic regimen is of any benefit.

193.5.8 Diffuse Idiopathic Skeletal Hyperostosis

193.5.8.1 Etiology and Pathogenesis

Diffuse idiopathic skeletal hyperostosis (DISH) is a diffuse ossifying condition of young dogs (predominantly large and giant breeds) or cats.[105,106] It has been suggested that four of the following five criteria be met for confirmation of DISH in dogs: (1) flowing calcification and ossification along ventral and lateral aspects of three contiguous vertebral bodies, leading to segmental bony ankylosis; (2) relative preservation of disk width in involved areas, and absence of extensive radiographic changes of degenerative disk disease (e.g., endplate sclerosis, nuclear calcification, or localized spondylosis deformans); (3) periarticular osteophytes surrounding true vertebral joints; (4) formation of pseudoarthrosis between the bases of spinous processes; and (5) periarticular osteophytes and calcification and ossification of soft tissue attachments (enthesiophytes) in both the axial and the peripheral skeleton.[105] Other associated findings may include periarticular osteophytes, sclerosis and ankylosis of sacroiliac joints, and bony ankylosis of the symphysis pubis.

The etiology of this condition is obscure. DISH is a disease that most likely represents a “vulnerable state” in which extensive vertebral ossification results from some stimulus that causes only modest new bone formation in most animals. These “bone formers” have a high incidence of associated extraspinal hyperostosis at the sites of ligament or tendon attachment. The pathologic alterations in DISH include findings consistent with spondylosis deformans; however, DISH differs quantitatively and qualitatively from spondylosis deformans and represents a regional ossification encompassing ligaments, paraspinal connective tissue, and anulus fibrosus, as well as periosteal new bone formation on the ventral surface of the vertebrae.[107–109] Spinal rigidity of several vertebrae resulting from DISH may result in syndromes caused by “dynamic overload” of an adjacent “mobile segment” of the vertebral column. Typically, a rigid fusion of several lumbar vertebrae may result in degenerative changes (e.g., sclerosis, spondylosis deformans, disk

protrusion) that affect the "overloaded" disk immediately cranial to the fused segments. The degenerative changes in the adjacent disk may result in clinical signs associated with spinal cord compression or nerve root entrapment.

193.5.8.2 Clinical Findings

Clinical signs, which may be minimal compared with the dramatic radiographic changes, include mild apparent spinal pain, stiff or stilted gait, and difficulty jumping. Rarely, clinical signs of spinal cord compression resulting from extreme bony proliferation and spinal canal stenosis may result in a transverse myelopathy between T3 and S3. Nerve entrapment may result from bony proliferation at the level of the intervertebral foramen.

193.5.8.3 Diagnosis and Treatment

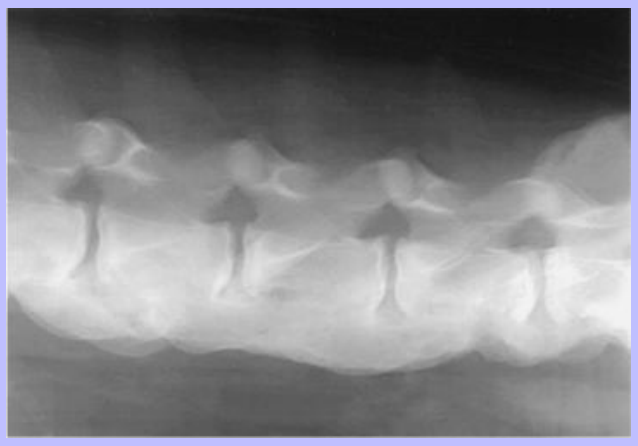
The diagnosis is based on radiographic confirmation of the diagnostic criteria listed above (Figure 193-5).[105] Analysis of CSF and myelography are necessary to rule out other disorders that may result in similar clinical signs. Advanced imaging (CT or MRI) may be useful for accurately investigating the possibility of spinal cord compression or nerve root entrapment resulting from bony proliferation.

Treatment for DISH has not been described. Conservative (medical) management is recommended unless clinical signs of spinal cord compression or nerve root entrapment are present, in which case surgical decompression may be considered.

857

858

Figure 193-5 Diffuse idiopathic skeletal hyperostosis (DISH). Lateral radiograph of the lumbar region of a 4-year-old neutered male Akita. Note the smooth proliferative laminar bridging of the ventral aspects of L4 through L7, consistent with a diagnosis of DISH. The intervertebral disks in this region do not appear to be narrowed. Spondylosis deformans is present at L7–S1. Proliferative remodeling changes are observed at multiple articular facets along the lumbar spine.



193.5.9 Discospondylitis (Spondylitis, Vertebral Osteomyelitis)

193.5.9.1 Etiology and Pathogenesis

Bacterial or fungal infection of the intervertebral disks and adjacent vertebral bodies (discospondylitis) or of only the vertebral bodies (spondylitis) may cause extradural spinal cord or cauda equina compression as a result of granulation tissue, bony proliferation, or pathologic fracture or luxation. Less commonly, discospondylitis may lead to diffuse or focal meningitis and myelitis.[110–113] These conditions result from implantation of bacteria or fungi introduced by migrating plant awns (grass seeds, foxtails), hematogenous spread, extension of a paravertebral infection, a penetrating wound, or previous disk or vertebral surgery.

Discospondylitis and spondylitis occur more commonly in dogs in areas where grass awn infections are a problem. Several theories attempt to explain the migration of grass awns to the vertebral column. Awns may be swallowed and migrate through the bowel wall (possibly at the caudal duodenal flexure), through the mesentery to the attachment to ventral epaxial muscles, and to the vertebral column. Evidence of scarring, however, has not been found in the gut or abdomen of dogs with discospondylitis. Because dogs with discospondylitis thought to be due to plant awn migration have lesions most commonly in the cranial lumbar spine (L2–L4), it has been suggested that awns may be inhaled and migrate through the lungs to the diaphragm, lodging at the crural insertion on the lumbar vertebrae. Plant awns may also migrate through skin and paravertebral or abdominal muscles to the vertebral column. Grass seeds are able to travel long distances owing to the direction of the barbs. Forward progress may be aided by muscle movements.

Hematogenous spread of bacteria or fungi is probably the most common cause of discospondylitis. Sources of infection include bacterial endocarditis, dental disease, and urinary tract infections. Retrograde flow in the vertebral veins has been suggested as a possible route of infection to the vertebral column. It is not known whether discospondylitis associated with urinary tract infection is due to venous or arterial dissemination of bacteria or whether a direct causal relationship exists between urinary tract infection and discospondylitis. Many dogs with discospondylitis have concurrent urinary tract infection. Discospondylitis caused by *Brucella canis* infection most likely results from bacteremic spread from a genital infection.

Affected intervertebral disks may show evidence of degeneration (collapsed disk space, spondylosis deformans) or trauma (traumatic disk protrusion, vertebral luxation). Discospondylitis may occur with increased frequency in immunocompromised animals.[114–116] The organisms most commonly isolated from the blood, affected vertebrae, and urine of dogs with discospondylitis are coagulase-positive *Staphylococcus* spp. *(S. aureus, S. intermedius),* although a number of other organisms have been identified.[110–112,116–120] Discospondylitis has been reported to occur in cats.[121]

193.5.9.2 Clinical Findings

Discospondylitis may occur in dogs or cats of any age, but it is most commonly seen in giant and large breed dogs. Any level of the vertebral column may be affected, and multiple lesions may be seen in either adjacent or nonadjacent vertebrae. Discospondylitis occurs more commonly in the thoracic and lumbar spine than in the cervical spine. The lumbosacral disk space frequently is involved.

Clinical findings depend on the location of the affected vertebra or vertebrae. The most common clinical signs are weight loss, anorexia, depression, fever, reluctance to run or jump, and apparent spinal pain (which

may be severe). Hyperesthesia may be present only over the site of the lesion or may be poorly localized, especially with involvement of multiple sites.[110]

193.5.9.3 Diagnosis

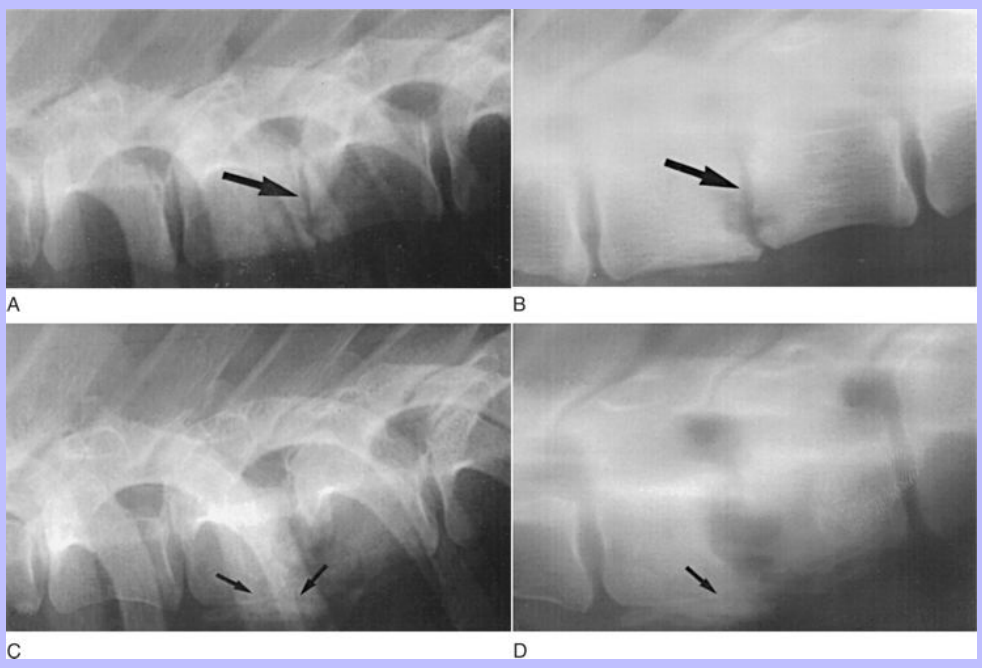
Diagnosis may be difficult, because clinical signs often are nonspecific. Discospondylitis should always be considered in an animal with fever of unknown origin. If the lumbosacral intervertebral disk is involved, dogs often show a stilted, short-strided pelvic limb gait and shifting pelvic limb lameness. Clinical signs may be present for several weeks or months before diagnosis.

Neurologic deficits associated with spinal cord or cauda equina compression may be present and may reflect either a transverse or a multifocal myelopathy. Neurologic deficits associated with a transverse myelopathy (T3–L3) occur most commonly and include paraparesis, decreased conscious proprioception, exaggerated spinal reflexes and, much less commonly, paraplegia. Cervical lesions most commonly cause only apparent cervical pain, and lumbosacral lesions may cause neurologic deficits due to compression of nerves of the cauda equina. Rarely, animals may demonstrate clinical signs of diffuse suppurative meningitis associated with extension of infection to involve the spinal meninges. Dogs may have a history of draining tracts in the paravertebral area associated with grass seed migration. Discospondylitis has been described in dogs with osteomyelitis in other sites (femur and sternum).

Affected animals may have a normal or elevated peripheral WBC count. Typical radiographic findings are destruction of the bony endplates adjacent to an infected disk, collapse of the intervertebral disk, and varying degrees of new bone production. Early lesions may consist only of lytic areas in affected vertebral endplates. More advanced lesions show a mixture of bone lysis and extensive new bone production, with osteophytes bridging adjacent vertebrae containing a central destructive focus (Figure 193-6). Affected vertebral bodies may be shortened, and bony proliferation may result in fusion of one or more vertebrae. Discospondylitis may be superimposed on other vertebral abnormalities, including fracture and associated callus formation, spondylosis deformans, or a surgical site.

Because discospondylitis may be present in more than one site in the vertebral column, it is important that the entire spine be radiographed in animals suspected of having discospondylitis. Occasionally clinical signs may occur before characteristic radiographic changes are evident. Tomography may also be a useful method of radiographic diagnosis of discospondylitis, particularly at the lumbosacral junction (Figure 193-7). Bone scintigraphy may be useful for detection of early lesions prior to the development of radiographically evident lesions and for investigation in animals in which it is uncertain whether lesions are due to infection or other causes (e.g., severe spondylosis deformans). Advanced imaging (CT or MRI) may be useful in the identification of subtle vertebral lesions.[110,122]

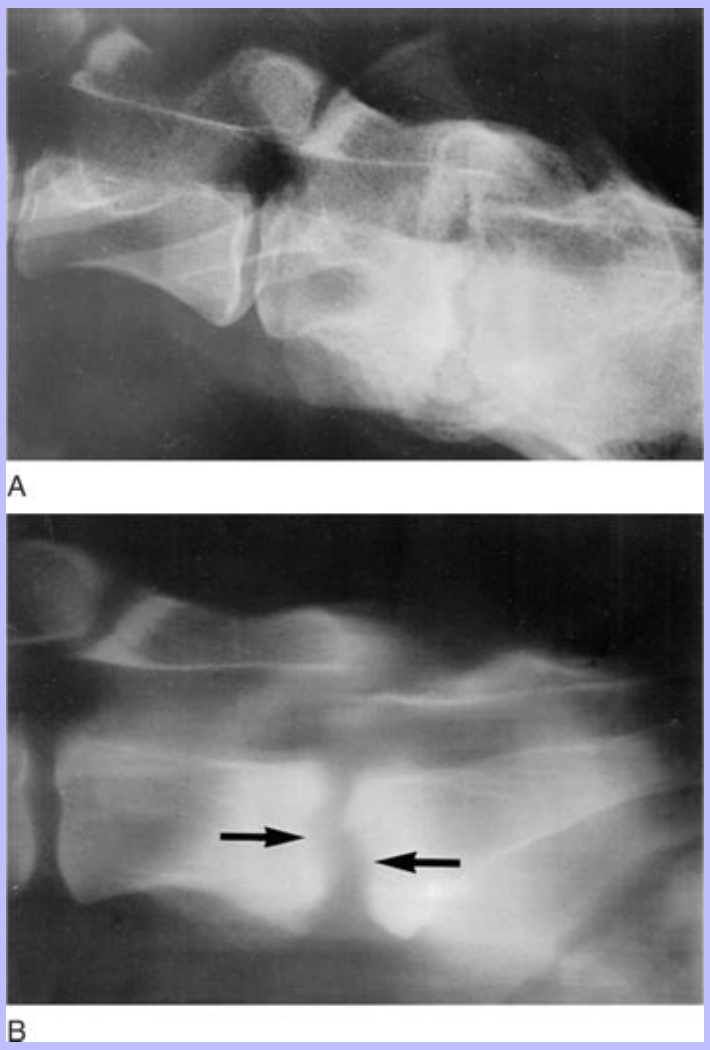
Figure 193-6 Discospondylitis. Lateral radiograph **(A)** and linear tomogram **(B)** of the midthoracic vertebral column of a 1-year-old female Doberman pinscher 8 weeks after the onset of apparent back pain. Note the collapse of the T6–T7 disk *(large arrow)*, the destruction of the vertebral endplates, and the well-delineated lysis of the T6 and T7 vertebral bodies. These changes are easily observed on the tomogram, where superimposed ribs are not a factor. Lateral radiograph **(C)** and linear tomogram **(D)** of the midthoracic vertebrae completed 3 months after **A** and **B.** The dog had undergone a 4-week course of a broad-spectrum antibiotic that resulted in clinical improvement after the initial radiographic examination; however, signs of spinal pain had returned. Note the progression of the radiographic changes seen 3 months earlier and the bony proliferation *(small arrows)* at T6–T7. After surgical biopsy and culture of the T6–T7 disk, therapy with an appropriate antibiotic drug was commenced. Complete radiographic resolution of the discospondylitis and fusion of the T6–T7 vertebrae were apparent after 6 months of continued antibiotic therapy.



Collection of CSF is indicated for animals with neurologic deficits. The CSF may be normal or may have an increased WBC count and/or protein content when discospondylitis lesions cause extradural compression of the spinal cord or result in meningitis and/or myelitis. Myelographic findings usually indicate extradural compression that results from extension of granulation tissue and bony proliferation in the spinal canal. Clinical signs do not always correlate well with the degree of compression seen on myelography and depend on factors such as the rate, duration, and degree of compression. Aerobic, anaerobic, and fungal cultures of blood and urine should be done prior to treatment in an attempt to isolate causative organisms. Some authors consider any organism other than *S. intermedius* cultured from the urine unlikely to be the causative organism unless it is also cultured from the blood or a vertebral lesion. Cultures of CSF are indicated if the WBC count is elevated. Cultures of fluid from draining sinuses may also be performed. In all dogs with discospondylitis, efforts should be made to determine whether *B. canis* infection is present.[117]

Surgical biopsy may be indicated in affected dogs in which a causative organism is not isolated from blood or urine and/or in animals that are unresponsive to treatment with broad-spectrum antibiotics. Fluoroscopy-guided needle aspiration of lesions is possible in some animals.[123] However, cultures of samples collected in this way are often negative, especially if animals have been treated with antibiotics prior to the biopsy.

Figure 193-7 Discospondylitis. Lateral radiograph **(A)** and linear tomogram **(B)** of the lumbosacral region of the vertebral column of a 4-year-old German shepherd that had a 1-month history of apparent pain and pelvic limb weakness. Note the sclerosis of the vertebral endplates, spondylosis deformans, new bone formation, and collapsed disk seen on the radiograph of L7–S1. A tomogram of this region confirms the presence of bone lysis *(arrows)* consistent with a diagnosis of discospondylitis. *Staphylococcus aureus* was cultured from the urine and blood and from material obtained from the L7–S1 disk by needle aspiration.



193.5.9.4 Treatment

Treatment consists of long-term use of an antimicrobial that is effective against the causative organism or organisms detected by blood and/or urine cultures. If an organism is not cultured, dogs without severe neurologic deficits may be treated empirically, assuming infection with the most common organism isolated from animals with discospondylitis (coagulase-positive *Staphylococcus* spp.). The antibiotics most effective for this purpose are cephalosporins or beta lactamase–resistant penicillins (e.g., oxacillin and cloxacillin). A trimethoprim/sulfonamide combination or chloramphenicol is less effective, but it is less expensive and may be effective in some cases.

Clinical signs may recur if the infection is not completely eliminated prior to cessation of antibiotic therapy, and repeated cultures of blood and urine, as well as ongoing treatment with an appropriate antibiotic, may be necessary. Treatment is continued for at least 6 weeks, and vertebral radiographs are taken every 2 to 3 weeks to monitor the progression or regression of a lesion and to monitor for the development of new lesions. Antibiotic administration may be necessary for up to 6 months before radiographic evidence of resolution of lesions is seen. Clinical improvement in animals with discospondylitis (resolution of fever, improved appetite, reduction of apparent spinal pain) should be seen within 2 weeks of initiation of antibiotic therapy. Surgical exploration of a lesion should be considered in animals that are unresponsive to treatment or that have persistent draining tracts suggestive of grass seed migration. The objectives of surgery are curettage of lesions and harvesting of material for bacterial and fungal culture. A cancellous bone graft has been recommended after curettage of a disk space. Decompressive surgery is indicated if evidence of spinal cord compression is found on myelography and if the animal shows severe or progressive neurologic deficits. Surgical stabilization of the vertebrae may be necessary after decompression.[124]

193.5.10 Distemper Myelitis

193.5.10.1 Etiology and Pathogenesis

Canine distemper (CD) virus is a neurotropic virus that may cause focal or diffuse demyelination in both gray and white matter of the CNS.[125] The mechanism by which demyelination occurs is not known, but the condition may be a primary effect of the virus on glial cells or may occur secondary to immunologic mechanisms. The white matter of the cerebellum, cerebellar peduncles, optic nerves, optic tracts, and spinal cord are most severely affected. Focal or diffuse demyelination may occur in the white matter of the spinal cord.[126,127] Further histopathologic changes seen in the spinal cord and throughout the CNS include perivascular cuffing by mononuclear cells, gliosis, microglial proliferation, inflammatory cell infiltration of the pia arachnoid, and neuronal changes (nuclear pyknosis, chromatolysis, shrunken cells, and neuronophagia). Intranuclear and intracyloplasmic inclusions may or may not be present.

193.5.10.2 Clinical Findings

Affected animals may or may not have a history of systemic illness. Dogs of any age may be affected, but those with myelitis due to CD infection are usually less than 3 years of age. Dogs that have been vaccinated according to recommended schedules may be affected. Clinical signs of CD myelitis reflect the location of the lesion or lesions, which may be focal or diffuse, at any point in the spinal cord. The T3 to L3 spinal cord segments are affected most often, and clinical signs indicative of a transverse myelopathy in this region are seen. Neurologic abnormalities include paraparesis or paraplegia and normal to exaggerated reflexes in the

pelvic limbs. Neurologic deficits are progressive and bilateral; however, they may be asymmetric. Affected dogs may have clinical signs indicative of current or previous systemic CD infection. Neurologic deficits commonly seen in dogs with CD infection are vestibular and/or cerebellar abnormalities and visual deficits.[128] Self-mutilation occasionally is seen in dogs with CD infection. The limbs and tail are the common sites of mutilation. Paresis or paralysis of the limbs may also be present.

193.5.10.2.1 Distemper myoclonus

Myoclonus, the rhythmic twitching of a muscle or muscle group, is most often associated with CD infection.[129] Any muscles may be involved, including the facial and masticatory muscles or the limb muscles. The pathogenesis of myoclonus is unknown. It is thought to result from an abnormality in the motor neuron and interneuron pools of the medulla and spinal cord. Animals may recover from systemic CD infection and occasionally from CNS infection; however, myoclonus may persist. Myoclonus is generally permanent and may persist during sleep. It may be alleviated by oral therapy with procainamide.

193.5.10.3 Diagnosis

Antemortem diagnosis often is difficult.[130] Clinical signs of multifocal CNS disease, particularly neurologic deficits indicative of spinal cord and cerebellovestibular disease, are highly suggestive of CD infection. Hematologic findings in dogs with CD infection are nonspecific. Abnormalities of the cerebrospinal fluid may be useful in the diagnosis of CD infection; however, the CSF may be normal. The WBC count and protein content of the cerebrospinal fluid are usually mildly to moderately increased. Cells seen in the CSF are predominantly lymphocytes (10 to 60 cells/μL). The presence of interferon in the CSF appears to be a reliable indicator of virus persistence.[129] CSF electrophoresis may also be performed and is useful for predicting the histopathologic changes in dogs with CD encephalomyelitis.[131] Determination of the IgG index may also aid the diagnosis of CD encephalomyelitis.[126]

860
861

Increased CD virus–specific antibody titers in the CSF may be useful in the diagnosis of CD infection. Increased anti–CD virus antibody in the CSF may offer evidence of chronic CD infection, because antibody is produced locally in the CNS, and significantly increased titers have rarely been present in vaccinated dogs or dogs with systemic CD infection without CNS involvement. Cerebrospinal CD antibody may be artifactually increased if whole blood contamination of the CSF occurs during collection. Negative CD antibody results do not rule out a diagnosis of CD.[40,129]

193.5.10.4 Treatment

Clinical signs of CD myelitis may be either rapidly or more slowly progressive. Periods of apparent improvement may be followed by progression of clinical signs. A specific antiviral drug that has an effect on CD in dogs is not currently available. Favorable results have been reported by some investigators with short-duration (1 to 3 days) corticosteroid therapy.[40] Intravenous administration of a modified live vaccine in dogs with CD is effective only if given before clinical signs appear. Treatment of CD myelitis is almost always unrewarding. The prognosis for recovery is poor. In dogs that recover from CD infection, residual signs such as myoclonus or optic neuritis may improve with time. Immunization by vaccination is the only effective approach to the prevention of CD.[126]

193.5.11 Dural Ossification

193.5.11.1 Etiology and Pathogenesis

Dural ossification is the formation of bony plaques on the inner surface of the dura mater.[6] Bony plaques are found most commonly in the cervical and lumbar spine and may occur laterally, ventrally, or dorsally. Dural ossification is found in more than 40% of large and small breed dogs over 2 years of age and in more than 60% of dogs 5 years of age or older. Although many dogs with dural ossification also have spondylosis deformans, no direct correlation exists between the two conditions. The etiology of dural ossification is unknown.

193.5.11.2 Clinical Findings

Dural ossification rarely results in neurologic deficits or apparent spinal pain in dogs. Other causes of spinal cord disease should be ruled out before clinical significance is attributed to dural ossification.

193.5.11.3 Diagnosis and Treatment

Radiographically, bony plaques appear as thin, radiopaque lines (linear shadows) that are most easily viewed at the site of intervertebral foramina. These linear shadows must be distinguished from calcified herniated disk material in the spinal canal, from vertebral osteophytes, and from the accessory processes of the lumbar vertebrae. No specific treatment exists for dural ossification; however, in rare cases surgical removal of a bony plaque from the vicinity of a nerve root may be necessary to alleviate apparent pain due to nerve root compression.

193.5.12 Feline Infectious Peritonitis, Meningitis, and Myelitis

193.5.12.1 Etiology and Pathogenesis

Feline infectious peritonitis is a serious, almost always fatal disease caused by a coronavirus.[132–137] Pyogranulomatous meningitis and myelitis may occur in cats with FIP, which is most commonly seen in younger animals between 6 months and 5 years of age. Meningeal and spinal cord lesions are probably the result of immune complex–mediated vasculitis. Involvement of the CNS is more frequently observed in the noneffusive (dry) form than in the effusive (wet) form of the disease.

193.5.12.2 Clinical Findings

Focal, multifocal, or diffuse involvement of the spinal cord, brain, and meninges may occur with FIP, and clinical signs reflect the location of these lesions. The most commonly recognized neurologic signs are pelvic limb ataxia, hyperesthesia (especially over the back), and generalized ataxia.[137] Affected animals usually manifest other clinical signs indicative of disseminated disease, such as persistent fever (frequently exceeding 105° F), weight loss, enlarged kidneys, chorioretinitis, panophthalmitis, or anterior uveitis.[137]

193.5.12.3 Diagnosis

Histopathologic examination of biopsy specimens is the only conclusive method for diagnosing FIP. Short of this, a variety of factors may be considered to support a diagnosis of FIP.[138–140] The CSF usually is abnormal, with an elevated WBC count and protein level. The differential WBC count for the CSF is variable, but PMN cells, lymphocytes, and monocytes usually are present.

PMNs may be the predominant cell type in the CSF. The protein concentration may be high (greater than 2000 mg/dL), and the CSF may be viscous and may clot. This should be taken into consideration when a CSF puncture is performed, because fluid may flow into the needle slowly. The results of cytologic examination of the CSF depend on the degree of meningeal involvement. Meningeal inflammation may be extensive, and the CSF in these cases is generally highly abnormal. With focal or parenchymal inflammation, the CSF may be normal.

193.5.12.4 Treatment

The prognosis for cats with FIP of the central nervous system is poor. The feline leukemia virus (FeLV) status of cats suspected of having FIP should be determined before treatment is started, because the prognosis for cats with both viruses is hopeless.[141] The most effective treatment protocols combine high levels of corticosteroids (prednisolone, 1 to 2 mg/lb given orally once daily in the evening), cytotoxic drugs (either cyclophosphamide [1 mg/lb given orally once daily for 4 consecutive days of each week] or melphalan [1 mg given orally every third day]), and broad-spectrum antibiotics (ampicillin, 10 mg/lb given orally every 8 hours), together with maintenance of nutrient intake and electrolyte balance. Cats receiving cytotoxic drugs should be routinely monitored for evidence of kidney dysfunction or bone marrow suppression. If a positive response to therapy is seen, treatment should be continued for at least 3 months.[141]

193.5.13 Feline Polioencephalomyelitis (Feline Nonsuppurative Meningoencephalomyelitis)

Feline polioencephalomyelitis is a chronic, slowly progressive encephalomyelitis of unknown etiology that has been described in immature and mature cats.[40,142] A viral etiology is suspected based on the histopathologic changes, although a specific viral agent has not been isolated. The chronic clinical course, distribution of lesions, and lack of inclusions distinguish this disease from rabies, pseudorabies, and FIP. It has been proposed that a tick-borne virus may be the causative agent in Sweden.[143–146]

Clinical signs include ataxia, paraparesis, tetraparesis, hypermetria, head tremors, and localized hyperesthesia. Spinal reflexes, pupillary light reflexes, and postural reactions may be normal or depressed. Clinical signs usually are indicative of multifocal CNS disease but may be suggestive of focal transverse myelopathy in the thoracolumbar region or lumbar enlargement. Clinical signs are slowly progressive over several months. Antemortem diagnosis is difficult and is made by ruling out other multifocal CNS diseases. Treatment of affected cats has not been reported.

193.5.14 Globoid Cell Leukodystrophy (Krabbe-Type Leukodystrophy)

193.5.14.1 Etiology and Pathogenesis

Globoid cell leukodystrophy is an inherited lysosomal storage disease that results from a deficiency of galactocerebrosidase (GALC) activity.[6,147] Globoid cell leukodystrophy is characterized by bilaterally symmetric demyelination of the white matter of the brain, spinal cord, spinal nerve roots, and peripheral nerves and by accumulation, especially perivascularly, of large phagocytic cells with foamy-appearing cytoplasm (globoid cells). Globoid cell leukodystrophy is inherited as an autosomal recessive trait in cairn terriers and West Highland white terriers, and findings in other dog breeds suggest a recessive factor. The condition may not be inherited as a simple autosomal recessive trait in cats. Cloning of the GALC cDNA has been completed and the disease–Causing mutation identified in both West Highland white and cairn terriers.[147]

193.5.14.2 Clinical Findings

Clinical signs generally are first seen between 2 and 6 months of age and are progressive. However, neurologic abnormalities were not evident in an affected basset hound until 4 years of age. Affected cats usually show abnormalities by 6 weeks of age. Progressive paraparesis and paraplegia predominate in some affected animals, whereas cerebellar signs predominate in others. Spinal reflexes in the pelvic limbs may be normal or exaggerated, indicative of T3–L3 transverse myelopathy. Neurologic signs in affected animals usually progress to quadriparesis, dysmetria, head tremor, behavioral changes, and/or blindness. Spinal reflexes may be decreased or absent and muscle atrophy may be evident in some animals, indicative of LMN disease. Clinical signs usually progress over 2 to 6 months, although they were observed to progress for 2 years in one dog. Clinical signs in cats with globoid cell leukodystrophy are generally more indicative of cerebellar disease and are more rapidly progressive than in dogs.

193.5.14.3 Diagnosis

The diagnosis is made on the basis of the animal's age and breed and the presence of progressive neurologic deficits, as well as by ruling out other causes of progressive myelopathy (e.g., CD myelitis). The CSF may have phagocytic cells containing periodic acid–Schiff (PAS)-positive material (globoid cells), and the CSF protein content may be increased. In some animals the CSF may be normal. Brain and/or peripheral nerve biopsy may show characteristic demyelination and globoid cell accumulation and may be done to confirm a diagnosis of globoid cell leukodystrophy. A rapid test for identification of the genotype at cDNA position 473 has been developed.[147] The results of this test may allow breeders to screen their dogs for this problem and may result in elimination of this disease in the future.

193.5.14.4 Treatment

Treatment for globoid cell leukodystrophy has not been described.[6] Selective breeding based on genetic testing may eventually eliminate this disease.[147]

193.5.15 Granulomatous Meningoencephalomyelitis

193.5.15.1 Etiology and Pathogenesis

Granulomatous meningoencephalomyelitis (GME) is a nonsuppurative meningoencephalomyelitis of undetermined etiology in dogs.[6,148–150] It is characterized histopathologically by large perivascular accumulations of mononuclear cells throughout the brain, spinal cord, and meninges. A recent immunomorphologic study suggested that inflammatory lesions in canine GME consist of a heterogeneous population of major histocompatibility complex (MHC) class II antigen–positive macrophages and predominantly CD3 antigen–positive lymphocytes.[151] These data suggest T cell–mediated, delayed-type hypersensitivity of an organ-specific autoimmune disease.[151]

193.5.15.2 Clinical Findings

A higher incidence of GME has been found in female dogs, small breed dogs, poodles, poodle–mixed breed dogs, and Airedale terriers. Affected dogs usually are between 1 and 9 years of age, although dogs may be affected at any age. Clinical signs may indicate focal or multifocal cerebral, brain stem, cerebellar, and/or spinal cord involvement. GME may involve the spinal cord at any level; however, lesions appear to be most severe in the cervical spinal cord, and clinical findings are often indicative of cervical spinal cord disease. Findings include apparent cervical pain, rigidity, reluctance to move, hyperesthesia, cervical paraspinal muscle spasms, exaggerated spinal reflexes, decreased conscious proprioception, paraparesis, tetraparesis, and paraplegia. Affected animals usually have an acute onset of clinical signs, which progress over several days to months.[148,149]

193.5.15.3 Diagnosis

Antemortem diagnosis is difficult and usually is made on the basis of clinical findings and the results of CSF analysis. Dogs with GME may have intermittent fever. The findings for a complete blood count and on spinal and skull radiographs frequently are within normal limits. The CSF is abnormal in most affected dogs. The WBC count of the cerebrospinal fluid is usually increased (may be greater than 1000 WBCs/μL). Mononuclear cells predominate. The percentage of lymphocytes and monocytes varies considerably. PMN cells may also be present and in one study constituted 0 to 62% of the differential WBC count.[152] In the same study, less than 1% of the differential WBC count consisted of macrophages with ingested debris, plasma cells, and cells undergoing mitosis. The total and differential CSF white blood cell counts do not reflect the severity of meningeal involvement or the degree of necrosis. The CSF protein concentration is usually elevated, and the CSF pressure may be normal or increased. Alterations in the CSF were similar in untreated and corticosteroid-treated dogs in one study.[152]

Meningeal lesions may render CSF collection from cisternal puncture difficult. Although CSF collected from the lumbar subarachnoid space of affected dogs may have fewer white blood cells than cisternal CSF, it is useful for diagnosis. The difference in WBC counts probably reflects the greater distance of the lumbar subarachnoid space from the site of most lesions. Bacterial and fungal cultures are negative, and organisms are not identified in CSF cell preparations. Noncontrast radiography, myelography, and advanced imaging (CT or MRI) may confirm an intramedullary space-occupying lesion of the spinal cord.

193.5.15.4 Treatment

GME is either continuously or episodically progressive, and the prognosis for recovery is poor. Treatment with cortico-steroids may result in improvement of clinical signs for several days to several months or years. Immunosuppressive doses of corticosteroids should be given, and therapy must be sustained indefinitely. The corticosteroid regimen used for treatment of corticosteroid-responsive meningitis should be used for therapy of dogs with GME. Clinical remissions of greater than 1 year occur in some cases; however, clinical signs usually recur with discontinuation of treatment with corticosteroids. Radiation therapy may be an effective treatment for dogs with focal GME.[150] Alternative immunomodulatory drugs may also play a role in the treatment of GME in the future.[153]

863

193.5.16 Hemorrhage

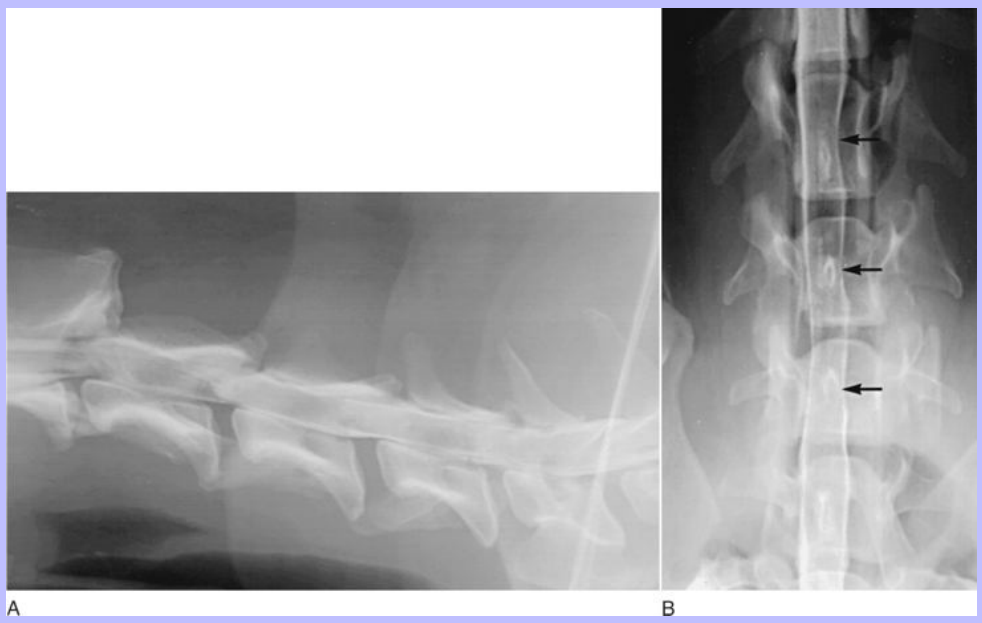
193.5.16.1 Etiology and Pathogenesis

Intramedullary, intrameningeal, or epidural hemorrhage may be due to coagulopathies, including thrombocytopenia, clotting factor deficiencies, disseminated intravascular coagulation, and anticoagulant poisonings (e.g., warfarin).[154] Acute hemorrhage may also occur in association with tumors, vascular malformations, acute intervertebral disk protrusion, trauma, parasitic migration, or meningitis (Figure 193-8). Spontaneous intramedullary hemorrhage with hematoma formation has been reported in the cervical spinal cord of a dog.[155] Spontaneous subperiosteal vertebral hemorrhage and hematoma formation associated with spinal cord compression and transverse myelopathy have been reported in dogs.

193.5.16.2 Clinical Findings

Neurologic deficits depend on the location of the hemorrhage and usually indicate a focal or multifocal myelopathy. Clinical signs most often are acute in onset, and neurologic deficits may be severe. Extensive gray matter necrosis may occur with intramedullary hemorrhage, resulting in LMN signs over a relatively large area of the spinal cord, especially if the cervical or lumbosacral spinal cord is involved. Subarachnoid hemorrhage may result in clinical signs suggestive of meningitis, including cervical rigidity, hyperesthesia, and elevated body temperature.

Figure 193-8 Hemorrhage. Lateral **(A)** and ventrodorsal **(B)** myelogram of the cervical vertebrae of a 10-year-old neutered male mixed-breed dog with an acute onset of tetraparesis. Narrowing of the C5–C6 intervertebral disk can be seen. The lateral myelogram **(A)** demonstrates inconsistent filling of the subarachnoid space. The ventrodorsal projection **(B)** confirms lateral deviation of the right contrast column and attenuation of the left contrast column *(arrows)*, owing to an extradural space-occupying mass. Exploratory surgery demonstrated that the extradural compression was caused by hemorrhage that had occurred secondary to the acute C5–C6 disk extrusion.



193.5.16.3 Diagnosis

Animals with coagulopathies may have evidence of hemorrhage elsewhere in the body. Diagnostic tests for coagulopathies should be undertaken. Subarachnoid CSF puncture may be contraindicated in animals with a coagulopathy because of the high probability of inducing further hemorrhage. Red blood cells may be present in the CSF for a short time after subarachnoid hemorrhage, and CSF supernatant may be red or pink in color. Xanthochromia may be present in the CSF 48 hours or more after the hemorrhage. The CSF white blood cell count and protein concentration may also be elevated.

Myelography is indicated when epidural hemorrhage is suspected to be the cause of spinal cord compression and when noncontrast radiographs and the results of CSF analysis are normal and no evidence of coagulopathy has been found. Epidural hemorrhage is not distinguishable from other extradural

space-occupying lesions on myelography. Hemorrhage may occur secondary to other abnormalities, such as intervertebral disk extrusion, as a result of laceration of a vertebral venous sinus.

193.5.16.4 Treatment

Treatment is directed at the underlying cause in animals with coagulopathies. Epidural and intramedullary hematomas not associated with coagulopathy may be removed surgically. The prognosis depends on the severity of the neurologic deficits at the time of diagnosis.

193.5.17 Hereditary Ataxia (Ataxia in Smooth-Haired Fox Terriers and Jack Russell Terriers)

193.5.17.1 Etiology and Pathogenesis

An inherited, progressive, generalized ataxia has been reported to occur in young, smooth-haired fox terriers and Jack Russell terriers.[6] This disease is characterized pathologically by demyelination bilaterally throughout the dorsolateral and ventromedial white matter of the spinal cord. In Jack Russell terriers, wide-spread wallerian-type degeneration in the white matter of the brain and degenerative changes in the central auditory pathways and peripheral nerves may be seen. Hereditary ataxia is inherited as an autosomal recessive trait in smooth-haired fox terriers. The etiology of ataxia in Jack Russell terriers is not known; however, clinical and pathologic findings suggest that it may be congenital. Degenerative myelopathies have been described in several dog breeds other than fox terriers and Jack Russell terriers, including English foxhounds, harriers, beagles,[156–158] boxers,[1] German shepherds,[99–104] poodles,[1] Afghan hounds,[1] a Pyrenees mountain dog,[159] a cairn terrier,[160] Dutch Kooiker dogs,[161] and Australian cattle dogs.[162] The pathogenesis of these conditions is unclear.

193.5.17.2 Clinical Findings, Diagnosis, and Treatment

Both males and females are affected. Neurologic abnormalities, first seen between 2 and 6 months of age, include pelvic limb ataxia and swinging of the hindquarters. The ataxia progressively worsens over 6 months to 2 years and involves all four limbs. Affected animals often have a prancing pelvic limb gait. Dysmetria may be severe, and affected dogs fall to the ground with a slight change in position. The diagnosis is made on the basis of the animal's age and breed and the clinical findings. Treatment is not effective. Affected animals are eventually unable to walk.

193.5.18 Hypervitaminosis A of Cats

193.5.18.1 Etiology and Pathogenesis

Hypervitaminosis A in cats is characterized by extensive, confluent exostosis that is most prominent in the cervical and thoracic spine.[6,7,163] It is caused by a chronic excess of dietary vitamin A and is usually a result of feeding of a diet consisting largely of liver. Exostosis may extend to involve the entire spine, ribs, and pelvic and thoracic limbs, with complete fusion of the spine and joints. Compression of spinal nerve roots or nerves may occur if new bone formation extends into the intervertebral foramina.

193.5.18.2 Clinical Findings, Diagnosis, and Treatment

Clinical signs in affected cats include apparent cervical pain and rigidity, thoracic limb lameness, ataxia, reluctance to move, paralysis, and hyperesthesia or anesthesia of the skin of the neck and forelimbs. The three most proximal diarthrodial joints of the cervical spine are almost always first affected. Osseous lesions develop insidiously, and clinical disease usually is advanced in cats older than 2 years of age before significant clinical features are recognized. Radiographic evidence of extensive exostosis of the cervical vertebral column and a history of excessive dietary intake of vitamin A or liver are necessary for the diagnosis. Reduction of dietary intake of vitamin A prevents the development of further exostosis, but it may be difficult to persuade affected cats to eat anything other than liver.

193.5.19 Intervertebral Disk Disease

193.5.19.1 Etiology and Pathogenesis

Degeneration of intervertebral disks may result in protrusion or extrusion of disk material into the spinal canal, causing spinal cord compression and clinical signs ranging from apparent pain to complete transverse myelopathy. Degenerative changes may occur in any of the intervertebral disks; however, they occur most commonly in the cervical, caudal thoracic, and lumbar spine. Because the intervertebral disks between T1 and T11 are stabilized dorsally by the intercapital ligaments, disk protrusion or extrusion is less likely in this region.[164–166]

Two types of disk herniation have been reported to occur in dogs.[167] Type I disk herniation occurs with degeneration and rupture of the dorsal anulus fibrosus and extrusion of the nucleus pulposus into the spinal canal. Type I disk extrusion is most commonly associated with chondroid disk degeneration (Figure 193-9). Although chondroid disk degeneration and type I disk extrusion occur most commonly in chondrodystrophoid breeds (dachshund, beagle, Pekingese, Lhasa apso, Shih Tzu) and in breeds with chondrodystrophoid tendencies (miniature poodle and cocker spaniel), these conditions may occur in any breed, including large breeds. Type II disk protrusion is characterized by bulging of the intervertebral disk without complete rupture of the anulus fibrosus. Type II disk protrusion is most commonly associated with fibroid disk degeneration (Figure 193-10). Chondroid metaplasia of the nucleus pulposus, chondroid disk degeneration, and type I disk extrusion may occur in any breed, including large breeds. The author (RAL) has noted an unusually high incidence of type I disk extrusion in Doberman pinschers. The smaller lumbar epidural space in dachshunds may explain the severe clinical signs seen in this breed in association with apparently small amounts of extruded disk material. Likewise, the larger epidural space in large breed dogs may account for the fact that small amounts of extruded disk material in the spinal canal in these breeds may not cause spinal cord compression and associated clinical signs.[168]

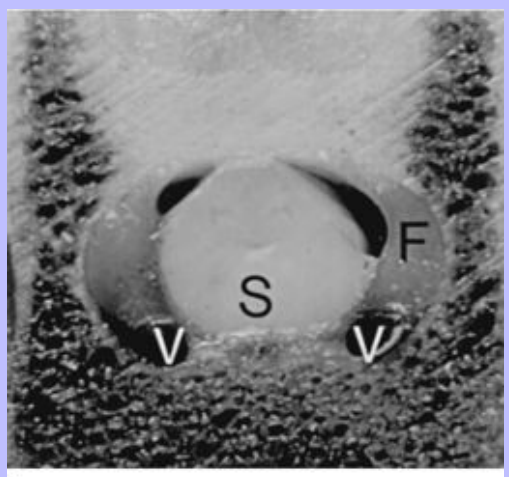
Chondroid degeneration of disks is characterized by an increase in the collagen content of the disk, alteration of the specific glycosaminoglycan concentration of the nucleus pulposus, and a decrease in the water content of the disk. The normally gelatinous nucleus pulposus becomes progressively more cartilaginous and granular and eventually may mineralize (calcify). Extrusion of degenerative nucleus pulposus occurs through fissures in or rupture of the anulus fibrosus. In chondrodystrophoid breeds of dog, 75% to 100% of all disks undergo chondroid metaplasia by 1 year of age.[169]

Fibroid disk degeneration occurs in older dogs of all breeds; however, it is most often recognized as a clinical problem in older, large breed, nonchondrodystrophoid dogs and is characterized by fibrous metaplasia of the nucleus pulposus. An increase in the noncollagenous glycoprotein content of the intervertebral disks occurs in nonchondrodystrophoid breeds with aging. Calcification of the disk may occur but is rare. Protrusion of the disk occurs, with a bulging of the anulus fibrosus as a result of partial rupture of the anular bands. Rupture of the anulus fibrosus and extrusion of the nucleus pulposus (characteristic of type I disk extrusion) infrequently is seen in association with type II disk protrusion.

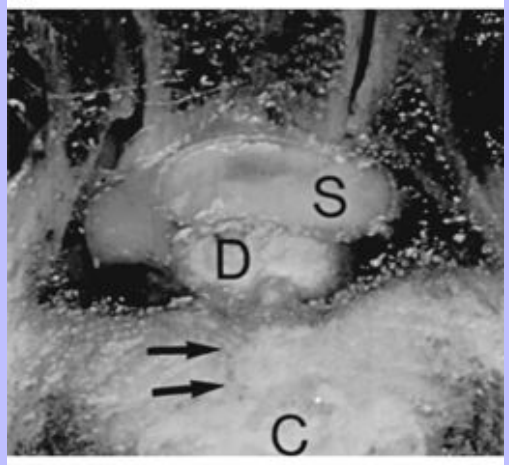
Intervertebral disk protrusion or extrusion may occur in a ventral, dorsal, or lateral direction. In most instances only dorsal protrusions or extrusions are of clinical significance, because meningeal irritation and nerve root and/or spinal cord compression may occur. Occasionally a lateral disk protrusion or extrusion may result in nerve root or spinal nerve compression with associated clinical signs. The cause of intervertebral disk degeneration is unknown. Trauma does not appear to play a major role; mechanical and anatomic factors are probably important. Disk extrusions are most common in the cervical and T11 to L3 regions of the vertebral column. Genetic factors probably also play a role.

864
865

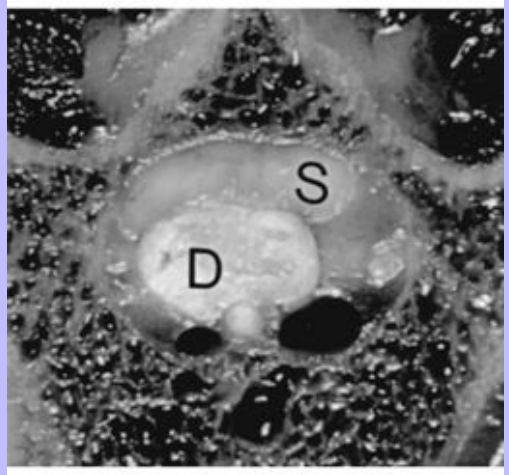
Figure 193-9 Type I disk extrusion. Gross necropsy specimens from a 4-year-old male dachshund that had an acute onset of pelvic limb paralysis. Pain perception was absent in the pelvic limbs. Myelography confirmed acute disk extrusion at T11–T12 that had caused severe spinal cord compression. **A,** Transverse section of the T12 vertebral canal 1 cm caudal to the extruded T11–T12 disk. Note the normal appearance of the spinal cord *(S)* in the spinal canal. Epidural fat *(F)* and internal vertebral venous plexus or vertebral sinuses *(V)* are also present in the spinal canal. **B,** Transverse section of the vertebral canal at the level of the T11–T12 disk. Calcified material *(C)* is present in the nucleus pulposus. A fissure (*arrows*) is present in the dorsal anulus fibrosus, and calcified material from the nucleus pulposus *(D)* has extruded through the fissure into the spinal canal. Dorsal displacement and compression of the spinal cord *(S)* have occurred. **C,** Transverse section of the vertebral canal 5 mm cranial to **B.** Extruded calcified material *(D)* from the nucleus pulposus is compressing the spinal cord *(S)* at this level.



A



B



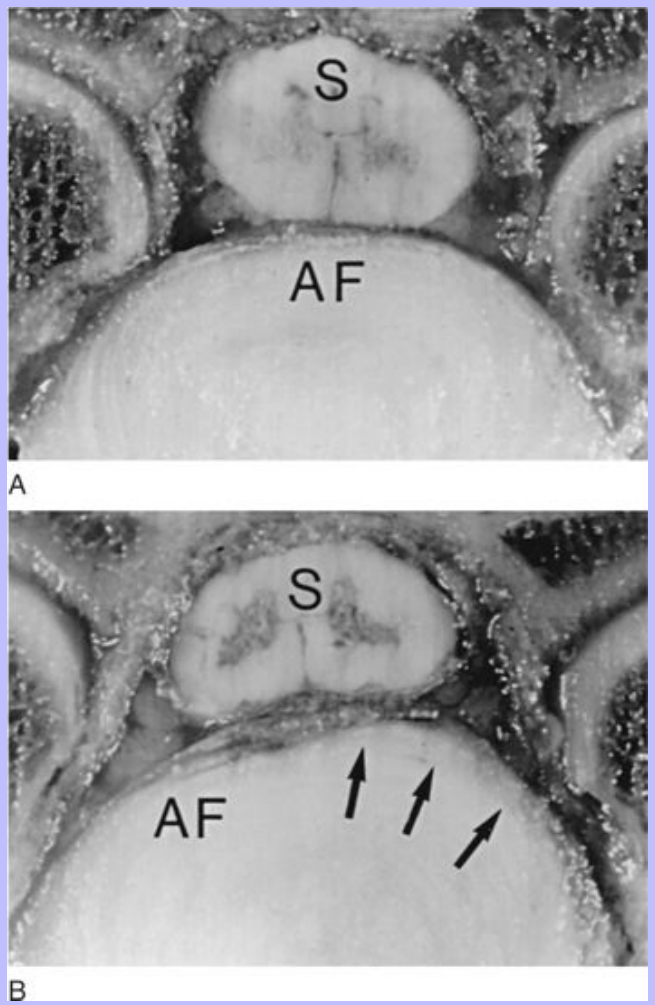
C

Type I disk extrusion often results in more severe clinical signs than type II protrusion, although the mechanical distortion and compression of the spinal cord caused by type II protrusion may be greater. The nucleus pulposus is most often extruded into the spinal canal acutely (minutes to hours) or subacutely (days) from disks undergoing chondroid degeneration, whereas slowly progressive spinal cord compression most often accompanies protrusion of disks undergoing fibroid degeneration, as the bulging fibrous mass increasingly enlarges within the spinal canal. The spinal cord changes seen in acute versus chronic spinal cord compression differ and are reflected in the difference in clinical signs and response to treatment seen in these two types of intervertebral disk disease. The severity of spinal cord injury depends on the velocity at which the compressive force is applied, the degree of compression, and the duration of the compression. Vascular factors, as well as mechanical distortion of the spinal cord as a result of herniated disk material, are important in the pathogenesis of resulting spinal cord lesions. Severe spinal cord lesions may be found without evidence of compression, presumably as a result of vascular changes.

865

866

Figure 193-10 Type II disk protrusion. Gross necropsy specimens from a 7-year-old female Doberman pinscher that had a history of progressively worsening tetraparesis and generalized ataxia. Myelography confirmed type II disk protrusion at C6–C7. The disk protrusion appeared to be predominantly on the left. **A,** Transverse section of the vertebral canal at the level of the C5–C6 disk. Note the normal appearance of the spinal cord (*S*) in the spinal canal, and the close anatomic relationship of the dorsal anulus fibrosus (*AF*) to the spinal cord. **B,** Transverse section of the vertebral canal at the level of the C6–C7 disk. Note the compression of the left spinal cord (*S*), caused by dorsal bulging (*arrows*) of the anulus fibrosus (*AF*) at this level.



Hemorrhage, edema, and necrosis of spinal cord gray and white matter are characteristic of acute spinal cord injury associated with acute type I disk extrusion. Hemorrhage and edema are not major features of chronic spinal cord compression in which white matter changes (e.g., demyelination, focal malacia, vacuolization, and loss of axons) are seen. Type I disk extrusions often are associated with rupture of vertebral venous sinuses, and hemorrhage into the epidural space may increase the degree of spinal cord compression. Pulmonary emboli arising from the nucleus pulposus have been described in three chondrodystrophoid dogs with acute thoracolumbar transverse myelopathies as a result of type I disk extrusions, presumably as a result of disk material entering the vertebral venous sinuses. The nucleus pulposus may also penetrate the dura mater. Traumatic rupture of the anulus fibrosus and extrusion of normal nucleus pulposus may occur, resulting in spinal cord compression and acute onset of clinical signs indicative of a transverse myelopathy.[170,171]

Degenerative disk disease also occurs in cats,[7,170,171] although the incidence of clinical signs associated with disk protrusion is low. The degenerative changes, distribution of disk protrusions, and clinical signs are similar to those seen with type II disk protrusions in nonchondrodystrophoid dogs. Type I disk extrusion associated with a calcification of intervertebral disks and an acute onset of neurologic deficits may occur in cats.

193.5.19.2 Clinical Findings

Chondroid degeneration and type I disk extrusion most commonly occur in dogs 3 years of age and older. Fibroid degeneration and type II disk protrusion most commonly occur in dogs older than 5 years of age. Clinical signs seen in association with type I disk extrusion include apparent pain and/or motor and/or sensory deficits. These clinical signs usually develop rapidly, within minutes or hours of disk extrusion. However, clinical signs may progress slowly over several days or may manifest periods of improvement and subsequent worsening over weeks or months. These findings are probably associated with extrusion of small amounts of disk material into the spinal canal over a period of time.

Clinical signs associated with type I disk extrusion in the cervical spine usually are less severe than those associated with extrusions in the thoracolumbar region because the vertebral canal in this region is larger in diameter in relation to the spinal cord than is the case in the thoracolumbar region. Apparent neck pain is the most common clinical finding in dogs with cervical disk extrusion. Affected dogs often hold the head and neck rigidly and cry out when moved, and they may show spasms of cervical musculature. Neurologic deficits indicative of a cervical myelopathy (e.g., proprioceptive deficits, tetraparesis, or tetraplegia) are seen less commonly.

Ipsilateral Horner's syndrome and hyperthermia have been described in cases of acute, severe, dorsolateral cervical disk extrusions. LMN deficits in the thoracic limbs may be seen in caudal cervical disk extrusions. Thoracic limb lameness may also be seen in caudal cervical disk extrusions as a result of nerve root compression, particularly from lateral disk extrusions in which disk material enters an intervertebral foramen.

Clinical findings with thoracolumbar type I disk extrusion, which depend on the severity of spinal cord injury, range from apparent back or abdominal pain to complete paraplegia and loss of deep pain perception. Neurologic deficits usually are indicative of a transverse myelopathy between T3 and L3, because most disk extrusions in this region occur between T11 and L3. LMN signs may be seen in the pelvic limbs if disk extrusion occurs caudal to L3 as a result of compression of the lumbosacral spinal cord or the nerves of the

cauda equina. LMN signs also may be seen in paraplegic animals with progressive hemorrhagic myelomalacia (PHM).

The panniculus reflex may be depressed or absent caudal to the site of disk extrusion. The site of a lesion is usually one or two vertebral spaces cranial to the loss or depression of the panniculus reflex. The Schiff-Sherrington sign may be seen in animals with acute type I disk extrusion caudal to T2.

The clinical signs seen in both cervical and thoracolumbar type I disk extrusion may be asymmetric, especially if the extrusion occurs dorsolaterally within the spinal canal.[172,173] Apparent pain associated with disk extrusions results from inflammation and/or ischemia caused by compression of meninges and/or spinal nerve roots. Extruded disk material initiates an extradural inflammatory reaction that results in fibrous adhesions between the dura mater and the extruded disk material. Pain may also arise from stimulation of sensory nerve endings in the anulus fibrosus and dorsal longitudinal ligament. The nucleus pulposus of each disk does not contain nerve fiber endings.

The clinical signs associated with type II disk protrusion generally progress slowly over a period of months. However, in some animals they may develop acutely over days. Neurologic deficits usually are indicative of a cervical or thoracolumbar myelopathy. Paraparesis or tetraparesis, depending on the site of the lesion, is the most common clinical finding, and deficits may be asymmetric. In the cervical spine, type II protrusions most commonly occur in caudal cervical disks. In some cases caudal cervical type II disk protrusion may be part of the spectrum of abnormalities associated with cervical spondylomyelopathy. Apparent neck or back pain may or may not be a feature of type II disk protrusion.

193.5.19.3 Diagnosis

A tentative diagnosis of type I disk protrusion or extrusion may be made on the basis of the patient's age, breed, history, and clinical signs; however, other causes of transverse myelopathy or apparent pain should be considered in the differential diagnosis. It must be remembered that apparent spinal pain is seen in animals with meningitis. Dogs with thoracolumbar disk extrusions may appear to have abdominal pain. The differential diagnosis in animals with type II disk protrusion includes other causes of progressive transverse myelopathy, the most likely being neoplasia or degenerative myelopathy.

Spinal radiographs and, in almost all cases, CSF analysis and myelography are necessary to confirm a diagnosis of disk extrusion or protrusion. General anesthesia is required to achieve the precise positioning needed to obtain radiographs of diagnostic value. Foam wedges or sandbags are usually needed to align the vertebral column parallel to the table top for lateral projections. Care must be taken, however, in anesthetizing and positioning animals suspected of having acute type I disk extrusions, because further extrusion of disk material and further spinal cord compression may occur with manipulation and movement of the spine.

Calcification of the nucleus pulposus is best seen on lateral radiographic views and usually is seen in one or more disks of most chondrodystrophoid dogs more than 1 year of age. Calcified disks also may be seen in older nonchondrodystrophoid breeds. The presence of calcified material in the nucleus pulposus is indicative of disk degeneration but by itself is not of clinical significance.

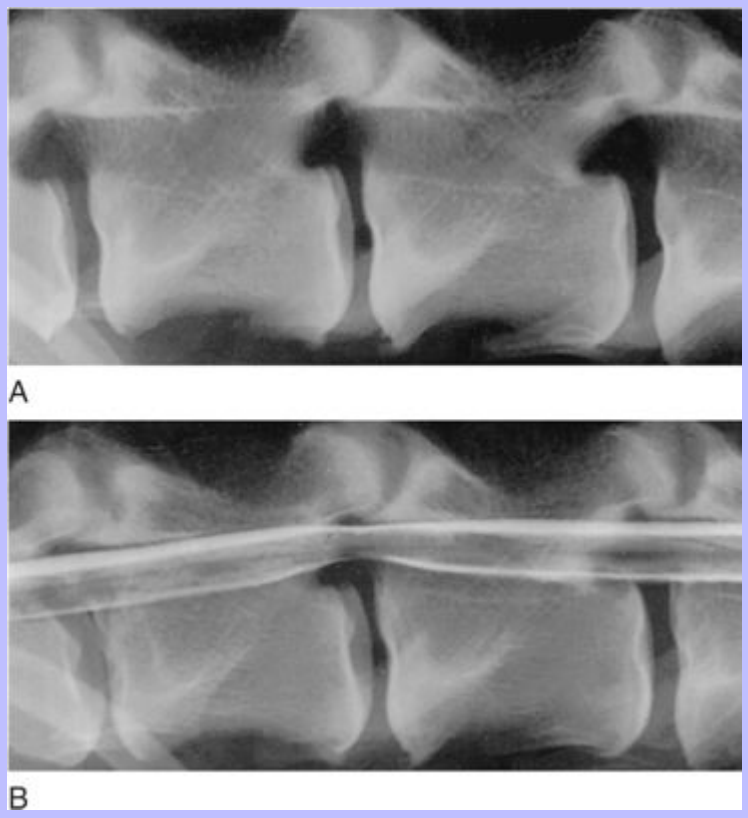
The disk space of an extruded disk may be narrower than adjacent disk spaces; it may be wedge shaped, with a decrease in the width of the disk space dorsally. However, positioning is important, because some disk spaces (C7–T1, T9–T10 or T10–T11, and L7–S1) are normally narrower than adjacent spaces, and cervical and lumbosacral disks are normally wedge shaped on hyperextension and flexion of the spine. “Spikes” of

calcified material suggestive of disk extrusion may extend dorsally from a disk. Calcified material may be present in the vertebral canal, but it often is difficult to visualize because of overlying vertebral articular processes or ribs. The intervertebral foramina are larger in the lumbar spine, and calcified material often is easily visualized in the spinal canal in this region. Disk material in the spinal canal may appear as a hazy, indistinct shadow or as a dense mass with distinct margins. In many cases of disk extrusion, calcified material is not visualized in the spinal canal, because the disk material is probably not sufficiently mineralized to be visible on radiographs. Ventrodorsal views, and in some cases oblique views, are important for determining the laterality of any visible mineralized material in the spinal canal. Vertebral osteophytes and vertebral endplate sclerosis may be seen in association with chronic disk degeneration and extrusion or, in cases of chronic disk degeneration, without disk extrusion or protrusion.

Type II disk protrusion may be associated with narrowing of the disk space, osteophyte production, and endplate sclerosis. Calcification of disk material rarely is seen with type II disk protrusion. In some animals with type I or type II disk herniation, obvious abnormalities are not seen on noncontrast vertebral radiographs (Figure 193-11).

Myelography is almost always necessary to confirm that disk material has herniated into the spinal canal, resulting in spinal cord compression.[173–175] Myelography is most important for determining the site (or sites) of disk herniation and for lateralizing disk material in the spinal canal prior to surgical decompression.[176] Myelography is necessary to distinguish disk protrusion from other causes of slowly progressive transverse myelopathy, such as spinal neoplasia and degenerative myelopathy.

Figure 193-11 Type II disk protrusion. Lateral radiograph **(A)** and myelogram **(B)** of the midlumbar vertebral column of a 7-year-old castrated male Great Dane with a 3-month history of corticosteroid-responsive back pain. The dog was neurologically normal at the time of this study. Slight narrowing of the L2–L3 disk and mild ventral spondylosis deformans are seen on the lateral radiograph. The myelogram confirms severe ventral spinal cord compression at the level of L2–L3 associated with a type II disk protrusion.



CSF should be collected and analyzed before myelography to rule out inflammatory or infectious disease of the spinal cord and/or meninges.[177] Clinical signs in animals with GME, distemper myelitis, FIP, spinal lymphoma, and other disorders may mimic those of cervical or thoracolumbar disk disease.

The characteristic myelographic findings in both type I and type II disk herniation into the spinal canal are extradural compression of the spinal cord with displacement of the spinal cord and narrowing of the subarachnoid space on lateral and/or ventrodorsal views, depending on the location of the compressive mass. Type II and most type I disk herniations result in a ventral or ventrolateral epidural mass that causes dorsal

displacement of the spinal cord. Disk material may extend over more than one vertebral segment in type I extrusions and may result in deviation or narrowing of contrast columns over more than one vertebral length. Disk material may completely encircle the spinal cord. Acute type I disk extrusions often are accompanied by spinal cord edema and swelling and occasionally by dural laceration.[178] The spinal cord may be widened over several segments, and the myelographic appearance is similar to that of an intramedullary mass, making precise determination of the site of disk extrusion difficult. In some animals, disk material is scattered along the spinal canal without obvious mechanical distortion of the spinal cord.

Rarely, in the cervical region type I disk extrusion may occur laterally or intraforaminally, resulting in neck pain or thoracic limb pain due to nerve root compression. In such cases myelograms may be normal; however, increased density associated with calcified disk material may be visualized intraforaminally on ventral oblique radiographs of the cervical spine. Traumatic disk protrusion is usually associated with narrowing of the intervertebral disk space on radiographs. Other abnormalities, such as vertebral fracture, luxation, or instability, also may be seen. Myelography is useful for determining whether spinal cord compression is present in such cases and therefore whether surgical decompression is indicated.

The use of advanced imaging techniques (CT or MRI) may aid in the exact localization of intervertebral disk extrusions, particularly in cases of intraforaminal disk extrusion.[179–181]

193.5.19.4 Treatment

193.5.19.4.1 Type I disk extrusion

The appropriate treatment for animals with type I disk extrusion depends on the individual animal's neurologic status. Medical treatment directed at reducing spinal cord edema with corticosteroid therapy is indicated only in animals with an acute onset of neurologic deficits that are examined within 8 hours of injury. The recommended agents and dosages are the same as those described for spinal cord trauma. The use of corticosteroids in dogs with type I disk extrusion has been associated with pancreatitis, gastrointestinal bleeding, and colonic perforation.

Nonsurgical (medical or conservative) treatment is recommended for animals with apparent pain only or animals that have mild neurologic deficits but are ambulatory and have not had previous clinical signs associated with disk disease. These animals should be strictly confined to a small area, such as a hospital cage or a quiet place away from other pets, for at least 2 weeks and walked (on a leash or harness) only to urinate and defecate. The objective of confinement is to allow fissures in the anulus fibrosus to heal, thus preventing further extrusion of disk material and allowing resolution of the inflammatory reaction caused by the small amounts of extruded disk material.

The use of analgesics, muscle relaxants, or nonsteroidal anti-inflammatory agents is not recommended in most cases, because it is believed that the pain relief they bestow encourages animals to exercise and thus risk further disk extrusion. Cautious use of analgesics or nonsteroidal anti-inflammatory agents occasionally may be indicated; however, strict confinement, followed by a period of restricted exercise, is imperative. Owners should also be warned that an animal's neurologic status may deteriorate, owing to extrusion of further disk material, despite this treatment. If the neurologic status worsens, treatment should be re-evaluated immediately. Owners should also be warned that recurrence of clinical signs is common, as a result of further disk extrusion at the same or a different site, and subsequent episodes may be more severe, especially in the thoracolumbar spine.

Animals with severe cervical pain frequently do not respond to cage rest. These dogs often have large amounts of disk material in the spinal canal. Dogs that do not show improvement after 7 to 10 days of confinement should be evaluated further using radiography and myelography, and ventral cervical decompression should be considered.

Surgical disk fenestration has been recommended as a prophylactic measure to prevent further extrusion of disk material into the spinal canal.[182,183] Fenestration of the disks most likely to herniate (C2–C3 through C6–C7 in the cervical spine and T11–T12 through L3–L4 in the thoracolumbar spine) is recommended in animals that have had one or more episodes of apparent neck or back pain and that have radiographic evidence of intervertebral disk disease. Various surgical techniques have been described.[164–166] However, fenestration of disks does not remove disk material from the spinal canal and therefore is not recommended as the sole surgical procedure in dogs that have radiographic and myelographic evidence of disk material in the spinal canal and of spinal cord compression.

The role of disk fenestration in the management of intervertebral disk disease is controversial.[182–185] Disk fenestration in the thoracolumbar region is not easily accomplished, and complications such as scoliosis, pneumothorax, and hemorrhage may occur. Disk fenestration in the cervical region is achieved more easily and rarely is associated with such complications. Fenestration does not prevent the recurrence of disk extrusion in all animals. The effectiveness of fenestration depends largely on the amount of nucleus pulposus removed. Completion of disk fenestration is recommended at the time of spinal cord decompression.

Animals with neurologic deficits such as paresis or paralysis in which deep pain perception is intact; animals with recurrent bouts of apparent back or neck pain; and animals with apparent back or neck pain (or mild neurologic deficits) unresponsive to strict confinement should be evaluated by means of spinal radiographs, CSF analysis, and myelography. Surgical decompression of the spinal cord and removal of disk material from the spinal canal should be considered. Although many dogs with moderate or severe paresis improve neurologically if treated with cage rest, neurologic recovery is often more rapid and more complete after surgical decompression of the spinal cord. In addition, the neurologic status of some dogs with type I disk extrusion, especially in the thoracolumbar spine, suddenly worsens over a period of hours or days despite medical treatment. Such deterioration usually results from further disk extrusion, which may cause irreversible spinal cord damage and permanent paralysis. This progression of signs always is a risk with medical treatment of animals with thoracolumbar disk disease. Progression is impossible to predict on the basis of the history, clinical signs, or radiography. Owners should be made aware of treatment options and offered the opportunity of referral to an appropriate surgical facility when animals are initially presented. Surgical decompression should be performed as soon as possible to prevent further spinal cord damage from sustained compression or further extrusion of disk material. Also, if surgery is delayed 2 to 3 weeks, disk material hardens and becomes adherent to the dura mater and is difficult or impossible to remove from the spinal canal.

The prognosis for neurologic recovery in animals that retain deep pain perception after surgery is fair to very good. The major factors that correlate with the degree of postsurgical neurologic improvement are the animal's neurologic status before surgery, the rapidity of onset of clinical signs, and the time interval between the onset of clinical signs and surgical decompression. Animals that have severe neurologic signs, a rapid onset of clinical signs (hours), and a long period before surgery generally have a prolonged recovery and may have varying degrees of permanent neurologic deficit.

The incidence of recurrence of clinical signs due to disk extrusion is greater in nonsurgically than surgically treated dogs. One author found that one third of dogs with type I disk herniation that were treated nonsurgically had a recurrence of clinical signs and generally showed greater severity of neurologic deficits at the time of recurrence.[1] Another author reported a recurrence rate of 40% in nonsurgically treated dogs.[1]

The advantages and disadvantages of various techniques for spinal cord decompression have been discussed.[125–127] Surgical treatment is not without risks. Anesthesia is necessary, and surgery occasionally results in further spinal cord damage, incurred through surgical manipulation. Nonsurgical treatment should be attempted in animals that are poor anesthesia or surgical candidates or if surgical treatment is not possible financially.

In animals that have clinical signs of a complete transverse myelopathy and in which deep pain perception has been absent for more than 24 hours, the prognosis for return of spinal cord function is poor despite medical or surgical treatment. Some of these animals may improve neurologically if given sufficient time; however, it is a matter of controversy whether surgical treatment increases the probability of improvement. When deep pain perception has been absent for less than 24 hours, the prognosis for return of spinal cord function is poor; however, surgical treatment may increase the likelihood of neurologic improvement.

Regardless of whether medical or surgical treatment is instituted, animals that are paretic or paralyzed require intensive nursing care.[186] Neurologic improvement may take weeks or months, and this requires owner co-operation and enthusiasm regarding care and physical therapy. Manual expression, intermittent catheterization, and/or indwelling catheterization of the bladder are often required to ensure emptying of the bladder. Weekly urinalysis, especially in animals that do not have voluntary control of micturition, is important in monitoring for urinary tract infection. It is also important to keep animals well padded, clean, and dry to prevent the formation of pressure sores, and to ensure that caloric and water intake is adequate. Physical therapy does not result in neurologic improvement but helps prevent disuse muscle atrophy associated with paraplegia or tetraplegia. Physical therapy should not be attempted in animals treated medically for at least the first 2 weeks after the onset of signs, because further extrusion of disk material may occur.[140]

193.5.19.4.2 Type II disk protrusion

Treatment with corticosteroids may result in neurologic improvement for variable periods in animals with type II disk protrusion. However, corticosteroid therapy is not curative. The reason for this improvement is not clear, because the intramedullary hemorrhage and edema seen in cases of acute spinal cord injury are not a feature of chronic spinal cord compression. In the thoracolumbar spine, surgical removal of protruded disk material may result in clinical improvement; however, the neurologic status of some dogs is worsened permanently despite careful surgical technique. The reasons for this are not known, but increased vascular permeability in the spinal cord has been described in association with release of chronic spinal cord compression, and this probably plays a role in the phenomenon. Ventral decompression in the cervical spine allows removal of protruded type II disk material, and neurologic improvement may occur over several months; however, some dogs, especially those with moderate to severe neurologic deficits prior to surgery, may manifest temporary or permanent worsening of clinical signs postoperatively.

193.5.19.4.3 Acupuncture

The use of acupuncture for the treatment of intervertebral disk extrusion in dogs is controversial. Acupuncture may be an excellent adjunctive therapy in nonsurgical management of affected dogs.[187] However, the use of acupuncture as an alternative to surgery for dogs that have severe spinal cord compression resulting from disk extrusion is not recommended.

193.5.19.4.4 Chemonucleolysis

Injection of the proteolytic enzyme chymopapain into the nucleus pulposus of intervertebral disks to cause discolysis has been used infrequently in veterinary medicine.[81,188–191] The precise mechanism by which chymopapain causes dissolution of the nucleus pulposus is unknown. In one study in dogs, dissolution of the nucleus pulposus was demonstrated histologically in all cervical intervertebral disks injected with chymopapain via a ventral surgical approach. Similar pathologic findings were found in the lumbar disks of dogs injected with chymopapain transcutaneously under fluoroscopic guidance via a lateral approach. Significant postoperative clinical complications were not seen. Radiographic narrowing of the intervertebral disk spaces was found in both the cervical and lumbar chymopapain-injected spaces. Cervical injection resulted in a more noticeable narrowing than did lumbar injection. However, successful injection, as determined histologically, was not always detected radiographically. These studies have described only the acute response to chymopapain. Another study has shown that chymopapain injection results in progressive dissolution of the nucleus pulposus and eventual regeneration of nuclear ground material.

Chemonucleolysis may be of benefit in animals with intervertebral disk disease when the nucleus pulposus is still contained within an intact or partly ruptured anulus fibrosus. Dissolution of the nucleus pulposus in these cases may relieve the pressure exerted by the protruding disk on the spinal cord and nerve roots. Chemonucleolysis may also be useful as a prophylactic measure in animals with evidence of intervertebral disk degeneration to prevent acute type I disk extrusion.

Chemonucleolysis is not indicated in cases of type I disk extrusion, because the enzyme is unable to reach sequestered nucleus pulposus in the spinal canal. Chemonucleolysis has been used in the treatment of type II disk protrusion in the cervical spine of large breed dogs. Most of the dogs in one study improved clinically despite a persistence or only slight decrease in the degree of spinal cord compression on myelography. Injection of chymopapain to the intervertebral disks via a surgical approach is recommended to prevent inadvertent intrathecal injection or accidental penetration of the vertebral arteries, spinal arteries, or spinal nerve roots. Further evaluation of the effect of chemonucleolysis in dogs with intervertebral disk disease is needed; however, it seems likely that this technique may have advantages over the methods used at present for surgical disk fenestration.

193.5.20 Ischemic Myelopathy Caused by Fibrocartilaginous Embolism

193.5.20.1 Etiology and Pathogenesis

Ischemic myelopathy results from ischemic necrosis of spinal cord gray and white matter associated with fibrocartilaginous emboli that occlude arteries and/or veins of the leptomeninges and spinal cord parenchyma of dogs[192–194] or cats.[195,196] This disease is characterized by an acute onset of neurologic deficits and is

generally nonprogressive after several hours. In most cases the substance occluding the spinal cord arteries and veins has histologic and histochemical properties similar to those of fibrocartilage of intervertebral disks and is presumed to originate from the nucleus pulposus of an intervertebral disk. The pathogenesis of this fibrocartilaginous embolism is not known. Acute spinal cord infarction has been reported secondary to neoplastic emboli and intravascular coagulation.[197] Most affected animals do not have evidence of degenerative intervertebral disk disease and are dog breeds that have a low incidence of degenerative disk disease and type I disk extrusion.

193.5.20.2 Clinical Findings

Ischemic myelopathy most commonly occurs in large and giant breed dogs, generally between 1 and 9 years of age, of either gender, but it has also been described in many other breeds, including smaller dogs such as miniature schnauzers and Shetland sheepdogs.[192–194] It has been described in cats.[195,196]

Ischemic myelopathy is characterized by an acute onset of neurologic deficits that may be severe. Clinical signs may progress over several hours but are generally not progressive after 12 hours. Affected animals usually do not have a history or evidence of trauma but may have a history of exercise prior to the onset of clinical signs. Apparent pain usually is not present at the time of examination or during the course of the disease, although dogs are often reported to cry out at the onset of clinical signs.

Neurologic deficits usually are bilateral and are often but not always asymmetric. The clinical signs seem to depend on the location and extent of the spinal cord lesion. Many spinal cord segments may be involved, and the neurologic deficits present may indicate extensive gray and white matter necrosis. If fibrocartilaginous embolism occurs in the cervical enlargement, unilateral or bilateral LMN signs in the thoracic limbs and UMN signs in the pelvic limbs are seen. The absence of the panniculus reflex unilaterally or bilaterally often is noted in lesions involving the T1 spinal cord segment. An ipsilateral Horner's syndrome commonly is seen in dogs with fibrocartilaginous embolism of the cervical enlargement as a result of damage to preganglionic sympathetic cell bodies in spinal cord segments T1 and T2. Horner's syndrome may also be seen in severe lesions in the cervical spinal cord, owing to interruption of the tectotegmental spinal tract.

Fibrocartilaginous embolism in the lumbosacral spinal cord causes unilateral or bilateral LMN signs in the pelvic limbs, anal and urinary sphincters, and tail. Lesions may also occur in the C1 to C5 and T3 to L3 spinal cord segments and may result in symmetric or asymmetric UMN signs in all four limbs or in the pelvic limbs, respectively. Neurologic deficits may range from decreased conscious proprioception and mild paresis to complete paralysis and analgesia in affected limbs.

193.5.20.3 Diagnosis

Ischemic myelopathy should be suspected in any dog (especially large and giant breed dogs) with an acute onset of nonprogressive neurologic deficits that are not associated with apparent spinal pain, especially if the deficits are asymmetric or indicate that at least several spinal cord segments are involved. A diagnosis is made by ruling out other causes of myelopathy. Spinal radiographs are normal. The CSF may be normal or may have an elevated protein concentration as a result of leakage of protein through damaged vascular endothelium. Xanthochromia may be present 48 hours or more after a subarachnoid hemorrhage. The myelographic appearance usually is normal, although mild intramedullary swelling as a result of spinal cord edema may be seen for as long as 24 hours after the onset of clinical signs.

193.5.20.4 Treatment

Corticosteroids (as recommended for spinal trauma) may be given initially to reduce any secondary spinal cord edema; however, such edema usually resolves after several days. Good nursing care is essential in recumbent animals to prevent pressure sores, urinary tract infections, and contracture of denervated muscles. The prognosis depends on the severity of an animal's neurologic deficits. Animals that retain pain perception in the affected limbs and tail usually regain neurologic function, although recovery may take several weeks to months, and LMN signs may persist (muscle atrophy and/or paresis). Animals with absent pain perception for 24 hours are likely to have irreversible spinal cord damage and have a poor prognosis for return of function in the affected limb or limbs. Many animals show improvement within 2 weeks of the onset of signs unless extensive gray matter destruction has occurred.

193.5.21 Leukoencephalomyelopathy of Rottweilers

193.5.21.1 Etiology and Pathogenesis

Leukoencephalomyelopathy is a demyelinating disorder of the brain and spinal cord that has been reported to occur in rottweilers. It is characterized by progressive tetraparesis and hypermetria, especially of the thoracic limbs.

Leukoencephalomyelopathy has been reported in two dogs in the United States,[198] and a similar disorder has been reported in 16 rottweilers in the Netherlands.[199] Histopathologic examination showed demyelination in the white matter of the spinal cord, brain stem, and cerebellum, with intact naked axons and thinly myelinated axons accompanied by reactive astrogliosis. The spinal cord lesions were found in the lateral funiculi and occasionally the dorsal funiculi, predominantly in the cervical and thoracic spinal cord, and tended to be bilaterally symmetric. The lack of neuronal fiber degeneration makes primary demyelination more likely than secondary demyelination.

The etiology of this disease is unknown. It may be the result of an acquired primary demyelinating disease, but whether the lesions seen are due to a single demyelinating event or are the result of repeated demyelination and remyelination is not known. The lesions' bilaterally symmetric character indicate that toxic, metabolic, and nutritional mechanisms may be involved. Infectious causes (e.g., CD virus) may also result in demyelination. Vascular mechanisms may be involved, because the lesions have a segmental distribution; however, axon degeneration would be expected. An inherited condition in which myelin formation is defective and cannot be maintained (leukodystrophy) is also possible. The two dogs in the U.S. report were related, as were the 16 dogs in the Netherlands.

Other leukodystrophies have been reported in young animals, although an adult-onset leukodystrophy has not been described in dogs. The relationship of this disease to neuroaxonal dystrophy of rottweilers is not known.[200] Histopathologic lesions and clinical findings differ from those described in dogs with neuroaxonal dystrophy; however, a dog related to a dog with leukoencephalomyelopathy was diagnosed as having neuroaxonal dystrophy.

193.5.21.2 ### Clinical Findings

Both males and females have been reported to be affected. Clinical findings included tetraparesis, hypermetria (especially of the forelimbs), decreased conscious proprioception (especially of the pelvic limbs), and exaggerated spinal reflexes. The clinical signs became apparent between 18 and 42 months of age, and the abnormalities progressed slowly over several months to 1 year. The neurologic abnormalities were consistent with a transverse myelopathy of the cervical spinal cord. Neurologic deficits referable to structures rostral to the foramen magnum were not detected.

193.5.21.3 ### Diagnosis and Treatment

The diagnosis may be made on the basis of the dog's age and breed and by ruling out other causes of cervical myelopathy, such as CD myelitis, GME, cervical spondylomyelopathy, and spinal neoplasia. The results of radiography, CSF analysis, and myelography were normal in the dogs reported. Treatment of leuko-encephalomyelopathy of rottweilers has not been effective.

193.5.22 ## Lumbosacral Vertebral Canal Stenosis

193.5.22.1 ### Etiology and Pathogenesis

The term *lumbosacral vertebral canal stenosis* encompasses a spectrum of disorders that result in narrowing of the lumbosacral vertebral canal, with consequent compression of the cauda equina. The term *cauda equina syndrome* describes a group of neurologic signs that result from compression, destruction, or displacement of the nerve roots and spinal nerves that form the cauda equina and that have a variety of causes, including lumbosacral vertebral canal stenosis (Box 193-6).[201]

Lumbosacral vertebral canal stenosis is defined as an acquired disorder of large breed dogs that results from several or all of the following: type II disk protrusion (dorsal bulging of the anulus fibrosus), hypertrophy and/or hyperplasia of the interarcuate ligament, thickening of the vertebral arches or articular facets and, infrequently, subluxation/instability of the lumbosacral junction. It is likely that several separate disorders currently are included in this definition. Other terms have been used to describe this syndrome, including *lumbo-sacral spondylolisthesis, lumbar spinal stenosis,* and *lumbosacral instability*. In humans, the term *spondylolisthesis* refers specifically to a forward (anterior) movement of a lower lumbar vertebra relative to a lumbar vertebra or sacrum directly below it. This problem rarely occurs in dogs, in which the most frequently encountered problem is a ventral slippage of the sacrum relative to the body of the L7 vertebra. The term *retrolisthesis* has been proposed to describe this “reverse spondylolisthesis” of dogs. *Lumbar spinal stenosis* is a term that perhaps is best used to describe a congenital (“idiopathic”) syndrome reported to occur in young dogs. *Lumbosacral instability* is a misleading term, because instability is not demonstrated consistently in association with lumbosacral vertebral canal stenosis.

193.5.22.1.1 **Box • 193-6 Disorders that Produce Signs of Cauda Equina Dysfunction in Dogs**

193.5.22.1.1.1 **Congenital Disorders**

Vertebral and/or nerve root anomalies (e.g., spina bifida)

Idiopathic lumbar stenosis

193.5.22.1.1.2 Acquired Disorders

Infections (e.g., discospondylitis)

Neoplasia (e.g., malignant nerve sheath neoplasia)

Intervertebral disk disease

Iatrogenic stenosis (e.g., postsurgical scarring)

Lumbosacral vertebral canal stenosis (with/without "retrolisthesis")

193.5.22.1.1.3 Combined Disorders

Combination of congenital and acquired disorders (e.g., disk degeneration and lumbosacral vertebral canal stenosis)

870

871

Certain similarities between vertebral and soft tissue alterations seen in dogs with lumbosacral vertebral canal stenosis and in Doberman pinschers with caudal cervical spondylomyelopathy have been noted. Because the etiology and pathogenesis of both conditions are incompletely understood, such comparisons are of little significance at the present time. An association has been reported between lumbosacral stenosis and transitional vertebrae in German shepherds.[202] In another report, more than 30% of German shepherds with clinical signs of cauda equina compression had radiographic and pathologic abnormalities consistent with osteochondrosis of the sacral endplate.[203]

193.5.22.2 Clinical Findings

Acquired degenerative lumbosacral vertebral canal stenosis occurs most commonly in large breed dogs, especially German shepherds.[204] Males appear to be affected more frequently than females. The congenital ("idiopathic") form appears to affect smaller breed dogs. Affected dogs in both categories are between 3 and 7 years of age, although the problem can occur at any age. Degenerative lumbosacral vertebral canal stenosis is rarely recognized in cats.[7,171,193]

Signs of cauda equina compression seen frequently in affected dogs include apparent pain on palpation of the lumbosacral region, on caudal extension of the pelvic limbs, or on elevation of the tail; difficulty rising; pelvic limb lameness (often unilateral); pelvic limb muscle atrophy; paresis of the tail; scuffing of the toes; urinary and/or fecal incontinence or inappropriate voiding as a result of an inability to assume a voiding posture; self-mutilation of the perineum, tail, or pelvic limbs; and rarely, paraphimosis. These signs most often are insidious in onset and progress gradually over months, and they are easily confused with the signs of hip dysplasia or degenerative myelopathy.[204–206]

Abnormalities detected on neurologic examination include gait deficits related to sciatic nerve paresis (e.g., dragging of toes). Depression or loss of conscious proprioception, normal or slightly exaggerated patellar reflexes ("pseudoexaggeration" related to loss of antagonism to femoral nerve–innervated muscles by sciatic nerve–innervated muscles), depressed or absent flexion reflexes in pelvic limbs, decreased anal tone and anal

sphincter reflexes, atonic bladder, hypesthesia of the perineum and tail, and muscle atrophy may be seen. These abnormalities relate to deficits of the sciatic, pudendal, caudal, and pelvic nerves, the nerve roots of which make up the cauda equina.[204–206]

193.5.22.3 Diagnosis

Characteristic clinical findings may be consistent with a diagnosis of degenerative lumbosacral vertebral canal stenosis. Careful mapping of areas of loss of cutaneous sensation may assist the detection of involved nerve roots. However, the syndrome must be confirmed with plain radiographs and special radiographic procedures.[207] Rarely can this condition be diagnosed on the basis of plain radiographic findings alone. Plain radiographic findings include spondylosis deformans ventral and lateral to the lumbosacral articulation, sclerosis of vertebral endplates, "wedging" or narrowing of the L7–S1 disk space, and secondary degenerative joint disease in the region of the L7–S1 articular facets (Figure 193-12). Ventral displacement of the sacrum with respect to L7 (retrolisthesis) and diminished dorsoventral dimensions of the lumbosacral spinal canal may be seen; however, such findings must be interpreted with caution, because they may be seen in normal dogs in association with slight rotation of the vertebral column on lateral radiographs. General anesthesia is mandatory for obtaining radiographs of the lumbosacral vertebral column. A ventrodorsal projection also is recommended.

"Stressed" plain radiographic projections (flexed and extended views), obtained with careful attention to avoid rotation, often help detect instability or retrolisthesis. Several attempts to separate normal dogs from dogs with lumbosacral vertebral canal stenosis by means of objective measurements made from radiographs have not been successful.[208] The appearance on plain radiographs helps eliminate other causes of cauda equina syndrome (e.g., discospondylitis or vertebral neoplasia). Linear tomography, when available, may provide specific information about the diameter of the lumbosacral vertebral canal that cannot be obtained from plain radiographs.

Electromyography may complement information available from a neurologic examination and from plain spinal radiographs by confirming denervation in muscles innervated by the nerves of the cauda equina. Motor nerve conduction velocity determinations in the sciatic and tibial nerves and measurement of evoked spinal cord potentials may also provide indirect evidence of cauda equina dysfunction.[209,210] Several contrast radiographic techniques can be used to examine the lumbosacral vertebral canal. Such techniques must be used to demonstrate soft tissue vertebral canal stenosis.[209,211] Myelography most often is useful in the diagnosis of lumbosacral problems, because the terminal portion of the subarachnoid space of dogs may fill with contrast material at this level. Many investigators have used transosseous vertebral sinus venography (filling of vertebral sinuses with contrast material) and epidurography (filling of the lumbosacral epidural space with contrast material) in an attempt to outline soft tissue stenosis of the lumbosacral vertebral canal. Th results obtained with either of these techniques must be interpreted cautiously, because false-positive studies occur with both.

Discography is useful for confirming the presence of lumbosacral soft tissue stenosis.[209,212] Discography consists of radiography performed after injection of contrast material into the nucleus pulposus of an intervertebral disk (Figure 193-13). This technique has special application in the lumbosacral disk space.

CT, either alone or combined with the contrast techniques listed above, and MRI may provide further information about soft tissue stenosis of the lumbosacral vertebral canal, particularly with regard to the L7–S1 intervertebral foramen.[213–217]

Surgical exploration may be indicated in dogs (with the appropriate history and clinical signs) in which the results of ancillary diagnostic tests do not provide a definitive diagnosis of soft tissue stenosis.

193.5.22.4 Treatment

Some affected dogs in which the clinical signs are mild or the apparent lumbosacral pain is the sole problem improve temporarily after strict confinement and restricted leash exercise for 4 to 6 weeks. The use of analgesic drugs or corticosteroids has been recommended; however, such use must be accompanied by strict confinement.

Clinical signs commonly recur in affected dogs treated only with medical therapy. Dogs with recurrence of signs and dogs that are moderately to severely affected at the time of initial presentation (especially those with urinary/fecal incontinence) should be considered candidates for surgery. Dorsal decompressive laminectomy of the L7 and S1 vertebrae is recommended. This procedure may be combined with foraminotomy or facetectomy in dogs in which compression of the spinal nerves at the level of the intervertebral foramina is suspected. In animals with radiographically confirmed instability or significant retrolisthesis, fusion of the lumbosacral articulation may be necessary. A dorsal approach for fusion has been recommended.[218]

Patients should be confined for 2 to 4 weeks after surgery. Postoperative complications include seroma formation at the surgical site and formation of a laminectomy scar at the site of the laminectomy. Both may be avoided by use of appropriate surgical technique and postoperative patient management.

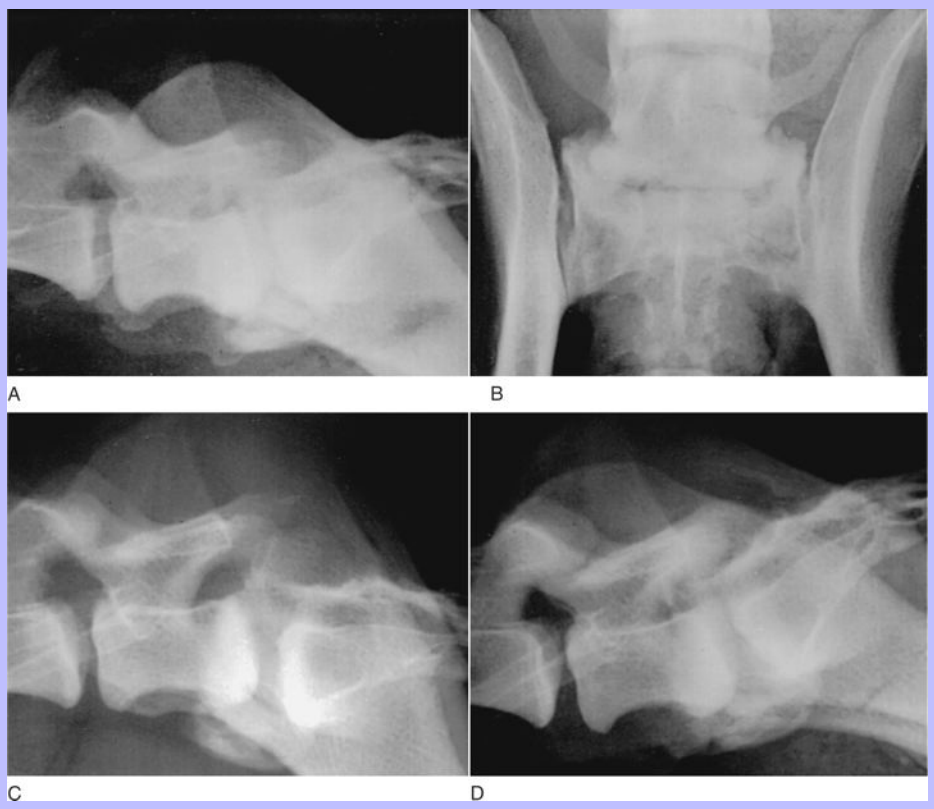
871

872

Attention to bladder emptying may be necessary in dogs with bladder atony prior to surgery. The bladder should be manually expressed three times a day in such dogs. Urine should be submitted for culture and sensitivity testing before and 2 weeks after surgery, and appropriate antibiotic therapy should be instituted as indicated by the results.

The prognosis for affected dogs depends on the severity of signs before surgery. Return to normal function may be expected in dogs that are mildly affected prior to surgery. Dogs with bladder atony or a flaccid anal sphincter prior to surgery have the poorest prognosis.

Figure 193-12 Lumbosacral vertebral canal stenosis. Lateral **(A)** and ventrodorsal **(B)** radiographs of the lumbosacral region of the vertebral column of a 7-year-old female vizsla. The dog had a history of apparent spinal pain, hypotonic tail, urinary incontinence, and pelvic limb paresis. Sclerosis of the vertebral endplates of L7 and S1, L7–S1 spondylosis deformans, "wedging" of the L7–S1 disk, and malalignment of L7–S1 are evident on the neutrally positioned lateral projection. Spondylosis deformans is seen lateral to the L7–S1 vertebral articulation on the ventrodorsal projection. A flexed lateral projection **(C)** confirms the presence of "retrolisthesis" with excessive ventral movement of the sacrum with respect to the body of L7. Instability of the lumbosacral articulation is further suggested by the extended projection **(D),** in which "wedging" of the L7–S1 disk can be seen. Use of these stressed projections is essential for confirmation of instability associated with lumbosacral vertebral canal stenosis.



193.5.23 Mucopolysaccharidosis

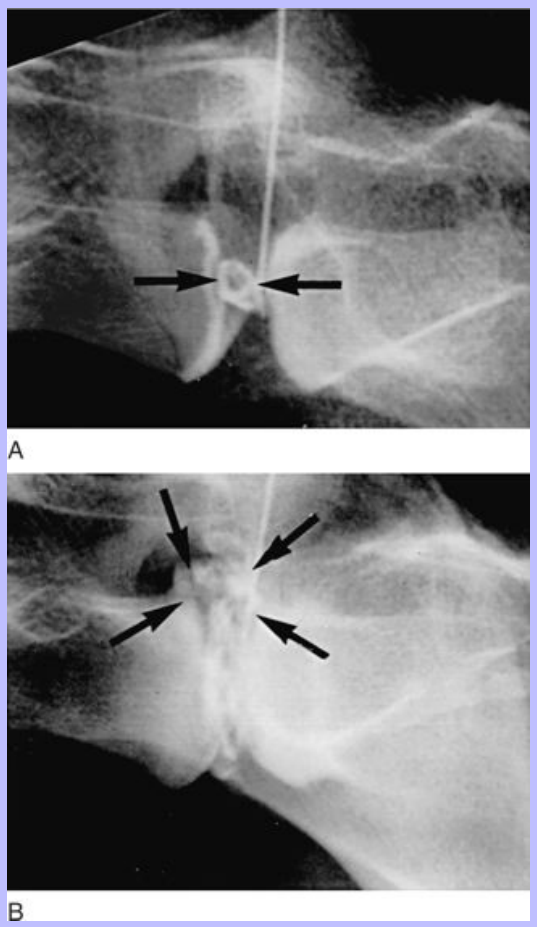
193.5.23.1 Etiology and Pathogenesis

The mucopolysaccharidoses are a group of genetic diseases that result from defects in the metabolism of glycosaminoglycans. Two subclasses have been recognized in cats, and paraparesis associated with spinal cord compression has been reported in Siamese cats with mucopolysaccharidosis VI (MPS VI).[6,7] MPS VI is the result of a deficiency of the lysosomal enzyme arylsulfatase B; in addition to causing characteristic physical deformities, it can result in (1) skeletal changes, including fusion of the cervical vertebrae, variable fusion of thoracic and lumbar vertebrae, and bony proliferation and protrusion into the vertebral canal in the thoracic and lumbar spine, causing compression of the spinal cord, and (2) bony proliferation in the intervertebral foramina, causing nerve root compression.[219] Bony proliferative changes and associated spinal cord compression occur prior to or at the time of epiphyseal closure (about 9 months of age) and are probably nonprogressive after this time. MPS VI is an inherited abnormality with an autosomal recessive mode of inheritance.

872

873

Figure 193-13 Lumbosacral vertebral canal stenosis. **A**, Discogram at L7–S1 in a normal 5-year-old male Saint Bernard. Note the placement of a spinal needle in the nucleus pulposus of the L7–S1 disk. Contrast material (0.2 mL) is confined to the region of the nucleus pulposus *(arrows)*. **B,** Discogram at L7–S1 in a 6-year-old male Great Dane with a history of apparent spinal pain and self-mutilation of the right side of the tail. Note the irregular pattern of contrast filling of the disk and the dome-shaped region of contrast material that has accumulated in the vertebral canal *(arrows)*. This abnormal discogram is consistent with a diagnosis of L7–S1 disk degeneration with bulging of the dorsal anulus fibrosus into the vertebral canal. This diagnosis was confirmed through dorsal laminectomy over this site.



MPS I, which is due to a deficiency of alpha$_l$-iduronidase, has been reported in a domestic short-hair cat. The clinical features were similar to those of MPS VI, but bony proliferative changes and associated spinal cord compression were not found. Although vacuolar changes were observed in the neurons of the brain and cervical spinal cord, presumably as a result of storage of glycosaminoglycans, neurologic deficits were not found clinically. MPS I probably has an autosomal recessive mode of inheritance.

193.5.23.2 Clinical Findings

The characteristic physical findings with MPS VI are a small head; a flat, broad face; widely spaced eyes; corneal clouding; small ears; depressed bridge of the nose; large forepaws; and a concave deformity of the sternum. Affected kittens are smaller than normal littermates, and physical deformities are noticeable by 8 weeks of age. Neurologic deficits due to skeletal changes and spinal cord compression are seen between 4 and 7 months of age and progress over 2 to 4 weeks. Neurologic findings, which are indicative of a transverse myelopathy between T3 and L3, include absent conscious proprioception, normal to exaggerated pelvic limb reflexes, and decreased pain perception in the pelvic limbs. The thoracic limb gait may be normal, or affected cats may have a crouching posture. Spinal reflexes in the thoracic limbs are normal.

193.5.23.3 Diagnosis

Radiographs of the spine show vertebral fusion and bony protrusions into the spinal canal and intervertebral foramina of the thoracolumbar spine.[219] However, bony proliferation is not an indication of neurologic dysfunction. Myelography is necessary to demonstrate spinal cord compression. Subarachnoid CSF puncture may be difficult, owing to proliferative changes around the vertebrae. MPS VI can be confirmed by measurement of arylsulfatase B activity in leukocytes.

193.5.23.4 Treatment

Because skeletal changes are nonprogressive after about 9 months of age, decompressive surgery may result in improvement in neurologic signs. However, spinal cord compression may be present at more than one site. The underlying lysosomal enzyme deficit is not amenable to treatment at present. Bone marrow transplantation is being investigated as a possible therapy for MPS VI.[220]

193.5.24 Myelodysplasia

193.5.24.1 Etiology and Pathogenesis

The term *myelodysplasia* describes a number of malformations of the spinal cord believed to result from incomplete closure or development of the neural tube.[6,7,221] Malformations identified histopathologically include anomalies of the central canal (hydromyelia, duplication of the central canal, or absence of the central canal); anomalies of the central gray matter, ventral median fissure, and dorsal median septum; gray matter ectopias, chromatolysis, and loss of nerve cell bodies; and syringomyelia, usually in the dorsal columns. Lesions are found throughout the spinal cord but are more severe in the lumbar region.

Myelodysplasia is considered to be an inherited condition in the weimaraner, transmitted by a mutant gene.[222] Both males and females are affected. Myelodysplasia has been described in other breeds of dogs

and cats, including a Dalmatian, a rottweiler, a West Highland white terrier, an English bulldog, mixed-breed dogs, and Manx cats.[7,221,223] The etiology and pathogenesis of the condition in these animals are unknown.

193.5.24.2 Clinical Findings

Clinical signs vary in severity and usually are referable to a transverse myelopathy between T3 and L3. Clinical abnormalities usually are evident at 4 to 6 weeks of age, when puppies become ambulatory, although abnormal reflexes have been reported in affected newborn puppies. The major clinical finding in affected dogs is a symmetric, "bunny hopping" pelvic limb gait. Other clinical findings are crouching stance, abduction or overextension of one or both pelvic limbs, decreased conscious proprioception in the pelvic limbs, scoliosis and, in one case, torticollis. The spinal reflexes and pain perception usually are normal. In weimaraners, other findings include abnormal hair "streams" in the dorsal neck region, koilosternia (a gutterlike depression in the chest) and, occasionally, a head tilt.

873

874

193.5.24.3 Diagnosis

The diagnosis is made on the basis of the history, signalment, clinical signs, plain radiography, CSF analysis, and myelography. Advanced imaging techniques (CT and MRI) have also been used.[223]

193.5.24.4 Treatment

No effective treatment exists. In weimaraners, and probably in other dogs and in cats, the clinical signs are not progressive, and affected animals may be acceptable pets.

193.5.25 Neoplasia

193.5.25.1 Etiology and Pathogenesis

The spinal cord may be a site of primary or metastatic neoplasia, or it can be compressed or invaded by primary or metastatic tumors arising from the vertebrae and surrounding tissues.[224–227] Primary neural tumors include astrocytoma, glioma, ependymoma, neuroepithelioma, malignant nerve sheath neoplasm (schwannoma, neurofibroma, neurofibrosarcoma), meningioma, meningeal sarcoma, and reticulum cell sarcoma. Primary lymphosarcoma of the spinal cord also has been reported in a dog.

Tumors of spinal nerves that extend into the spinal canal or spinal nerve roots may cause extradural or intradural compression of the spinal cord.[228] These tumors may also invade the spinal cord parenchyma. The distinction between schwannoma, Schwann cell sarcoma, neurofibroma, and neurofibrosarcoma is difficult to make histologically, but all have similar features clinically and on gross pathology.[224] The term *malignant nerve sheath neoplasm* has been proposed for this tumor.[224] These tumors may involve any cranial or spinal nerve or dorsal or ventral nerve root and commonly spread to involve adjacent nerves and nerve roots. Malignant nerve sheath tumors commonly arise from nerve roots or spinal nerves contributing to the brachial plexus. The tumors may arise from more than one site. Lymphosarcoma may also involve peripheral nerves and may extend along spinal nerves and nerve roots into the spinal canal, resulting in clinical signs of spinal cord disease.[229] Meningeal sarcomatosis is a rare condition characterized by diffuse infiltration of the leptomeninges by neoplastic mesenchymal cells.

The spinal cord may also be compressed by tumors originating from surrounding structures. These tumors most commonly arise from bone, cartilage, fibrous tissue, and blood vessels of vertebrae and less commonly from the hematopoietic elements of bone and tissue outside the vertebral column, including muscle, fat, and paraganglia.[224] Primary vertebral tumors, which may cause compression of the spinal cord as a result either of extension of the tumor mass into the spinal canal or of pathologic fracture of the vertebra, include osteosarcoma, chondrosarcoma, fibrosarcoma, hemangioma, hemangiosarcoma, plasma cell myeloma, giant cell sarcoma (arising from primitive stromal elements of bone marrow), and undifferentiated sarcomas.[224] Tumor metastases from sites elsewhere in the body may also be found in vertebrae, epidural space, meninges, and rarely the parenchyma of the spinal cord.

Secondary tumors, which result from hematogenous or lymphatic spread of tumor emboli, include hemangiosarcoma, lymphosarcoma, mammary adenocarcinoma, pulmonary carcinoma, prostatic carcinoma, and malignant melanoma. Clinical signs associated with secondary spinal tumors may occur early or late in the course of the disease. With the prolonged survival times that accompany recent therapeutic regimens for osteosarcoma of long bones, an increased frequency of vertebral metastases can be expected, particularly in cranial thoracic vertebrae. Embolic tumor cells may pass directly to the lumbar vertebrae from tumors in the pelvic area by reversal of blood flow in the vertebral veins with increases in central venous pressure.

Retrospective studies have shown the most commonly occurring spinal tumors in dogs to be primary and secondary bone tumors and tumors of spinal nerves and nerve roots. Primary intramedullary tumors occur less commonly than extradural or intradural-extramedullary tumors. Spinal tumors of all types occur more frequently in large breed dogs. Epidural lymphosarcoma is the most commonly occurring spinal tumor in cats.[229–233] Primary intramedullary tumors rarely occur in cats. The etiology of vertebral and spinal cord tumors is unknown. Lymphosarcoma in cats may be associated with FeLV or feline immunodeficiency virus (FIV) infection; however, not all cats with spinal lymphosarcoma test positive for FeLV or FIV.[230]

Spinal tumors may occur in animals of any age. Although tumors more commonly occur in animals more than 5 years of age, spinal cord blastoma (nephroblastoma) in dogs[234] and lymphosarcoma in cats are found most commonly in young animals. Spinal cord blastoma has been reported in large breed dogs 6 months to 3 years of age. German shepherds have a higher incidence of this tumor than other breeds. These tumors are generally found in an intradural and extramedullary location, closely associated with the pia mater of the spinal cord and separated from the spinal cord by a thin band of connective tissue. The tumor may replace most of the spinal cord and may also have an intramedullary component. These tumors occur in the T10 to L2 spinal cord segments and may be the result of neoplastic transformation of remnants of embryonic medullary (neuro)epithelium in this region of the spinal cord. However, immunocytochemical studies do not support a neuroectodermal origin. The mixed epithelial and mesenchymal patterns seen in these tumors are similar to those of nephroblastomas.[234]

Metastatic spinal tumors have also been reported to occur in dogs.[226] Primary spinal cord, meningeal, and nerve root tumors rarely metastasize outside the spinal canal; however, tumors may arise from multiple sites or may metastasize along CSF pathways (meningioma, ependymoma). Primary vertebral tumors commonly metastasize to other organ systems.

193.5.25.2 Clinical Findings

The clinical signs depend on the location of the tumor. Tumors may involve more than one spinal cord segment, and more than one spinal tumor may be present, resulting in multifocal signs. However, most animals have clinical signs referable to a transverse myelopathy. Tumors may occur anywhere in the spinal cord or spinal canal and usually result in progressive neurologic deficits. The duration of clinical signs may vary considerably (from 1 week to 1 year in one study). Animals may have acute onset of severe neurologic deficits associated with pathologic fracture of a vertebra, resulting in spinal cord compression; epidural, subarachnoid, or intramedullary hemorrhage; or spinal cord ischemia associated with tumor expansion. Neurologic deficits are usually bilateral but may be asymmetric.

Tumors of nerves of the brachial plexus initially cause progressive LMN signs in the ipsilateral thoracic limb, including muscle atrophy and paresis. The affected limb is often painful on palpation or movement; cutaneous sensation generally remains intact.[224] If the tumor extends into the spinal canal, UMN signs in the pelvic limbs may become apparent. Tumors of nerves of the cauda equina or lumbosacral plexus, with extension into the spinal canal, may cause unilateral or bilateral LMN signs in the pelvic limbs, tail, perineum, urinary bladder, and anal sphincter.

874

875

Apparent pain is a common finding with extradural and intradural tumors[227] and was the predominant clinical sign in a study of dogs with vertebral tumors. Apparent pain may be intractable, especially in animals with a tumor that affects spinal nerve roots. This may be due to stretching or inflammation of the meninges surrounding the expanding tumor. Intramedullary tumors are reported to cause a more rapid progression of clinical signs and are much less likely to be painful than extradural or intradural-extramedullary tumors. In general, however, extradural, intradural-extramedullary, and intramedullary tumors cannot be distinguished on the basis of clinical findings.

193.5.25.3 Diagnosis

A tentative diagnosis of spinal tumor can be made on the basis of radiographic, CSF, and myelographic findings. A definitive diagnosis can be made only after biopsy of a suspected lesion.

193.5.25.3.1 Radiography

Bone lysis with a cortical break is the most common radiographic finding in animals with vertebral tumors. Other radiographic findings include destruction of vertebral endplates, collapse of an adjacent disk space, collapse and shortening of a vertebral body, pathologic fracture, bone sclerosis and bony production, cystlike expansile lesions, and adjacent soft tissue masses. Bone tumors most commonly occur in the vertebral body but may also be found in the dorsal spinous processes, transverse processes, and articular facets. Primary and secondary bone tumors or specific tumor types cannot be distinguished radiographically. Primary bone tumors usually but not always involve one vertebra. More than half of the secondary bone tumors in one study involved more than one vertebra. Rarely, metastatic tumors (e.g., carcinoma) may arise in a disk space. The radiographic appearance of such tumors may resemble that of discospondylitis. Metastases from intrapelvic soft tissue tumors often produce periosteal new bone on the ventral aspect of multiple lumbar vertebral bodies in association with the formation of a paravertebral soft tissue mass. The characteristic vertebral lesions of multiple myeloma are “punched out” lytic lesions.

Vertebral lesions may also occur with the spread of tumors from surrounding soft tissues into the vertebrae. Bone tumors are not always easily detected radiographically because of inconsistent vertebral shape, overlying rib and soft tissue shadows, and improper positioning. Other diseases, such as bacterial or fungal discospondylitis, spondylitis, or vertebral osteomyelitis, must be considered in the differential diagnosis of vertebral tumors.

Expanding tumors in the spinal canal may result in widening of the vertebral canal and loss of bone density because of ischemia and necrosis of overlying bone. Similarly, tumors of spinal nerves extending into the spinal canal may cause widening of intervertebral foramina.

193.5.25.3.2 Cerebrospinal fluid analysis

The CSF may be normal or may have an elevated protein concentration and/or WBC count.[13] A mild to moderate increase in the WBC count of the cerebrospinal fluid may occur in animals with tumors that arise from or invade the leptomeninges. PMN cells may predominate, probably as a result of meningeal inflammation and necrosis. Tumor cells rarely are found in the CSF, except in CSF from animals with lymphosarcoma, in which abnormal lymphocytes are often present in association with meningeal infiltration. Collection of CSF from the lumbar subarachnoid space may yield more cells than cisternal collection, owing to probable caudal flow of the CSF in animals. Inability to demonstrate tumor cells in the CSF may be the result of the methods used to analyze it. Cell-concentrating techniques, which show a greater percentage of cells present in the CSF, may result in preservation of more neoplastic cells. Xanthochromia, which suggests previous subarachnoid hemorrhage, occasionally is present. The CSF protein concentration may be increased because of abnormal permeability of the blood–spinal cord or blood–meningeal barrier, the result of extradural compression or meningeal or parenchymal tumor infiltration.

193.5.25.3.3 Myelography

Myelography may be helpful in differentiating intramedullary, intradural-extramedullary, and extradural tumors. Cisternal and lumbar injection of contrast material may be necessary to outline both the cranial and caudal extent of a tumor. It is important to obtain survey radiographs of the entire vertebral column prior to and after the injection of contrast, because more than one tumor may be present, and the neurologic deficits of one tumor may mask those produced by another. Several radiographic views (at least lateral and ventrodorsal views) are necessary to determine whether a tumor is intramedullary, intradural-extramedullary, or extradural. Tumors may have a mixed myelographic appearance, with extradural, intradural, and/or intramedullary components (e.g., nerve root tumors, meningioma, and spinal cord blastoma). Myelographic findings may also be misleading, because extradural tumors may appear intramedullary on some views, or spinal cord edema associated with acute extradural compression may appear the same as an intramedullary mass. Other mass lesions that result in spinal cord compression, intramedullary swelling, and intradural lesions must be considered in the differential diagnosis of spinal tumors.

Both CT (Figure 193-14) and MRI aid the exact determination of the location and extent of spinal tumors.[235,236] Use of these advanced imaging modalities also helps in the planning of precise surgical approaches and radiation therapy.

193.5.25.3.4 Biopsy

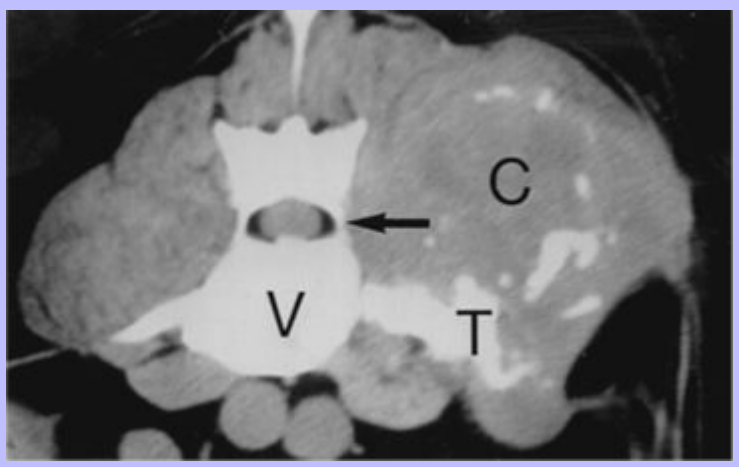
Biopsy of suspected lesions is necessary to differentiate neoplasms from other vertebral and spinal cord abnormalities and to determine the histologic type.[237]

193.5.25.4 Treatment

Most vertebral tumors are not surgically resectable because of their malignant characteristics and because of the decreased stability of the vertebral column that may result from extensive surgery. Surgical decompression of the spinal cord and debulking of the tumor mass may be palliative in some cases. Some tumors in the spinal canal are surgically resectable, including some tumors that appear intramedullary on myelography, such as spinal cord blastoma.[238] Surgical exploration of solitary tumors in the spinal canal is recommended for animals with clinical signs indicative of an incomplete transverse myelopathy, even those in which myelographic findings are consistent with an intramedullary mass.[231] Intradural nerve root tumors are rarely completely surgically resectable, and the recurrence rate is high. Resection of ventral nerve roots that contribute to the brachial or lumbosacral plexus may necessitate amputation of the affected limb.[224]

875 876

Figure 193-14 Vertebral neoplasia. Transverse computed tomography (CT) image of the vertebral column of a 13-year-old spayed female Old English sheepdog at the level of the L4 vertebral body *(V)*. Note the chondrosarcoma *(C)* arising from the transverse process *(T)* of L4. Areas of calcification can be seen in the neoplasm. The tumor involves the lateral lamina *(arrow)* of L4. CT allows exact determination of the location and extent of a neoplasm.



No direct correlation exists between tumor size and the severity or rate of progression of clinical signs. The spinal cord is able to compensate for pressure applied gradually, and animals with spinal tumors may remain

ambulatory despite having little normal spinal cord tissue remaining. Compression applied to the spinal cord rapidly, such as may occur with a pathologic fracture, may cause severe, irreversible spinal cord damage.

Corticosteroids may reduce spinal cord edema associated with spinal cord tumors and may produce clinical improvement for a variable period. Radiation therapy and chemotherapy may be helpful in animals with spinal lymphosarcoma. Most chemotherapeutic agents do not cross the blood–spinal cord or blood-CSF barrier in concentrations sufficient to eliminate tumor cells in the meninges or spinal cord. Several chemotherapeutic agents, including methotrexate and cytosine arabinoside, may be given intrathecally and have been used in the treatment of meningeal lymphosarcoma and leukemic meningitis. Complications of intrathecal use of chemotherapeutic agents include arachnoiditis and seizures. Chemotherapy may be helpful in the treatment of plasma cell myeloma.

Chemotherapy and radiation therapy have not been used in the treatment of a sufficient number of primary spinal cord, nerve root, or meningeal tumors to allow assessment of the results; however, initial experience suggests that further use of radiation therapy is warranted.[239] Various chemotherapeutic regimens have been used in the treatment of bone tumors and tumors that metastasize to bone, generally with poor results. Chemotherapy regimens in the future may offer more hope in the treatment of vertebral tumors. In general, the prognosis for animals with nonresectable spinal tumors is poor.

193.5.26 Neuroaxonal Dystrophy of Rottweilers

193.5.26.1 Etiology and Pathogenesis

Neuroaxonal dystrophy is a disease of rottweilers characterized by the accumulation of axonal spheroids throughout the neuraxis.[200,240,241] Clinically, affected animals have progressive ataxia in all limbs and severe hypermetria, especially of the thoracic limbs. Histologically, axonal spheroids are found in massive numbers throughout the brain and spinal cord, especially in the dorsal horns of the spinal cord and in the nucleus gracilis and nucleus cuneatus. The cerebellum is mildly atrophic in some dogs. Afferent fibers entering the sensory nuclei in the spinal cord, brain stem, and diencephalon are primarily affected. Electron microscopy has shown axonal spheroids to be enlarged, distal portions of axons and synaptic terminals that contain accumulations of smooth membrane–bound vesicles, membranous lamellae, dense bodies, and other organelles. Histologic lesions may be mild in young dogs.

A recessive mode of inheritance, with variable penetrance in rottweilers, is suspected from preliminary breeding studies. The etiology and pathogenesis of distal membranous axonopathies are not understood, but the location of the lesions suggests a derangement in the presynaptic portion of neurons or abnormalities in axonal transport. Axonal dystrophies have been associated with toxins, nutritional deficiency, aging, and genetic disorders in other species and in humans. A progressive neuroaxonal dystrophy was reported in a Jack Russell terrier pup, with pathologic alterations similar to those reported in rottweilers.[242]

193.5.26.2 Clinical Findings

Affected dogs may be clumsy as puppies, or clinical signs may not be seen until the dog is more than 12 months of age. Both male and female dogs are affected. Clinical signs may progress slowly over several years. The initial clinical finding is progressive ataxia of all limbs. Paresis or abnormalities in conscious proprioception have not been found in affected dogs. The patellar reflexes may be exaggerated, but other reflexes are normal. These findings are consistent with a transverse myelopathy of the cervical spinal cord or

multifocal spinal cord disease. As the disease progresses, other signs become apparent, including hypermetria (especially of the thoracic limbs), incoordination, tremors of the head, positional nystagmus, decreased menace response, and crossed extensor reflexes. Thoracic limb hypermetria may be severe in older dogs, especially when they climb stairs. The neurologic deficits seen in older dogs are predominantly referable to abnormalities in the cerebellum or input to the cerebellum.

193.5.26.3 Diagnosis

The diagnosis is made on the basis of the animal's age and breed, as well as the neurologic findings, and by ruling out other causes of cervical spinal cord and cerebellar disease. This disease is unusual in that it is slowly progressive over several years, but in the initial stages it may appear clinically similar to other causes of a cervical myelopathy, including CD myelitis and cervical spondylomyelopathy. The CSF may have an elevated protein concentration (40 mg/dL was reported in one dog[240]). Spinal radiographs and myelograms are normal.

193.5.26.4 Treatment

Currently, no effective treatment is available. Clinical improvement has not been detected during treatment with corticosteroids. Owing to the slow progression of the disease, affected dogs may be acceptable pets for several years. Affected dogs should not be used for breeding, although a diagnosis of neuroaxonal dystrophy may not be made until after these dogs have produced litters.

193.5.27 Osteochondromatosis (Multiple Cartilaginous Exostoses)

193.5.27.1 Etiology and Pathogenesis

A skeletal osteochondroma is a cartilage-capped exostosis arising from the surface of a bone formed by endochondral ossification. An animal with a monostotic lesion has a *solitary osteochondroma*. Polyostotic skeletal involvement is called *osteochondromatosis* (also *multiple cartilaginous exostoses, hereditary multiple exostoses, multiple osteochondromatosis, diaphyseal aclasis, dyschondroplasia,* and *hereditary deforming chondrodysplasia*). Consistent differences exist between cats and dogs with regard to the age of onset of lesions, patterns of skeletal involvement, and pathogenesis.[243,244]

The incidence of feline osteochondromatosis is unknown.[7] Feline osteochondromatosis is characterized by an initial appearance of lesions in the skeleton of mature cats (2 to 4 years of age). Growth of the lesions is progressive. In cats, the disease has no apparent gender or breed predilection, and a hereditary pattern has not been demonstrated. Malignant transformation to osteosarcoma was reported to have occurred in an osteochondroma of a cervical vertebra in a cat.

The incidence of osteochondromatosis in dogs remains undetermined. The disease is frequently demonstrated in the skeleton of dogs radiographed for unrelated reasons. The onset of clinical disease usually occurs in dogs less than 18 months of age.[245] Onset in mature dogs is infrequently recognized.[246] A hereditary basis has been indicated in dogs, but a gender or breed predilection is not apparent. Continued growth or reactivation of growth of exostoses in dogs is suggestive of neoplastic transformation.

The etiology of canine osteochondromatosis is unknown. The current view of the pathogenesis of feline osteochondromatosis is that the disease is virus related and probably virus induced. The random distribution

of the lesions is compatible with hematogenous distribution of a virus. The virus may be FeLV, feline fibrosarcoma virus acting in an atypical manner, or another member of the feline retrovirus family.

193.5.27.2 Clinical Findings

Osteochondromatosis may occur anywhere in the vertebral column but most commonly is found in the thoracic and lumbar spine. The disease may result in spinal cord compression and clinical signs indicative of a progressive transverse myelopathy between T3 and L3. Neurologic deficits are often asymmetric.

193.5.27.3 Diagnosis

Radiographically, vertebral lesions tend to be circular and smooth with sclerotic borders. The lesions are usually multiple and may be cystic or proliferative, with an increased radiodensity. Myelography is necessary to demonstrate associated spinal cord compression. Extension of exostoses into the spinal canal results in extradural compression of the spinal cord. Surgical biopsy is necessary to differentiate osteochondromatosis from benign bone tumors (osteomas), neoplastic lesions, or infectious processes.

193.5.27.4 Treatment

Treatment of canine osteochondromatosis affecting the vertebral column is unnecessary unless a lesion results in clinical sequelae. An osteochondroma should be removed if it impinges on the spinal cord or if malignant transformation is suspected. Surgical excision of cartilaginous exostoses and spinal cord decompression are the recommended treatments for lesions causing spinal cord compression and neurologic deficits. Intraoperative spinal stabilization may be indicated after removal of the lesion.[247] The prognosis for dogs that have stopped growing is good; however, the prognosis for animals that are still growing is guarded, because lesions may continue to expand and may subsequently cause spinal cord compression.

Treatment of feline osteochondromatosis is complicated by the association with FeLV and the progressive nature of the lesions in cats. It seems that at best, surgical removal of a lesion may provide only temporary relief to a cat because of the tendency for excised lesions to recur and for new lesions to develop.

193.5.28 Pilonidal Sinus, Epidermoid Cyst, and Dermoid Cyst (Dermoid Sinus, Pilonidal Cyst)

193.5.28.1 Etiology and Pathogenesis

A pilonidal sinus is an invagination of the skin dorsal to the spine that extends below the skin to variable depths and in some cases as far as the dura mater, where it may communicate with the subarachnoid space. The formation of pilonidal sinuses is related to failure of complete separation of the neural groove from the epidermis during embryonic development. Pilonidal sinuses may occur anywhere along the dorsal midline from the cervical to the sacrocaudal regions and may be single or multiple. Purebred and crossbred Rhodesian ridgeback dogs are most commonly affected, although other dog breeds may be affected.[248] There have been no reports of sinuses occurring along the ridge of hair of Rhodesian ridgebacks. The sinuses contain inspissated sebum, hair, and exfoliated cells and commonly become inflamed or infected. If the sinuses communicate with the subarachnoid space, extension of infection results in meningitis or myelitis. Pilonidal sinuses are likely to occur as a hereditary defect in Rhodesian ridgebacks, but the mode of inheritance is not definitely known.[6]

Dermoid cysts have been reported to occur in the brain and spinal cord of dogs and cats.[249] In one report, a dermoid cyst in the spinal cord of a cat at the level of T3 was considered a congenital anomaly.[1]

Epidermoid cysts have been reported to occur in the brain and spinal cord of dogs.[191] Such cysts are thought to arise from entrapment and subsequent growth of primordial epithelial cells during closure of the neural tube. Morphologically similar cysts have developed in humans after injury or after repeated lumbar subarachnoid punctures for CSF collection, presumably from mechanical implantation of epidermal cells. An intramedullary spinal epidermoid cyst reported in a dog was thought to have a congenital cause. Apparently, spinal epidermoid cysts rarely occur in dogs.[250]

193.5.28.2 Clinical Findings

Clinical signs of meningitis and myelitis may be seen in animals as a result of extension of infection from a pilonidal sinus to the subarachnoid space. Localized or generalized spinal pain and rigidity may be seen associated with meningitis. Neurologic deficits indicative of a transverse or diffuse myelopathy may be seen as a result of myelitis. Signs resulting from a spinal dermoid or epidermoid cyst depend on its location.

193.5.28.3 Diagnosis

A pilonidal sinus may be palpable as a cord of fibrous tissue under the skin of the dorsal midline. Palpation may be painful if the sinus is infected. An opening in the skin on the dorsal midline is usually found, and hair may or may not be seen protruding from this opening. The CSF in animals with meningitis or myelitis is generally abnormal and indicative of bacterial infection. Fistulography (performed by injecting a radiographic contrast material, such as metrizamide, which is not an irritant to nervous tissue, into the sinus) demonstrates whether pilonidal sinuses are continuous with the subarachnoid space. Myelography may also demonstrate communication.

The diagnosis of a spinal dermoid or epidermoid cyst is based on the clinical signs and on the results of plain spinal radiography, CSF analysis, and myelography. Typically an epidermoid cyst should be suspected with an intramedullary, expansile lesion on myelography in a young dog with progressive neurologic deficits. The diagnosis is confirmed by open surgical biopsy, which may provide the only means of ruling out spinal neoplasia (e.g., spinal cord blastoma). Advanced imaging (CT or MRI) may be useful for fully delineating the extent and location of these cystic structures.

193.5.28.4 Treatment

Animals with meningitis and/or myelitis associated with a pilonidal sinus should be treated as an animal with meningitis and myelitis due to another cause. Antibiotic therapy should be selected on the basis of the CSF culture, culture of the contents of the pilonidal sinus, and sensitivity testing. Complete surgical excision of the pilonidal sinus is essential.[251] Laminectomy may be necessary to remove portions of a pilonidal sinus from within the spinal canal. Recurrence of infection is likely in dogs in which a pilonidal sinus is incompletely removed. The prognosis depends on the severity of the neurologic deficits before surgery, the response to antibiotic therapy, and whether the pilonidal sinus was removed completely. Complications of surgical removal include wound dehiscence and seroma formation. Affected animals should not be used for breeding.

Treatment of spinal dermoid or epidermoid cysts of dogs has not been reported. Surgical excision may be possible in some animals.

193.5.29 Progressive Hemorrhagic Myelomalacia

193.5.29.1 Etiology and Pathogenesis

Acute, severe spinal cord injury may result in progressive ascending and descending infarction and hemorrhagic necrosis of the spinal cord parenchyma. Progressive hemorrhagic myelomalacia occurs infrequently and usually follows peracute explosive extrusion of a thoracolumbar disk, but it may also be seen after other types of spinal cord trauma.[6] PHM previously was known as hematomyelia. Most dogs with thoracolumbar disk extrusions have evidence of a localized myelopathy affecting up to four spinal cord segments. In animals with PHM, hemorrhagic necrosis of a large number of spinal cord segments may occur over a period of hours to days. The etiology of this syndrome is not known; however, spinal cord pathology indicates severe ischemia.

193.5.29.2 Clinical Findings

The clinical signs depend on the location of the lesion; however, most affected animals initially have clinical signs indicative of a transverse myelopathy between T3 and L3. Neurologic deficits usually are severe (paraplegia and absent deep pain perception in pelvic limbs) and peracute in onset (over several hours). Clinical signs indicating a diffuse myelopathy progress over a period of hours to 1 to 2 days. As infarction and hemorrhagic necrosis of the spinal cord progress caudally, LMN signs may be seen in the pelvic limbs and anus. As PHM progresses cranially, the level of cutaneous anesthesia and LMN signs in intercostal muscles extend cranially until thoracic limbs exhibit LMN signs. The Schiff-Sherrington sign may be present before involvement of the spinal cord cranial to T3. Diaphragmatic paralysis and bilateral Horner's syndrome may be seen with involvement of the cervical spinal cord. Affected animals often are in extreme pain, are anxious, and have an increased body temperature.

193.5.29.3 Diagnosis

The diagnosis is made on the basis of progressive clinical signs indicative of a diffuse myelopathy. Any animal with an acute onset of paraplegia due to a lesion between T3 and L3 that shows LMN signs in the pelvic or thoracic limbs should be suspected of having more than one lesion or PHM.

193.5.29.4 Treatment

In most cases PHM is fatal within 24 to 48 hours as a result of respiratory paralysis. There is no effective medical or surgical treatment, and euthanasia is recommended. Difficulty often arises in the treatment of animals that have an acute onset of paraplegia, with or without deep pain perception, within hours after the onset of clinical signs. Ideally, if decompressive surgery is indicated, it should be performed as soon as possible; however, a small percentage of these cases may show clinical signs of PHM after surgery. Hemorrhagic myelomalacia in some cases may not progress to involve the cervical cord, and affected animals may survive; however, the spinal cord damage incurred and the associated severe neurologic deficits are permanent.

193.5.30 Protozoal Myelitis

193.5.30.1 Etiology and Pathogenesis

Toxoplasma gondii is an obligate, intracellular, coccidian parasite. Cats are the only known definitive host of the organism and as such pass environmentally resistant oocysts in feces. The seroprevalence of infection varies by region but is approximately 30% in cats in the United States. Despite this high seroprevalence, clinical disease caused by *T. gondii* is rare.[252,253]

T. gondii infection may cause a focal or disseminated myelopathy in dogs or cats.[6] Animals are infected after ingesting meat containing *Toxoplasma* bradyzoites and/or tachyzoites; after ingesting cat feces containing sporulated oocysts; or by transplacental or congenital infection. The infective organism is spread hematogenously to most organs of the body, including the CNS. Although the incidence of disease associated with *T. gondii* is low, opportunistic infection in immunosuppressed animals may be more widespread than previously reported. Immaturity and concurrent CD virus infection may result in an increased susceptibility of dogs to toxoplasmosis. In dogs with systemic toxoplasmosis, the incidence of CNS involvement is high. In cats, concurrent infection with FeLV or FIV or administration of corticosteroids may predispose the animal to the development of clinical signs of toxoplasmosis through immunosuppression and reactivation of latent infection.[254–256]

Neospora caninum is a recently discovered, cyst-forming coccidium in the phylum Apicomplexa that is structurally similar to but distinct from *T. gondii*.[257–264] This protozoal parasite is associated most commonly with natural infection in dogs and cattle. The organism forms meronts in many tissues of dogs, especially the brain and spinal cord, resulting in meningoencephalomyelitis. Clinical signs result from host cell death caused by rapid intracellular multiplication of the parasite and the ensuing inflammatory response of the host. Cats have been infected experimentally and have been shown to develop clinical disease. *N. caninum* organisms do not react to *Toxoplasma* immunoperoxidase staining techniques, and the life cycle is unknown. Clinically, this protozoal disease appears similar to toxoplasmosis; however, CNS signs (progressive ascending paralysis) and myositis are seen more commonly than in toxoplasmosis, and *T. gondii* almost always has been associated with concurrent disease in dogs (e.g., CD infection), whereas *N. caninum* appears to be a primary pathogen.

193.5.30.2 Clinical Findings

Animals with CNS involvement by *T. gondii* usually have clinical signs of progressive multifocal or disseminated disease. Clinical signs indicating a focal transverse or diffuse myelopathy may be seen initially. Neurologic deficits depend on the site of involvement and may be either UMN or LMN deficits. If lower motor neurons are involved, denervation may result in severe muscle atrophy.

In dogs less than 1 year of age, a syndrome of progressive paralysis and rigid extension of one or both pelvic limbs may be seen in association with *T. gondii* infection. Muscle atrophy and contracture of affected limbs are seen, and limbs cannot be flexed. Muscle changes may be the result of myositis and myonecrosis and/or denervation caused by myelitis or radiculitis in the caudal lumbar and sacral spinal cord segments. Animals with CNS toxoplasmosis may or may not have other clinical signs indicative of systemic infection, such as fever, lymphadenopathy, pneumonia, apparent muscle pain, gastrointestinal tract disease, iritis, or chorioretinitis.

Overall, neosporosis is an increasingly prevalent infectious disease that merits consideration in juvenile and adult dogs with progressive paraparesis. Neosporosis may cause fatal disease in dogs of all ages (several weeks to 15 years). Puppies are affected more severely than older dogs. Young dogs develop an ascending paralysis, with the pelvic limbs affected more severely than the thoracic limbs. Other signs of dysfunction include difficulty swallowing, paralysis of the jaw, muscle flaccidity, and muscle atrophy.

193.5.30.3 Diagnosis

Antemortem confirmation of CNS toxoplasmosis or neosporosis in dogs or cats is extremely difficult and may be tentatively based on all of the following: (1) demonstration of serologic evidence of infection, (2) clinical signs of disease referable to toxoplasmosis or neosporosis, (3) exclusion of other common causes of these clinical signs, and (4) positive response to appropriate treatment.

878

879

193.5.30.4 Treatment

Several antibacterial agents have been recommended for the treatment of both toxoplasmosis and neosporosis in dogs as well as cats.

193.5.31 Sacrocaudal Dysgenesis in Manx Cats

193.5.31.1 Etiology and Pathogenesis

Manx cats have varying degrees of taillessness associated with sacral and/or caudal vertebral deformities.[6,7,267] Some tailless cats have a normal sacrum, spinal cord, and cauda equina. Others show varying dysgenesis or agenesis of the sacral and/or caudal vertebrae that may be associated with spina bifida and/or malformations of the terminal spinal cord and/or cauda equina. Spinal cord malformations include the absence or partial development of the sacral and caudal spinal cord segments or the cauda equina; myelodysplasia; meningocele; meningomyelocele; diastematomyelia of sacral segments (duplication); myeloschisis (cleft within the spinal cord); syringomyelia in the lumbar and sacral spinal cord segments; shortening of the spinal cord and subcutaneous cyst formation. These spinal cord and cauda equina malformations are associated with a variety of neurologic deficits.

Sacrocaudal dysgenesis is inherited as an autosomal dominant trait and may be lethal in some homozygote cats. Sacrocaudal dysgenesis and associated malformations have been recognized in most breeds of cats, many not of true Manx breeding.

193.5.31.2 Clinical Findings

Clinical signs vary, depending on the degree of spinal cord and cauda equina malformation; they include paraparesis, paraplegia, megacolon, atonic bladder, absent anal and urinary bladder sphincter tone, absent anal reflex, urinary and fecal incontinence, and perineal analgesia. Affected cats often walk plantigrade in the pelvic limbs with a “bunny hopping” gait. Vertebral abnormalities may be palpable in the lumbosacral region, and in some cats a meningocele (congenital or the result of necrosis of the overlying skin) may exit through the skin and drain CSF.

Clinical signs usually are evident soon after birth and may remain static or may progress. Worsening of neurologic deficits may be due to progressive syringomyelia in the lumbar and sacral spinal cord.

193.5.31.3 Diagnosis

The diagnosis is made on the basis of clinical findings, in addition to radiographic findings indicative of dysgenesis or agenesis of the sacral and caudal vertebrae. Myelography may demonstrate meningocele or attachment of the spinal cord to subcutaneous tissues in the lumbosacral region. The degree of spinal deformity does not always correspond with the degree of neurologic impairment. Clinical findings are the most important factors to consider in the determination of the prognosis.

193.5.31.4 Treatment

The prognosis for severely affected cats is hopeless, and treatment is not available. Cats with urinary and fecal incontinence may be managed with manual bladder expression and fecal softening agents; however, recurrent urinary tract infection, megacolon, and chronic constipation are common problems. Meningocele in cats with minimal neurologic deficits may be surgically correctable. Many tailless cats do not have neurologic deficits, and sacral and caudal deformities often are an incidental radiographic finding.

193.5.32 Spina Bifida

193.5.32.1 Etiology and Pathogenesis

Spina bifida, which occurs in both dogs and cats, describes a group of developmental defects characterized by failure of fusion of the vertebral arches with or without protrusion or dysplasia of the spinal cord and meninges.[6,7] This defect is part of the complex of spinal dysraphism and is the most commonly occurring dysraphic defect. *Dysraphism* is a defective fusion of parts that normally unite. Spina bifida is the absence of a portion of the dorsal elements of the vertebrae. The spinal cord and meninges may be normal (spina bifida occulta), or they may be abnormal, and the meninges and/or spinal cord may protrude through the vertebral defect.

Myelodysplasia consisting of hydromyelia, syringomyelia, anomalies of the dorsal septum, anomalies of the central gray matter, abnormal position of the central gray matter, anomalies of the dorsal and ventral horns, and myeloschisis (cleft in the dorsal part of the spinal cord) may occur in association with spina bifida. The most severe defects involve myelorachischisis, with superficial location of the neuroectoderm that is continuous with the skin. Spina bifida with myelorachischisis has been reported to occur in dogs and cats.

The etiology of spina bifida is unknown and probably is multifactorial, with genetic and environmental components. The relatively high incidence of spina bifida in some breeds of animals (e.g., bulldogs and Manx cats) suggests a heritable basis for the disorder. Teratogenic compounds, nutritional deficiencies, and environmental changes during pregnancy are also known to induce this defect.

193.5.32.2 Clinical Findings

Spina bifida is usually an incidental radiographic finding; however, if associated with spinal cord malformations, it may result in clinical signs of spinal cord or cauda equina dysfunction. English bulldogs

have a high incidence of spina bifida. Spina bifida may be found anywhere in the spinal column but most commonly occurs in the caudal lumbar spine, where clinical signs are indicative of a transverse myelopathy from the L4 to the S3 spinal cord segments. Clinical signs usually become evident when affected animals start to walk.

Spina bifida also has been reported in the thoracic spine of a dog and may be associated with other spinal deformities, such as scoliosis. Other associated anomalies include dimpling of the skin or "streaming" (abnormal direction) of the haircoat over the affected region or a palpable abnormality in the spinal column. Meningoceles may cause necrosis of the overlying skin and drainage of CSF. Meningoceles may be present in the absence of clinical signs associated with spinal cord malformation.

193.5.32.3 Diagnosis

Radiographically, absence of the vertebral arch or failure of fusion of the spinous processes in one or more vertebrae may be seen (Figure 193-15). Myelography may demonstrate meningocele. Advanced imaging (CT or MRI) may be used to accurately define the location and extent of bony and soft tissue abnormalities in animals with spina bifida.

193.5.32.4 Treatment

Treatment of spina bifida rarely is attempted. Treatment is not effective for affected animals with clinical signs of spinal cord malformation. Meningocele may be amenable to surgery if neurologic abnormalities are not evident. Treatment is not necessary for animals with vertebral defects in the absence of spinal cord dysfunction. When planning therapy, the veterinarian must consider the possible existence of additional spinal cord malformations (e.g., hydromyelia) seen in association with spina bifida.

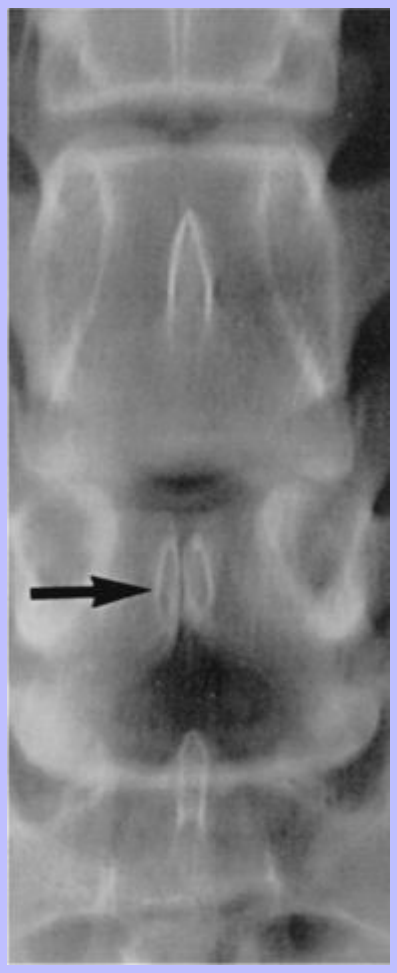
193.5.33 Spinal Intra-Arachnoid Cysts

193.5.33.1 Etiology and Pathogenesis

Intra-arachnoid cysts are intra-arachnoid membrane accumulations of CSF that may occur in any location along the cerebrospinal axis of cats or dogs.[268–273] The intra-arachnoid accumulation of CSF in the cyst results in expansion of the cyst between the overlying dura mater and the underlying pia mater, causing compression of the spinal cord. Intra-arachnoid cysts may be congenital in origin or may occur secondary to trauma, infection, inflammation, or subarachnoid hemorrhage.

879
880

Figure 193-15 Spina bifida. Ventrodorsal radiograph of the caudal lumbar vertebral column of an 8-year-old spayed female chow chow. A deficit in fusion of the embryologic neural tube has resulted in nonfusion of the spinous process of L7 *(arrow)*. This congenital defect was an incidental finding in this dog.



193.5.33.2 Clinical Findings

A single intra-arachnoid cyst has been described in either the cranial cervical or caudal thoracic spinal canal. The author (RAL) has diagnosed multiple intra-arachnoid cysts in the caudal cervical region of three rottweilers. The neurologic deficits were indicative of a progressive transverse myelopathy in either the C1 to C5 or the T3 to L3 spinal cord region. Apparent cervical pain and spasms of the cervical muscles were a feature of cervical lesions; however, apparent pain was not evident in dogs with thoracic lesions. Neurologic deficits may be asymmetric.

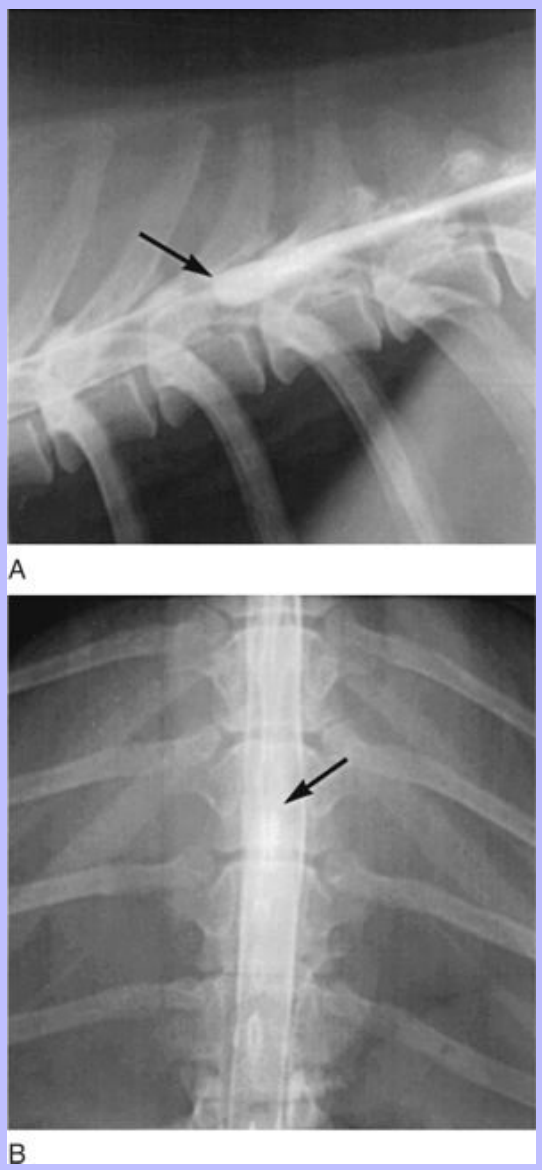
193.5.33.3 Diagnosis

The diagnosis is made on the basis of myelographic or advanced imaging (CT or MRI) findings. Surgical findings and histopathologic examination of excised tissues confirm the diagnosis.

Plain radiographs of the spine may be normal or may show enlargement of the vertebral canal with smooth cortical margins, presumably as a result of pressure atrophy of bone overlying the cyst. Abnormalities in the results of CSF analysis have not been reported. Care should be taken in attempting a cisternal subarachnoid puncture in an animal suspected of having a cervical arachnoid cyst, because lesions may be located on the dorsal midline. One reported dog was injured inadvertently during an attempted cisternal puncture.

On myelography, pooling of contrast material in the subarachnoid space may be seen, resulting in a characteristic widening of the subarachnoid space and spinal cord compression (Figure 193-16). In all reported cases, the lesions have been intradural-extramedullary and located on the dorsal midline. The author (RAL) has seen intra-arachnoid cysts in dorsolateral and ventral locations in the cervical region of dogs. The lesions may extend over more than one spinal cord segment.

Figure 193-16 Spinal intra-arachnoid cyst. Lateral **(A)** and ventrodorsal **(B)** projections of a myelogram of the midthoracic region of a 2-year-old toy poodle that had a 1-year history of progressive pelvic limb paresis and ataxia. Note the widening of the dorsal subarachnoid contrast column at T9–T10 on the lateral projection *(arrow)*. The ventrodorsal projection shows apparent intramedullary expansion of this area *(arrow)*. An intra-arachnoid cyst was removed by dorsal laminectomy.



Advanced imaging (CT or MRI) may be used to fully delineate intra-arachnoid cysts. Although intra-arachnoid cysts have a characteristic appearance on advanced imaging, they must be differentiated from other cystic lesions (e.g., cystic neoplasms or cysts associated with infections).

193.5.33.4 Treatment

Surgical exploration is necessary to confirm a diagnosis of intra-arachnoid cyst and to decompress the spinal cord. Complete surgical excision of an intra-arachnoid cyst usually is not possible, although partial excision of the cyst (called *surgical fenestration*) may result in decompression of the spinal cord and permanent clinical improvement. 880 881

193.5.34 Spinal Nematodiasis

193.5.34.1 Etiology and Pathogenesis

Aberrant migration and growth of parasites in the spinal canal rarely occur in dogs or cats. The route of migration of most parasites that enter the CNS is unknown, with the exception of hematogenous-borne *Dirofilaria immitis*. Parasites may cause extensive damage to neural parenchyma as a result of infarction, spinal cord compression, or granuloma formation. Parasites reported to occur in the CNS of dogs include *D. immitis*, *Toxocara canis* larvae, *Angiostrongylus cantonensis* (rat lungworm of Australia), *Ancylostoma caninum* (Australia),[274–276] *Baylisascaris* sp.,[277] and *Spirocerca lupi*.[278]

193.5.34.2 Clinical Findings

Clinical signs depend on the location of the migrating parasite, and the lesions may be focal or multifocal. Spinal nematodiasis usually is seen in immature animals, with the exception of *D. immitis*. Clinical signs often have an acute onset and usually are progressive. Clinical signs rarely occur with aberrant *Toxocara* migration in dogs; however, a single *Toxocara* larvae has been found in the cauda equina of a dog. Clinical signs reported to be associated with *A. cantonensis* infestation in the dog include paraparesis, paraplegia, urinary and fecal incontinence, paralysis of the tail, and apparent pain. *A. caninum* migration in the spinal cord has been reported to result in paraparesis, apparent neck pain, and tetraplegia.

193.5.34.3 Diagnosis

Definitive diagnosis is difficult antemortem because it requires isolation or demonstration of the parasite in the CNS.

The CSF may show an increase in the WBC count, especially in eosinophils, and/or in the protein concentration.[275] Affected animals usually have a large parasite burden, and nematode eggs or larvae may be found in the feces. Dogs with *D. immitis* infestation may have circulating microfilaria. Lesions may be located by means of myelography or advanced imaging (CT or MRI).

193.5.34.4 Treatment

The prognosis for animals with spinal nematodiasis depends on the severity of resulting neurologic deficits, and it usually is poor. Medical therapy often is ineffective at eliminating parasites in the CNS. Surgical removal of *D. immitis* adults from the spinal epidural space has been reported.

193.5.35 Spinal Cord Trauma

193.5.35.1 Etiology and Pathogenesis

Acute spinal cord injuries of dogs or cats result most commonly from direct physical trauma, such as missile injury or vertebral fracture or luxation. Also, spinal cord trauma is the underlying cause of neurologic signs in numerous myelopathies (e.g., intervertebral disk disease). Chronic spinal cord compression usually is seen in association with chronic progressive diseases such as neoplasia or type II disk protrusion.[279] After injury, the spinal cord may undergo sustained compression or distraction, or both. The severity of a spinal cord injury, as determined by the eventual degree and quality of recovery, is related to three factors: the velocity with which the compressive force is applied, the degree of compression (transverse deformation), and the duration of the compression. An understanding of the differences between acute and chronic spinal cord injury is essential for effective management and determination of the prognosis in cats or dogs with spinal trauma.[280]

193.5.35.1.1 Acute spinal cord injury

Blunt traumatic injury to the spinal cord causes neurologic deficits through both direct and indirect mechanisms. The direct effects are due to immediate mechanical disruption of neural pathways, and these effects have been considered by most investigators not to be amenable to therapy. Indirect effects develop during the first few hours after injury and result in delayed secondary injury to the spinal cord. It is likely that they result in part from the release of endogenous pathophysiologic factors in response to the initial trauma and that such factors produce injury by reducing spinal cord blood flow or by altering the local metabolic environment in injured spinal cord tissue. The spinal cord remains physically intact but is functionally deranged. A common feature of acute spinal cord injury is early, often progressive hemorrhage in the central region of the injured spinal cord, especially in the gray matter. Direct mechanical disruption of vessels at the site of injury is expected; however, the loss of circulation spreads for a considerable distance cranial and caudal to the site of injury. Angiographic studies have consistently shown that the large arteries remain patent, and the major loss of microcirculation involves capillaries and venules. The secondary damage has been considered potentially reversible through the use of either physical (e.g., hypothermia) or pharmacologic interventions.

Trauma to the spinal cord triggers a series of progressive, autodestructive events that lead to varying degrees of tissue necrosis, depending on the severity of the injury.[280] Despite extensive investigation, the mechanisms responsible for the initiation and propagation of these pathophysiologic and biochemical events remain undetected. However, recent evidence suggests that the overall initiator of this autodestructive cascade of events is mechanical deformation of any type (i.e., impact or compression injury), and that the primary sites of injury are the cellular and subcellular membranes of glia, neurons, and vascular endothelial cells. Lipid peroxidation and activation of membrane lipases, with the release of

fatty acids, leading to production of eicosanoids, are the earliest mechanically stimulated biochemical events described.

Within 5 minutes of spinal cord injury, postcapillary venules become congested. This is followed by opening of endothelial gap junctions there and at the capillary level, resulting in diapedesis of red blood cells and extravasation of fluid proteins and electrolytes through the "leaky" vasculature. Within 30 minutes of injury, microscopic hemorrhages appear in the central gray matter and coalesce over the following several hours (central hemorrhagic necrosis). Vacuolization develops in endothelial cells, indicating a profound ischemic or hypoxic insult, and subsequently leads to coagulative necrosis of the neuronal population. Adjacent white matter is relatively less severely affected; however, periaxonal swelling and retraction balls may be observed. These events may lead to autodissolution of the spinal cord within 24 hours, even in the absence of ongoing mechanical compression.

These phenomena would appear to have an ischemic basis, and considerable effort has been expended in characterizing the associated microcirculatory alterations. One cause of the ischemia may be direct mechanical irritation that results in vasospasm and biochemical damage due to the release of glutamate, intracellular calcium, catecholamines, and prostaglandins. Other studies point to intravascular thrombosis, possibly owing to the release of thromboxane, as an additional cause of post-traumatic ischemia. One of the most damaging biochemical alterations to the injured spinal cord is the accumulation of the excitatory amino acid neurotransmitter glutamate. Glutamate also causes an elevation of intracellular calcium that may in turn cause activation of calcium-dependent proteases or lipases, leading to further breakdown of cytoskeletal components.

A special feature of acute spinal cord injury is progressive hemorrhagic myelomalacia. This condition may occur after spinal cord injury, and appears to be a progression of central hemorrhagic necrosis and edema to areas of the spinal cord not directly involved in the initiating injury. 881 882

193.5.35.1.2 ## Chronic spinal cord compression

It has been shown experimentally that when slow compression of the spinal cord is compared with rapid compression of an equal amount, the extent of spinal cord dysfunction is determined by the contact velocity of compression. The major pathologic substrate for neural dysfunction after slow balloon compression is thought to be physical injury to the neural membranes, irrespective of blood flow changes, and the ability of that membrane to recover appears to be related to the rapidity and duration of compression. Clinical observations support the conclusion that spinal cord conduction is resistant to slow compression. Furthermore, it has been demonstrated that levels of compression that do not have an effect when applied slowly cause an immediate loss of conduction through the injured site when applied rapidly.[281]

Chronic spinal cord compression results either from a slowly developing lesion (e.g., neoplasia) or from an acute compression that is sustained. In contrast to acute spinal cord injury, chronic compression injury affects the white matter more severely than the gray matter. Hemorrhage and edema, the major findings of acute trauma, are not significant in chronic compression. Characteristic lesions are degeneration of myelin, focal areas of malacia, vacuolization, and loss of white matter axons. Mechanical deformation is likely to be the major factor in the pathogenesis of these lesions; however, ischemia and venous obstruction also may be important considerations.

193.5.35.2 Clinical Findings

193.5.35.2.1 Acute spinal cord injury

Dogs or cats with a spinal injury frequently have serious injuries to other organ systems. A primary concern is to balance the relative urgency of non-neurologic injuries (hemorrhage, shock, airway obstruction, or limb fractures) and the need for early treatment of spinal cord injury.[279]

A complete neurologic examination is performed to localize the site or sites of injury and to determine the severity of injury. Careful palpation of the vertebral column may aid identification of a vertebral fracture or luxation. Administration of tranquilizers or analgesic drugs should be delayed until the neurologic examination has been completed, because such medications may alter an animal's responses. The neurologic examination should be performed with care to prevent further injury from excessive movement of a vertebral instability.

Several aspects of the neurologic examination are of special importance in the assessment of a dog or cat with a spinal cord injury. Recognition of the Schiff-Sherrington sign is important. After trauma, this sign must be differentiated from other postures associated with cranial injury (e.g., decerebrate rigidity or decerebellate posture). Both deep and cutaneous pain perception should be assessed, because the results of these tests are important in the determination of the prognosis. It should be remembered that vertebral column injuries may be multiple and that a neurologic examination may not detect a second lesion.

193.5.35.2.2 Chronic spinal cord compression

Clinical signs of chronic spinal cord compression may progress over weeks or months or may be seen to occur acutely. Acute onset of neurologic signs with chronic spinal cord compression frequently is seen with such disorders as spinal neoplasia or type II disk protrusion. Sudden onset of signs may accompany pathologic fracture of a vertebra or spinal cord hemorrhage or infarction. In some cases sudden decompensation of a chronically compressed spinal cord may occur in the absence of pathologic changes. In these cases it is assumed that compensatory mechanisms in the spinal cord have been exhausted, allowing the sudden decompensation.

193.5.35.3 Diagnosis

193.5.35.3.1 Acute spinal cord injury

The results of a neurologic examination are used to determine the site and severity of a spinal injury. Radiographs of the entire spinal column should be taken. Two radiographic views are essential only when ventrodorsal views may be accomplished by means of a horizontal beam. The objectives of radiographic examination of an animal after acute spinal trauma are to determine precisely the location and extent of a lesion; to demonstrate the presence of multiple lesions, which may not be apparent from a neurologic examination; and to assess the need for surgical therapy and determine the most appropriate surgical procedure. Accurate interpretation of radiographs depends on a knowledge of the results of a neurologic examination.

Myelography is recommended for animals that have sustained spinal trauma. The results of a myelogram may determine the extent of spinal cord swelling caused by concussion in animals without evidence of a spinal fracture or luxation and may confirm that surgical decompression through laminectomy is not necessary in animals with a fracture that is evident on plain radiographs. In the diagnosis of intervertebral disk disease, a myelogram is essential prior to surgery.

The use of advanced imaging (CT or MRI) in acute spinal cord injury may be reserved for patients in which the results of the above diagnostic techniques do not fully explain the results of a neurologic examination.

193.5.35.3.2 Chronic spinal cord compression

The methods for diagnosing chronic spinal cord compression are the same as those used to diagnose acute spinal cord injury. A myelogram is considered essential in all such cases.

193.5.35.4 Treatment

The management of an animal with spinal trauma follows a list of priorities, and the focus of treatment is the prevention of secondary spinal cord damage that occurs after the initial injury. Immediate treatment of non-neural injuries is limited to life-threatening problems, such as shock or hemorrhage.

193.5.35.4.1 Acute spinal cord injury

Treatment of acute spinal cord trauma should always be instituted as soon as possible after injury. The specific objectives of therapy are relief of edema, control of intramedullary or extramedullary hemorrhage, relief of spinal cord compression and, in cases of vertebral fracture/luxation, removal of bone fragments from the spinal canal and realignment and stabilization of the vertebral column. Treatment of acute spinal cord trauma may be medical or surgical or a combination of these two therapies. The goal of medical therapy is to control the chemical and vascular changes that result in secondary spinal cord injury. Numerous drugs have been described for the treatment of spinal cord injury; however, the efficacy of many of these drugs for such injuries remains undetermined.

Corticosteroids are routinely and widely used in the treatment of acute spinal cord injury. Despite a positive clinical impression that corticosteroids have beneficial effects, their use is controversial. Some studies have failed to demonstrate significant improvement of neurologic recovery with cortico-steroid administration. The use of low versus high doses of corticosteroids in the treatment of spinal trauma also has yielded conflicting results. Use of corticosteroids may result in complications leading to increased morbidity and mortality (e.g., gastrointestinal bleeding, pancreatitis, colonic perforation).

882

The only corticosteroid with proven efficacy in the management of spinal cord injury is methylprednisolone sodium succinate (MPSS). MPSS has been studied intensely in both the research and clinical settings for the past 10 years.[282–289] The drug must be administered as soon as possible after injury, and the effective dose range and the interval after injury when the drug may be given are narrow. Spinal cord uptake of MPSS rapidly decreases with time after injury, probably owing to secondary post-traumatic tissue loss and progressive blood flow decrease to the injury site. The molecular mechanism of action of MPSS may involve intercalation into the cell membrane and suppression of lipid peroxidation and hydrolysis. Inhibition of injury-induced lipid peroxidation results in attenuation of

883

progressive post-traumatic ischemia and hypoxia, together with reversal of intracellular calcium accumulation. MPSS also directly retards secondary neuronal degeneration. The beneficial effects of antioxidant doses of MPSS support the contention that post-traumatic lipid peroxidation is a critical degenerative mechanism that may be interrupted with an antioxidant agent.

Current recommendations in humans are that patients with acute spinal cord injury receive MPSS (30 mg/kg given intravenously over 15 minutes) within 3 hours of injury; that they be maintained on an infusion of 5.4 mg/kg/hr for 24 hours; and that those that receive the initial bolus 3 to 8 hours after injury receive the infusion for 48 hours. Higher doses and initiation of treatment more than 8 hours after injury may exacerbate spinal cord damage. Complications include an increase in the incidence of pneumonia (2.6-fold in humans), gastrointestinal hemorrhage, and perforation. Although some experimental and clinical studies have found an improved recovery in research animals and humans treated with MPSS after spinal cord injury, a number of other studies have not found a significant improvement. One of the conclusions of the Third National Acute Spinal Cord Injury Randomized Controlled Trial[284] was that although the improvements in spinal cord injury patients after MPSS treatment were statistically significant, the actual functional differences were relatively small and benefited upper body function as opposed to actual locomotion.

The 21-aminosteroid tirilazad mesylate is a potent inhibitor of lipid peroxidation. In the Third National Acute Spinal Cord Injury Randomized Controlled Trial,[284] administration of tirilazad (2.5 mg/kg every 6 hours for 48 hours) after an initial 30 mg/kg bolus of MPSS to spinal cord injury patients resulted in motor recovery rates equivalent to those of patients who received MPSS for 24 hours. The reasons cited for failure of a 48-hour tirilazad regimen to improve neurologic recovery as much as the 48-hour MPSS regimen included the possibility that important mechanisms other than lipid peroxidation are involved in spinal cord injury and that a less than optimal dose was used. Another randomized, controlled trial of the drug in humans with spinal cord injuries is currently underway.

One of the most damaging effects of spinal cord injury is the accumulation of intracellular calcium in injured neurons, and neuronal death is closely related to the rise in intracellular calcium. Administration of a calcium channel antagonist (i.e., nimodipine or flunarizine) after spinal cord injury has had mixed results.

A decision on surgical therapy must be made as soon as non-neural injuries have been treated and medical management has been instituted. Ideally, this is within 2 hours of injury. Indications for surgery after spinal cord injury are moderate to severe paresis, or paralysis, associated with myelographic evidence of spinal cord compression; progressive worsening of neurologic signs despite adequate medical therapy; and luxation or fracture of the vertebral column in association with distraction, malalignment, instability, or myelographic evidence of spinal cord compression. Any animal with sustained compression of the spinal cord after injury, regardless of the cause, must be considered a candidate for surgical decompression of the spinal cord. In general, it is best to initiate surgical therapy in any animal in which uncertainty exists regarding the indications for surgical versus medical therapy. Neurosurgical procedures require specialized knowledge and equipment, and prompt referral to a qualified surgeon may be indicated.

The major objectives of surgical management of spinal trauma are decompression of sustained spinal cord compression and realignment and stabilization of vertebrae if necessary. Laminectomy alone is not sufficient for decompression in most cases, and the compressing mass (e.g., disk material, hematoma, bone fragments) should be removed when possible. When spinal cord swelling is the major source of compression or when discoloration of the spinal cord is present, durotomy or myelotomy may be combined with laminectomy.

No satisfactory methods of external fixation of spinal fractures exists for cats and dogs.[290] The author (RAL) favors the use of polymethyl methacrylate and Steinmann pin fixation for most spinal fractures or luxations.[291,292] Surgical management of spinal cord injuries provides the best opportunity for rapid, complete recovery in animals with sustained compression or instability and also facilitates postinjury care, because the risk of further injury from movement of an unstable vertebral column is minimized. However, conservative management, including strict confinement for 4 to 6 weeks, may be efficacious in animals with minimal neurologic deficits and without myelographic evidence of sustained spinal cord compression or vertebral displacement or instability.

Regardless of the type of stabilization used, strict confinement is recommended for 6 weeks after surgery. Potential complications encountered in dogs or cats with a spinal injury include the development of a urinary tract infection and pressure sores. Careful nursing care is essential, regardless of the type of therapy.[293]

The prognosis for an animal with an acute spinal cord injury depends on numerous factors; however, the results of the neurologic examination should be the main determinant. Assessment of pain perception is essential for an accurate prognosis. Perception of a painful stimulus must be differentiated from reflex activity mediated at the level of the spinal cord. Owners of affected animals should be made aware at the outset of therapy of factors such as the prognosis, the expense involved, the expected time from treatment to recovery, and the need for prolonged physical therapy in most cases. After a severe spinal injury, an animal may require many months to recover, and residual neurologic deficits may persist.

193.5.35.4.2

Chronic spinal cord compression

The approach to treatment of chronic spinal cord compression is different from that for acute spinal cord injury. As previously stated, hemorrhage and edema usually are not prominent factors in chronic compression, therefore medical management with corticosteroids would not be expected to be efficacious; however, many animals with chronic spinal cord compression improve clinically with corticosteroid administration. The reason for such a response has not yet been determined; however, it may be due to the effects of corticosteroids at the membrane level, resulting in improved conduction in remaining axons. Occasionally, animals may be maintained for months or years with corticosteroid therapy alone.

Surgical decompression and stabilization should be considered in dogs or cats with neurologic deficits associated with chronic spinal cord compression. Surgical decompression in such animals should be approached cautiously, because pathologic alterations in the spinal cord may be irreversible, and the most that may be achieved is arrest of the progression of neurologic deficits. In some cases, compensation for the irreplaceable loss of neural tissue may occur. Neurologic status may be worsened by surgical decompression, even with meticulous surgical technique. Such deterioration may be the result of reactive hyperemia that follows decompression, which in turn results in vascular protein leakage in the affected spinal cord segments.

193.5.36 Spinal Stenosis

193.5.36.1 Etiology and Pathogenesis

The term *spinal stenosis* indicates a narrowing of the vertebral canal, a condition that may produce a variety of neurologic syndromes.[31] The stenosis may be focal, segmental (affecting several adjacent vertebrae), or generalized (present throughout the vertebral column). Spinal stenosis may result either from bony impingement on neural elements (congenital stenosis, developmental stenosis resulting from inborn errors in skeletal growth, idiopathic developmental stenosis, or acquired stenosis) or from compression of neural tissue by nonosseous components of the walls of the vertebral canal (hypertrophy of the dorsal longitudinal ligament or ligamentum flavum or disk extrusion/protrusion).

Congenital spinal stenosis Congenital stenosis may occur as a primary lesion or may be seen in association with other congenital anomalies of the spinal cord or vertebral column.[294,295] In dogs, congenital stenosis may occur with block vertebrae or hemivertebrae.[31] Congenital spinal stenosis has been reported in association with transitional vertebrae, especially at the lumbosacral junction of dogs.[31,204] Despite the congenital origin of this stenosis, the initial manifestation of clinical signs may not occur until after an animal has reached skeletal maturity.

193.5.36.1.1 Thoracic vertebral canal stenosis

Segmental vertebral stenosis frequently occurs in the cranial thoracic spine of several dog breeds (e.g., Doberman pinscher).[31] Vertebrae T3 through T7 are affected most frequently. A decrease in the dorsoventral diameter of the vertebral canal, compared with adjacent vertebrae, is seen, and spinal cord compression may be seen. Mild lordosis, kyphosis, or scoliosis may be seen in association with the stenosis.

193.5.36.1.2 Developmental stenosis resulting from inborn errors in skeletal growth

This condition has been reported to occur in dogs.[168] The term *inborn errors* indicates incoordination of ossification and bone growth as a result of hereditary transmission or fresh mutation of a normal gene.[31] The errors are based on metabolic or other disturbances of cells involved in skeletal development. The disproportionate bone growth is already present at birth; however, the causative agents remain active during maturation. Therefore the term *developmental* is used to distinguish this group from the congenital stenoses. These conditions result in generalized spinal stenosis, which is more pronounced in the lumbar vertebral column. The vertebrae have a narrowed vertebral canal; however, the spinal cord and cauda equina are of normal size. This results in a disproportion between the dimensions of the vertebral canal and the volume of its contents. The relative spinal stenosis of chondrodystrophic dog breeds may contribute to the increased incidence of disk extrusion in these breeds. As with congenital stenosis, clinical signs may not develop until later in life and may be related only to a single level of the stenotic vertebral canal.

193.5.36.1.3 Idiopathic developmental stenosis

A genetic disturbance in which pathologic effects are apparent in their entirety only when growth is complete and the vertebrae have attained full size is termed *developmental*.[31] Clinical signs of spinal stenosis may result if some additional factor (e.g., disk protrusion) compromises the available diameter of the spinal canal in adult life. Hypertrophy of the bone of the vertebral arch or of the ligamenta flava may be present in this condition, which has been reported to occur in dogs.

193.5.36.1.4 Hypertrophy of the nonosseous components of the vertebral canal

Spinal stenosis resulting from ligamentous proliferation at C2–C3 has been reported in young rottweilers.[31,296]

193.5.36.2 Clinical Findings

Clinical signs of spinal stenosis reflect the location of the lesion, regardless of the precise cause.

193.5.36.3 Diagnosis

The diagnosis of spinal stenosis is made primarily by radiography. Myelography is essential for precise localization of the spinal stenosis. Other contrast-enhanced radiographic techniques may be used to define stenosis affecting the lumbosacral junction. Advanced imaging (CT or MRI) may aid in the determination of the location and extent of lesions associated with spinal stenosis.

193.5.36.4 Treatment

Spinal stenosis may be treated either medically or surgically. Relief of apparent pain with analgesic or anti-inflammatory drugs, combined with exercise restriction, may be adequate in dogs with mild clinical signs. In animals in which apparent pain persists or the stenotic condition worsens, decompressive surgery is indicated. Surgery is best performed early in the course of the disease. Internal spinal stabilization or fusion may be necessary when instability is evident on stress radiographs or after extensive decompressive procedures.

193.5.37 Spondylosis Deformans

193.5.37.1 Etiology and Pathogenesis

Spondylosis deformans is characterized by the formation of osteophytes (bony spurs) around the margins of vertebral endplates.[297] Osteophytes may form at one or more intervertebral disk spaces and may appear to bridge or almost bridge intervertebral disk spaces. The radiographic appearance of solid bony bridges may represent only an interdigitation of the adjacent osteophytes. Osteophyte production in spondylosis deformans is the noninflammatory bony response to degenerative changes in the intervertebral disks. These degenerative changes involve the anulus fibrosus and lead to the formation of intradiskal fissures.

The incidence and size of vertebral osteophytes increase with age. All dog breeds are affected, although large canine breeds may have a higher incidence of spondylosis deformans.[298] The caudal thoracic, lumbar, and lumbosacral spinal segments are affected most frequently. Because these segments are the areas of greatest spinal mobility, dynamic and mechanical factors may play a role in osteophyte formation. Spondylosis deformans is uncommon in the cervical and cranial thoracic segments in dogs. In cats, the incidence of spondylosis deformans forms a bell-shaped curve, with the highest incidence at the level of T7–T8.

The terms *ankylosing spondylosis* and *ankylosing spondylitis* have been used by some authors to describe spondylosis deformans, despite the fact that it is not an inflammatory condition and ankylosis is uncommon.

193.5.37.2 Clinical Findings

In most affected animals, spondylosis deformans is not of clinical significance. Rarely, bony spurs may project into the spinal canal or intervertebral foramina, resulting in compression of the spinal cord or spinal nerves. In such affected animals, the clinical signs, which depend on the location of the lesion, include apparent spinal pain, lameness, and signs of transverse myelopathy or peripheral neuropathy. Other causes of spinal cord disease, peripheral nerve disease, and apparent spinal pain should be investigated and ruled out before clinical signs are attributed to spondylosis deformans. Localized pain or lameness is reported to occur in animals with fracture of vertebral osteophytes.

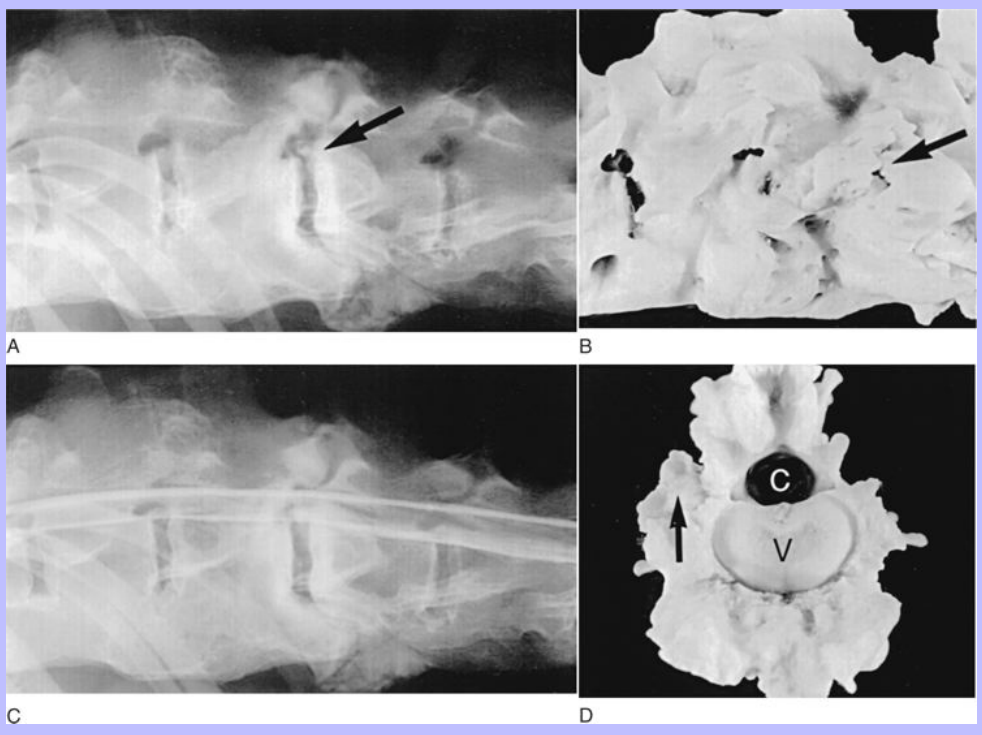
884

885

193.5.37.3 Diagnosis

A diagnosis of spondylosis deformans is based on the results of radiographs of the spine (Figure 193-17). Bony osteophytes associated with spondylosis deformans may be seen at one or more intervertebral disk spaces ventral to the vertebral bodies on lateral projections and lateral to the vertebral bodies on ventrodorsal views. These osteophytes have a curved, beaklike appearance with smooth ventral and lateral borders. Osteophytes range in size from small bony spurs to those that equal the dorsoventral dimensions of the vertebral body. Spurs from adjacent vertebrae may interdigitate. Osteophytes form predominantly around the ventral and lateral margins of the vertebral endplates, and those seen on lateral radiographs appear to be projecting dorsally into the spinal canal. Such osteophytes generally are located lateral to the spinal canal. Extensive osteophyte production dorsolateral to the vertebral body may compress spinal nerves at the level of the intervertebral foramina.

Figure 193-17 Spondylosis deformans. Lateral radiograph **(A),** gross pathologic specimen **(B),** and lateral myelogram **(C)** of the cranial lumbar vertebral column of a 12-year-old male golden retriever. Note the extensive spondylosis deformans present in the absence of myelographic abnormalities. Osteophytes *(arrow)* may appear to project into the vertebral canal on the lateral projection; however, these are actually dorsolateral and do not result in spinal cord compression. The typical location of osteophytes is seen in **D,** in which the spinal canal *(C)* of the L2 vertebrae *(V)* is not encroached upon by the ventrally and laterally located osteophytes. The arrow in **D** indicates osteophytes located close to the intervertebral foramen. This dog was neurologically normal.



Bone may form in the mass of connective tissue formed between developing osteophytes and may remain unattached to the vertebral bodies. These apparently free bone fragments are usually seen ventral to the intervertebral disk and may eventually become incorporated into developing osteophytes. These bone fragments may appear radiographically to be fractured osteophytes, but in fact they are not formed as a result of trauma.

Vertebral osteophytes may occur at either normal or narrowed disk spaces. Dorsally or dorsolaterally projecting osteophytes need to be distinguished from calcified disk material on lateral radiographs. Vertebral osteophytes may also form as a result of instability between adjacent vertebrae as a result of vertebral fracture or luxation, discospondylitis, congenital vertebral malformations, and surgery (e.g., disk fenestration). However, the term *spondylosis deformans* is used specifically to define the formation of vertebral osteophytes secondary to disk degeneration. Disk protrusion may occur at the same site as spondylosis deformans, resulting in spinal cord compression. Myelography or advanced imaging (CT or MRI) is necessary to determine whether disk protrusion or dorsal vertebral osteophyte formation is causing spinal cord compression. 885 886

193.5.37.4 Treatment

Spondylosis deformans rarely results in spinal cord compression. However, should spinal cord compression or nerve root entrapment be demonstrated in an animal with neurologic deficits, surgical decompression may result in clinical improvement. Analgesics may be of benefit in animals with evidence of pain suspected to be the result of spinal nerve compression by the production of vertebral osteophytes. In most animals, spondylosis deformans is not of clinical significance, and treatment is not necessary.

193.5.38 Synovial Cysts

Spinal synovial cysts may arise from the articular facets and surrounding connective tissues of the cervical and thoracolumbar vertebrae of dogs. These cysts may result in progressive extradural compression of the spinal cord. The etiology of synovial cysts is unknown; however, both degenerative changes and trauma have been suggested as likely causes.[299,300] Clinical signs resulting from compression of the spinal cord by a synovial cyst reflect the location of the cyst (or cysts) and are usually slowly progressive. The diagnosis of synovial cyst is made primarily by means of radiography. Myelography is essential for precise localization of the cyst or cysts. Advanced imaging techniques, particularly CT, may further delineate the location and extent of a synovial cyst. Surgical decompression of the spinal cord and excision of the cyst appear to provide long-term resolution of clinical signs.

193.5.39 Syringomyelia and Hydromyelia

193.5.39.1 Etiology and Pathogenesis

Syringomyelia (cavitation of the spinal cord) and hydromyelia (dilatation of the central canal) result in similar signs of spinal cord dysfunction. Syringomyelia may occur secondary to hydromyelia (communicating syringomyelia) or may not communicate with the central canal (noncommunicating syringomyelia). Syringomyelia may be associated with spinal cord tumors, myelitis, meningitis, and spinal cord trauma. The cause of syringomyelia is not known, but the condition may result from venous obstruction or distention or may be due to mechanical disruption or shearing of spinal cord tissue planes.

Hydromyelia with or without syringomyelia may be idiopathic or it may be associated with congenital malformations such as myelodysplasia, meningomyelocele or hydrocephalus, or lesions resulting in obstruction of CSF flow into the spinal subarachnoid space at the foramen magnum (e.g., chronic arachnoiditis, trauma, congenital malformations, and vascular malformations).[301–304] Hydromyelia and

syringomyelia in these animals probably results from intracranial and spinal cord venous or arterial pressure changes and associated CSF pressure changes.

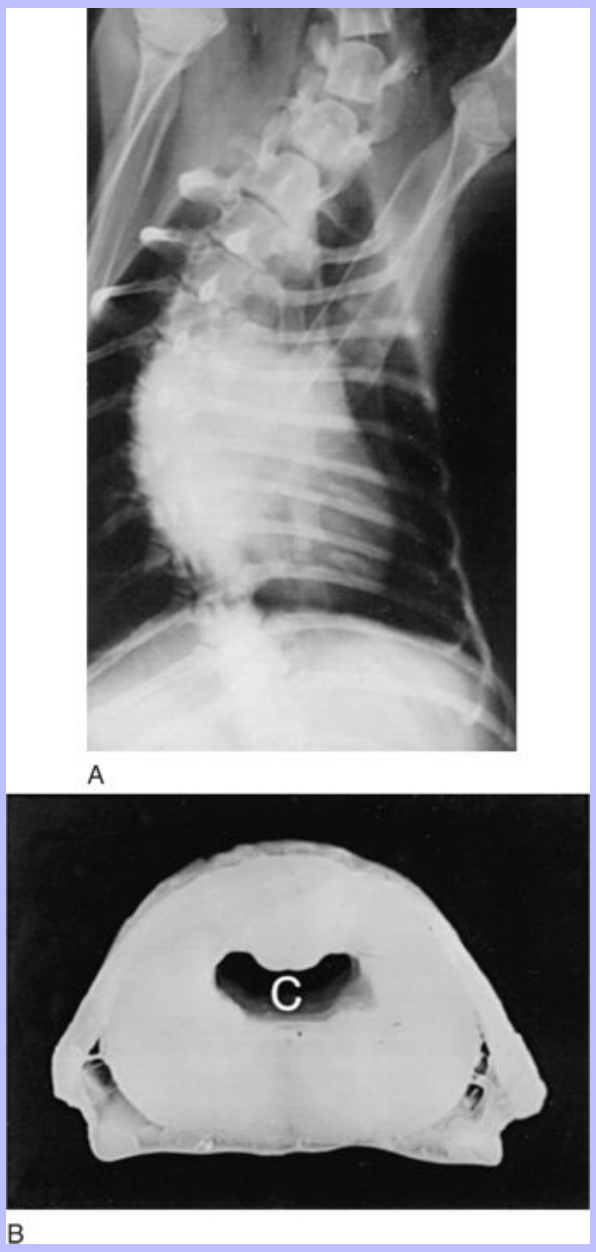
Syringomyelia in weimaraners with myelodysplasia may be the result of progressive hydromyelia, abnormalities in the central canal, or abnormal vascular patterns in local areas of the spinal cord leading to low-grade ischemia, degeneration, rarefaction, and cavitation in the spinal cord.

Regardless of the cause, cavitation may be progressive, probably along planes of structural weakness, such as the gray matter of the dorsal horns, and subsequent necrosis and edema of the spinal cord parenchyma around such a cavitation (or dilated central canal) can result in the onset and progression of clinical signs.

193.5.39.2 Clinical Findings

Clinical signs depend on the location of the lesion and whether other spinal cord lesions are present. Clinical findings include progressive spinal deformity (scoliosis, torticollis); LMN or UMN signs, depending on the location; and apparent spinal pain (Figure 193-18). Clinical signs may be acute or may be progressive over weeks to several years. In weimaraners with myelodysplasia, clinical signs do not appear to be progressive.

Figure 193-18 Hydromyelia and scoliosis. Ventrodorsal radiograph **(A)** of the caudal cervical and thoracic vertebral column of a 1-year-old female beagle. Note the scoliosis of the vertebral column. The spinal cord throughout the region of scoliosis **(B)** had an enlarged central canal *(C)* consistent with a diagnosis of hydromyelia.



193.5.39.3 Diagnosis

Myelography may show obstruction of the flow of CSF at the foramen magnum if hydromyelia or syringomyelia is due to chronic arachnoiditis or arachnoid adhesions. Cisternal puncture for the collection of CSF is contraindicated in these animals, owing to likely inadvertent puncture of the spinal cord. Lumbar CSF may show evidence of chronic inflammation. Myelographic results in other cases may be normal or may show intramedullary swelling of the spinal cord. Advanced imaging (CT or MRI) is extremely useful for identifying the location and extent of cavitary lesions of the spinal cord.[305]

886

887

193.5.39.4 Treatment

Treatment of scoliosis in a dog after drainage of an intraspinal cystic lesion has been reported.[306] Surgical drainage of cavitary lesions in humans has resulted in improvement in some cases.

193.5.40 Vascular Malformations and Benign Vascular Tumors

193.5.40.1 Etiology and Pathogenesis

Spinal arteriovenous malformations and benign vascular tumors (hemangioma, cavernous angioma) have been reported in dogs. Arteriovenous malformations consist of one or more anomalous arteries arising from radicular arteries that drain without a capillary bed into one or more veins communicating with veins on the surface of the spinal cord, resulting in the formation of tangles of tortuous distended vessels on or in the spinal cord. These malformations may be extramedullary or intramedullary, or both. Hemangioma is regarded as a benign neoplasm of endothelium that consists of discrete masses of tangled capillaries with or without cavernous or solid areas. Multiple hemangiomas may occur. These tumors, which arise from the meninges, are predominantly extramedullary but may be intramedullary.

193.5.40.2 Clinical Findings

Arteriovenous malformations and vascular tumors may occur anywhere in the spinal canal, and clinical signs usually reflect a progressive transverse myelopathy. An acute onset or sudden worsening of clinical signs may occur as a result of hemorrhage or thrombosis associated with abnormal vasculature of the malformation or tumor. Clinical signs may be the result of spinal cord compression or ischemia.

193.5.40.3 Diagnosis

The CSF may be normal or may have an elevated protein concentration. It may be xanthochromic, and the WBC count may be mildly elevated if subarachnoid hemorrhage has occurred or if a meningeal inflammatory response is associated with tumor growth.

Myelography may show evidence of an intradural or intramedullary mass. Advanced imaging (CT or MRI) may be used to further define the lesions. Surgical biopsy is necessary to distinguish these lesions from other neoplasms, subarachnoid cysts, and other intradural and intramedullary lesions.

193.5.40.4 Treatment

Surgical removal of a vascular malformation or vascular tumor may be possible.

194 CHAPTER • 194 Peripheral Nerve Disorders

Karen Dyer Inzana

The peripheral nervous system can be defined as those portions of the nervous system that reside partially or entirely outside the central nervous system (CNS) and are invested by a unique set of glial elements, Schwann cells, fibroblasts, and satellite cells. Using this definition, the peripheral nervous system includes cranial nerves II through XII, all of the spinal nerves with their roots, peripheral nerves, and the peripheral components of the autonomic nervous system.[1] Collectively they function to relay information about the environment to the CNS and in turn provide motor control of peripheral structures. Because peripheral nerves are the sole neural structure that controls skeletal muscle, they provide the most elemental level of motor control to the nervous system.

Structurally, peripheral nerves are collections of neuronal cell processes enveloped in fibrous connective tissue.[1] Three distinct supportive tissue sheaths (the endoneurium, the perineurium, and the epineurium) surround individual axons, fascicles of axons, or the entire peripheral nerve, respectively (see Figure 194-1). Neurons are the principle cells that make up the peripheral nerves.[1] Cell bodies are located in the brain stem and spinal cord (motor neurons) or in clusters of cells (ganglia; sensory and autonomic) located in the periphery. Cell bodies extend processes (axons) outside the nervous system, which either receive information from sensory receptors (sensory or afferent neurons) or transmit information regarding movement to peripheral muscles (motor or efferent neurons). All axons are invested with a Schwann cell covering. In most axons 1 μm in diameter, the Schwann cell also generates a myelin sheath that facilitates propagation of action potentials along the axon. Motor axons terminate on multiple skeletal muscle endplates, whereas sensory axons either terminate in secondary neurons, many of which form connections with the motor axons of the same or nearby peripheral nerves, or they continue uninterrupted to the brain stem as sensory spinal tracts.

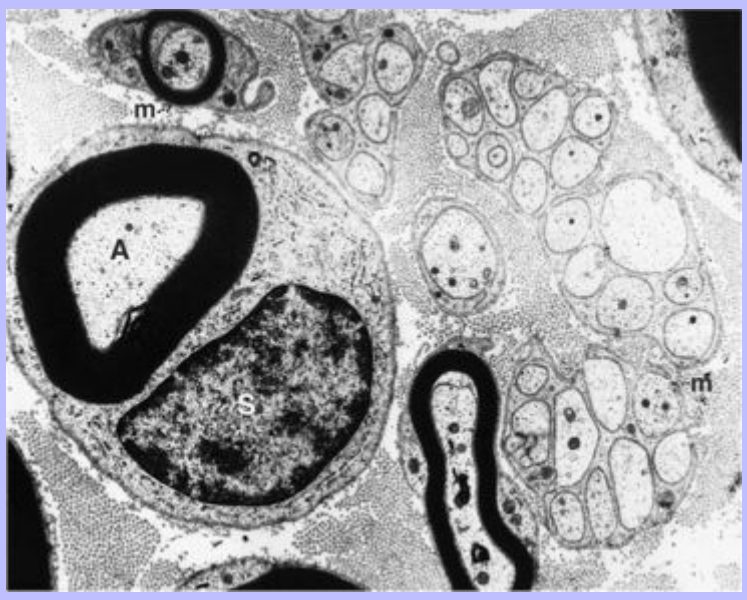
Functionally, information is transmitted along axons electrically in the form of an action potential.[1] The action potential is created by ion influxes, primarily sodium, that change the electrical gradient across the axonal cell membrane. In myelinated axons, sodium ion channels are concentrated at nodes of Ranvier and action potentials are propagated along the axon from node to node (saltatory conduction), whereas ion channels are uniformly located along the entire length of nonmyelinated axons and conduction is continuous along the cellular membrane. Information is transmitted to muscles or other neurons—most commonly chemically—by the physical release of a neurotransmitter at the axon terminal, which interacts with receptors linked to additional ion channels on the receptor surface.

194.1 METHODS OF EVALUATION

There are main methods of evaluating the peripheral nervous system: (1) clinical evaluation, (2) electrophysiological evaluation, and (3) histological evaluation. Clinically, the hallmarks of peripheral nerve disease are motor deficits ranging from weakness to paralysis, hypotonic muscles with rapid muscle atrophy, and diminished or absent spinal reflexes. Sensation may be altered if the disease process affects sensory nerves. These clinical signs may be diffuse or confined to one or more peripheral or cranial nerves. The clinical signs attributed to individual peripheral nerve or cranial nerve injury are outlined in Tables 194-1 and 194-2. Most peripheral neuropathies are “diffuse.” Weakness is often more pronounced in the pelvic limbs. With the exception of the recurrent laryngeal, hypoglossal, and vagal nerves, cranial nerves are usually only affected in more severe cases. Clinical signs of laryngeal paralysis including stridor, inspiratory dyspnea, voice change, and exercise intolerance may be an early sign of a more diffuse peripheral neuropathy.[1] Similarly, dysphagia and megaesophagus have

been associated with generalized peripheral nerve disease.[1] In rare cases where sensory nerves are affected alone, weakness is less apparent than poor coordination. Muscle atrophy is less marked, but spinal reflexes are uniformly depressed.

Figure 194-1 Electron micrograph of a peripheral nerve (×12000). Cross-sections of both myelinated (*A*) and unmyelinated (*a*) axons are present, surrounded by Schwann cell membranes (*m*). The section of the medium-sized myelinated axon in the center was taken through the Schwann cell nucleus (*S*).



Measuring the electrical activity of skeletal muscle via needle electromyography (EMG) is useful to confirm suspicions of peripheral nerve or muscle disease and to map the distribution of injury.[1] A variety of spontaneous electrical potentials may be recorded from denervated or otherwise injured skeletal muscle. These spontaneous potentials have been broken down into several characteristic potentials including fibrillation potentials, positive sharp waves, and high-frequency discharges.[1]

Because nervous tissue is electrically excitable tissue, the functional integrity of specific regions can be evaluated by measuring their ability to conduct an action potential evoked by electrical stimulus or stimulation of specific receptors. Using a combination of neuroanatomic and physiologic principles, any region of the central and peripheral nervous system can be electrophysiologically evaluated. The techniques most useful for peripheral nerve disease include motor and sensory nerve conduction, brain stem auditory evoked potentials, and occasionally spinal cord evoked potentials. These have been described in detail elsewhere.[1] Briefly, in demyelinating neuropathies, motor and sensory nerve conduction is slowed but the evoked action potential remains near normal in amplitude and duration. With axonal loss, significant reduction in nerve conduction velocity is not seen but the evoked action potential is often reduced in amplitude and prolonged. The distinction

between axon or myelin loss is not as readily apparent in central conduction studies. Instead, either conduction block or changes in the evoked potentials are simply an indication of disease.

Finally, the peripheral nervous system can be evaluated histologically without creating marked functional impairment. Muscle biopsies may be useful at distinguishing denervation from primary muscle disease. Denervated skeletal muscles develop characteristic changes of angular atrophy. By evaluating histologic types of muscle fibers in unfixed, frozen samples, both type grouping and large grouped atrophy can be useful indicators of chronicity of disease and regenerative attempts.[1] Fascicular biopsies of peripheral nerves can be obtained from both motor and sensory nerves. Briefly, the peripheral nerve to be sampled is surgically isolated, and a thin strip, less than one third the nerve diameter and extending 2 to 3 cm, is excised. Nerve samples should then be secured in a stretched position prior to fixation in 2.5% glutaraldehyde. Samples may then be sent to a laboratory that specializes in neuromuscular evaluation, where they will usually be osmicated and embedded in plastic for both light and electron microscopy. Postosmicated peripheral nerve biopsies can also be suspended in resin and individual fibers teased apart so that the pathology of successive internodes can be appreciated.[1]

194.2 MECHANISMS OF DISEASE

Because at least a portion of most peripheral nerves resides in the CNS, CNS diseases can affect them. However, this chapter concentrates on diseases unique to the peripheral nervous system and neuromuscular junction. Before considering individual diseases, it is useful to understand some of the complex interrelationships between neurons, axons, and Schwann cells that might contribute to disease processes.

The neuron is a specialized cell with an unusually large surface area that aids in recognition of synaptic inputs from adjacent cells. The neuron contains many of the typical cellular organelles, including a single nucleus, one or more nucleoli, Golgi, and mitochondria. Under most conditions the cytoplasm of neuronal cell bodies contains abundant rough endoplasmic reticulum or Nissl substance.[1] Unlike most cells, neurons must support cellular processes that often extend great distances from the cell body. Damage to a neuron results in degeneration of all of its cellular processes and dissolution of the myelin sheath produced by Schwann cells. Unlike damage to other peripheral nerve structures, regeneration is extremely limited in neuropathies.

Damage to the axon results in wallerian degeneration of all distal sections no longer in contact with the cell body. Histologically, this appears initially as dissolution of the myelin sheath with some clumping of the cytoskeletal elements and degenerating organelles within the axon. This is followed by progressive loss of axonal contents. Schwann cells survive, but peripheral nerve myelin degenerates with the axon. Complete severance of the axon and attendant wallerian degeneration is not difficult to identify histologically. More subtle lesions that result from metabolic alterations of the neuron or its ability to supply constitutive elements to the distal axon are more problematic.

Any disease process that injures the axon will cause secondary demyelination. However, examples of neuropathies exist that primarily target Schwann cells. In cross-section, myelin degeneration appears first as vacuolation, followed by separation of lamellae and finally removal of myelin debris by macrophages. This is usually associated with attempts at remyelination by surviving Schwann cells. Finding inappropriately thin myelin sheaths surrounding large axons or numerous "onion bulbs," concentric layers of Schwann cell membranes surrounding demyelinated or remyelinated axons, are indications of remyelination.[1]

Table • 194-1 Nerves of the Brachial Plexus

NERVE	SPINAL CORD SEGMENT	MUSCLES INNERVATED	SPINAL REFLEX ALTERATIONS WITH INJURY	MOTOR FUNCTION	CUTANEOUS DISTRIBUTION	CLINICAL SIGNS OF DYSFUNCTION
Suprascapular	C6–C7	Supraspinatus, infraspinatus	None	Extension and lateral support of the shoulder	None	Little gait abnormality
Axillary	C6–C8	Deltoid	No deficits or incomplete withdrawal reflex	Flexion of shoulder	Dorsolateral brachium, behind scapular spine	Little gait abnormality
Musculo-cutaneous	C6–C8	Biceps brachii	Decreased or absent biceps tendon reflex; no elbow flexion with withdrawal reflex	Flexion of elbow	Medial forelimb, medial humeral condyle	Little gait abnormality; unable to raise paw to table top (flex elbow)
Radial	C6–T2	Triceps brachii, extensor carpi radialis, ulnaris lateralis common and lateral digital extensors	Decreased or absent triceps tendon reflex and extensor carpi radialis response	Extension of elbow, carpus, and digits	Dorsolateral forelimb, dorsal surface of paw	Loss of weight bearing; unable to fix limb in extension
Median and ulnar	C8–T2	Flexor carpi radialis, superficial digital and deep digital flexors, flexor carpi ulnaris	Decreased or absent flexion of carpus and digits during withdrawal reflex	Flexion of carpus and digits	Palmar surface of paw, caudal forelimb	Little gait abnormality
Nerves of the Pelvic Plexus						
Obturator	L4–L6	Pectineus, gracilis	None	Adduction of pelvic limb	None	Little gait abnormality; limb may slide laterally on slick floor
Femoral	L3–L6	Quadratus femoris	Decreased or absent patellar reflex	Extension of stifle	Saphenous branch supplies medial thigh and digit	Inability to extend stifle
Sciatic	L6–S3	Gluteus semimem-branosus semitendinosus, all muscles innervated by peroneal and tibial nerves	Decreased or absent withdrawal reflex	Flexion and extension of hip	Caudal and lateral surfaces of limb	Cannot flex or extend digits and hock or flex stifle
Peroneal	L6–S3	Peroneus longus, cranial tibial, lateral and long digital extensor	Decreased or absent cranial tibial response	Flexion of hock extension of digits	Dorsal aspect of paw, hock and distal limb	Cannot extend paw (therefore knuckles on dorsum), poor hock flexion
Tibial	L6–S3	Gastrocnemius, superficial and deep digital flexors	Decreased or absent gastrocnemius tendon reflex	Extension of hock, flexion of paw	Plantar surface of paw	Unable to fix hock in extension

Table • 194-2 Cranial Nerves

CRANIAL NERVE	ANATOMIC COURSE	FUNCTION	EVALUATION
CN I: olfactory	Sensory ending in nasal mucosa, entercribriform plate to olfactory bulb ofpyriform cortex	Smell	Not routinely evaluated
CN II: optic	Retinal ganglion cells form optic nervethat traverses optic foramen to opticchiasm and optic tracts in diencephalons	Vision and pupillarylight reflexes (PLRs)	Menace reaction, PLRs, avoids objects
CN III: oculomotor	Cell bodies in mesencephalon sendprocesses through the orbital fissureto extraocular eye muscles and iris	Motor to extraoculareye muscles, parasympathetic to eye	Eye movement, PLRs; damage causesventrolateral strabismusand mydriasis
CN IV: trochlear	Cell bodies in mesencephalon; processescross in rostral medullary velum andpass through orbital fissure toextraocular eye muscles	Motor to dorsal obliquemuscle that rotates globe	Not routinely tested in dogs; damage causes rotationaldeviation of globe
CN V: trigeminal	Motor bodies in metencephalon; sensory cell bodies in trigeminalganglion terminate on metencephalicneurons; axons divide in to mandibular, maxillary, and ophthalmic branchesthat pass through oval foramen, around foramen, and orbitalfissure respectively	Motor to muscles ofmastication includingmasseter, temporal, pterygoids, rostraldigastricus, and myohyoidsensory to the face	Jaw tone, masticatorymuscle mass, sensationto face
CN VI: abducent	Cell bodies in metencephalon; have a long intracranial course toexit the orbital fissure to eye	Motor to extraocular eyemuscles including lateralrecturs and retractor bulbi	Eye movement; damagecauses ventromedialstrabismus
CN VII: facial	Cell bodies in myelencephalon; passthrough internal acoustic meatusand petrous temporal bone tostylomastoid foramen	Motor to muscles of facialexpression; sensory tosmall area of pinna; parasympatheticinnervation to lacrimalglands, mandibular andsublingual salivary glands	Ability to blink, retract lip, move ear, produce tears
CN VIII: vestibulocochlear	Sensory neurons arise fromreceptors in inner ear, traverse internal acousticmeatus to myelencephalon	Balance, linearacceleration, hearing	Body posture, eyemovement, hearing; damage causespositional strabismusand nystagmus
CN XI: glossopharyngeal	Cell bodies in myelencephalon exitexternal jugular foramen	Sensory and motor to thepharynx; parasympatheticinnervation to zygomaticand parotid salivary glands	Gag reflex, swallowing
CN X: vagus	Cell bodies in myelencephalonexit external jugular foramen	Sensory and motor topharynx; parasympathetic tocardiac, pulmonary, and gastrointestinal(GI) systems	Gag reflex, swallowing, oculocardiac reflex

CN XI: accessory	Cell bodies in myelencephalon androstral spinal cord exit externaljugular foramen	Motor to larynx, trapezius, andsternobrachiocephalicus	Vocalization, muscle tone
CN XII: hypoglossal	Cell bodies in myelencephalon exithypoglossal canal	Motor to tongue muscles	Tongue movement

194.2.1 Developmental and Congenital Disorders

Developmental and congenital disorders are peripheral neuropathies that occur in specific breeds with a predictable clinical course and characteristic pathology. A genetic basis is likely. The age of onset, specific clinical signs, and rate of progression varies from disease to disease. Because these disorders are, together, quite rare, the names and brief descriptions are listed in Table 194-3. More complete descriptions are available in neurology textbooks.

194.2.2 Metabolic and Toxic Disorders

194.2.2.1 Diabetes Mellitus

Diabetic neuropathy represents one of the most significant late complications of diabetes mellitus in human beings. The reported incidence in human diabetic populations varies with diagnostic criteria but ranges from 5% to 100%.[1] Although similar incidence statistics have not been reported in animals, a casual relationship between diabetes mellitus and peripheral nerve disease has been identified in dogs and cats as well. In dogs the neuropathy is usually subclinical.[1] In cats clinical signs are much more common.[1] Diabetic cats may develop a plantigrade stance, pelvic limb weakness, muscle wasting, and depressed myotatic reflexes. Electrodiagnostic abnormalities in some cats consists of spontaneous activity in skeletal muscle and slowed nerve conduction with smaller evoked muscle responses suggestive of an axonal neuropathy. In others a relative paucity of abnormal muscle activity with slowed nerve conduction or conduction block suggests demyelination may be more prominent.[23,24]

Pathologic findings are equally mixed. Some have described a loss of axons in distal nerves similar to distal sensorimotor axonal neuropathy in human diabetic patients.[1] Others have focused on changes in Schwann cell structure and suggested that some cases of diabetic neuropathy result from primary Schwann cell injury and demyelination.[24–27] Recently, significant changes in perineural thickness caused by perineural cell hyperplasia, basement membrane thickening, and increased interlamellar space was described in dogs with diabetes mellitus, whereas another study found thickening of endoneurial capillary basement membrane along with an increase in endoneurial capillary density and luminal area.[28,29] These findings suggest that the pathogenesis of diabetic neuropathy, regardless of the primary neural target, includes compression of endoneurial structures by a nondistensible perineurium, alterations in the nerve and blood barrier, and changes in vascular perfusion.

A number of metabolic derangements are thought to be involved, including increased aldose reductase activity leading to the accumulation of sorbitol and fructose, increased production and decreased scavenging of reactive oxygen species leading to cellular oxidative stress and impaired mitochondrial function, together with activation of protein kinase C, which promotes vasoconstriction and nerve ischemia. Altered protein synthesis and delayed axonal transport of molecules necessary to maintain distal axonal segments, together with immunologic mechanisms, may also play a role.

194.2.2.2 Hypothyroidism

The frequent association between hypothyroidism and a vast array of neurologic symptoms has lead to a casual association between the two conditions. Despite hypothyroidism being one of the most widely recognized causes of neuromuscular disease in both man and animals, it remains one of the least well characterized.

The most common neurologic problem described is paresis. This varied from monoparesis to hemiparesis to quadriparesis, with an equally variable onset and rate of progression. Cranial neuropathies are the second most common disorder with the facial, vestibulocochlear, and trigeminal nerves appearing most susceptible. Megaesophagus and laryngeal paralysis are also possible in dogs with hypothyroidism. Whether these are manifestations of a more generalized neuromuscular disorder or represent a unique form of the disease is unclear. Electrophysiologic evidence of a generalized neuropathy including spontaneous activity in all limb muscles and slowed nerve conduction velocities has been found. In addition, brain stem auditory evoked potentials are often reduced in amplitude and have prolonged latencies.[1]

In human patients and experimental models, hypothyroidism has been associated with both Schwann cell and primary axonal injury, with glycogen aggregates occurring in the cytoplasm of both cells.[1] Remaining axons often appear to have shrunken axons with inappropriately thick myelin sheaths, suggesting that axonal atrophy may be a feature of the neuropathy in some cases.

194.2.2.3 Botulism

Botulism in an acute, rapidly progressive, generalized lower motor neuron (LMN) paralysis that results from ingestion of the exotoxin produced by *Clostridium botulinum*.[1] *C. botulinum* is a saprophytic soil organism with a worldwide distribution. Under anaerobic conditions the toxin is elaborated from both vegetative cells and, to a lesser extent, spores. Although eight antigentically different types of botulinum neurotoxins have been identified; most cases of botulism in dogs are caused by type C.[1]

Clinical signs may begin within hours of toxin ingestion or may be delayed for up to 6 days. The severity of signs varies with both the amount and potency of toxin ingested, as well the susceptibility of the individual animal. Most often, clinical signs begin as an ascending paralysis in the rear limbs preceding forelimb involvement. In severe cases, complete flaccid paralysis is accompanied by weakness of facial, pharyngeal, and esophageal musculature.

Electrophysical changes characteristic of botulism include a marked reduction in the amplitude of the muscle action potential evoked by electrical stimulation of a motor nerve, whereas motor conduction velocities are normal or only mildly reduced. EMG is usually normal. The diagnosis of botulism is confirmed by identifying toxin in the food, serum, stomach contents, or feces. A mouse neutralization is available. By injecting toxin alone and in combination with specific antitoxins, both the type and potency of the botulinum toxin can be identified. Radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), and passive hemagglutinations tests have been developed that will evaluate the toxin and type but do not evaluate potency. Recovery of *C. botulinum* from fecal culture is also presumptive evidence of intoxication because the organism rarely colonizes the normal canine intestine.

Pathophysically, ingested toxin is absorbed from the gastrointestinal (GI) tract and is transported to cholinergic nerve terminals. The toxin binds to presynaptic terminals, is internalized, and then blocks

acetylcholine release, presumably by inhibition of calcium ion increases necessary for transmitter release. Recovery usually occurs in 2 to 3 weeks, after regrowth of terminal motor branches. Because most animals recover within weeks, treatment is largely supportive. Antibiotics should only be used to treat secondary infections because they may facilitate intestinal colonization of *C. botulinum* by altering the normal GI flora. An antitoxin is available and should either be a polyvalent antitoxin or specific for type C. Antitoxin is not effective after the toxin has entered nerve terminals; therefore it will only halt the progression of the disease and not reverse clinical signs. Recommended antitoxin dose is 10,000 to 15,000 U, intravenously or intramuscularly administered twice at 4-hour intervals. Anaphylaxis is possible, so a test injection of 0.1 mL interdermally 20 minutes prior to antitoxin administration is advisable.

893

Table • 194-3 Developmental/Congenital Disorders in Dogs and Cats Involving the Peripheral Nervous System

SPECIFIC NEUROPATHY, BREED AFFECTED, AND REFERENCE(S) CITED	INITIAL SIGNS	HISTOLOGY
Loss of Motor Neurons		
Progressive neuropathy in Cairn terriers[1]	Rear limb weakness	Central and peripheral chromatolysis
Focal spinal muscular atrophy in German shepherd dogs[1]	Forelimb weakness	Asymmetrical degeneration of somatic motor neurons
Hereditary progressive spinal muscle atrophy in English pointers[1]	Generalized weakness	Chronic denervation
Spinal muscular atrophy in rottweilers[1]	Regurgitation and generalized weakness	Central chromatolysis and marked cell body swelling
Neuronal abiotrophy in Swedish Lapland dogs[1]	Weakness to tetraplegia	Neuronal degeneration and central and peripheral chromatolysis
Spinal muscle atrophy in Brittany spaniels[2,3]	Weakness to tetraplegia	Neuronal chromatolysis and proximal axonal swelling
Loss of Peripheral Axons		
Giant axonal neuropathy in Alsatians[1]	Rear limb weakness	Swelling in axons
Peripheral neuropathy in aged German shepherds[1]	Rear limb weakness	Endoneural fibrosis
Hereditary polyneuropathy in Alaskan malamutes[1]	Rear limb weakness	Demyelination of axons
Idiopathic polyneuropathy in Alaskan malamutes[1]	Rear limb weakness and hyperesthesia	Axonal degeneration
Neuropathy in Birman cats[1]	Rear limb weakness and hypermetria	Loss of myelinated fibers
Polyneuropathy in rottweiler dogs[1]	Paraparesis then tetraparesis	Degeneration of peripheral nerves
Progressive axonopathy in boxer dogs[1]	Rear limb weakness	Mild axonal swellings
Laryngeal paralysis-polyneuropathy in dalmatians and rottweilers[1,4]	Respiratory distress and syncope	Peripheral neuronal degeneration
Schwann Cell Dysfunction		
Hypomyelinating neuropathy in golden retrievers[1]	Rear limb weakness	Hypomyelination and elevated Schwann cell cytoplasm
Hypertrophic neuropathy in Tibetan mastiffs[1]	Tetraparesis	Extensive demyelination
Loss of Sensory Neuron or Axon and Laryngeal Nerves		
Sensory neuropathy in long-haired dachshunds[1]	Abnormal rear limb abduction	Distal loss of sensory nerve fibers
Acryl mutilation in English pointers and shorthaired pointers[1]	Biting paws to severe self-damage	Lowered number of ganglionic cell bodies
Laryngeal paralysis in Bouvier des Flanders[1]	Inspiratory stridor and dyspnea	Axonal degeneration
Laryngeal paralysis in Siberian huskies[1]	Inspiratory stridor and dyspnea	Neuronal loss
Inborn Errors in Metabolism		
Hyperchylomicronemia in cats[1,5–8]	Horner's syndrome tibial/radial nerve compression	–
Hyperoxaluria type 2 in domestic shorthaired cats[1,9–11]	Acute renal failure	–
α-L-fucosidosis in English springer spaniels[1,12–18]	Behavior changes and generalized ataxia	Neuronal infiltration with macrophages

Atypical GM2 gangliosidosis in cats[1]	CNS dysfunction	Wallerian degeneration of peripheral axons, lamellar inclusions of Schwann cells
Globoid cell leukodystrophy[1,19,20]	Paraparesis and/or cerebellar signs	Axonal degeneration
Neiman-Pick disease in Siamese cats[1]	Tetraparesis and hypotonia	Marked demyelination; vacuolated and granular nerve distention
Glycogen storage disease IV in Norwegian forest cats[1,21,22]	Hyperthermia, tremors, ataxia	Peripheral asymmetrical Schwann cell accumulations throughout nervous tissue

194.2.2.4 Tick Paralysis

Tick paralysis is an acute, rapidly progressive generalized LMN paralysis caused by a salivary neurotoxin produced by ticks.[1] Adult female *Dermacentor andersoni* (the Rocky Mountain wood tick) and *D. variabilis* (the American dog tick) are most often incriminated in North America, whereas *Ixodes holocyclus* is most often incriminated in Australia. Adult females, nymphs, and larvae of *Ixodes* ticks may produce the neurotoxin. Although additional sites of neuronal dysfunction may result from intoxication, the predominate clinical signs are produced by inhibition of acetylcholine release from motor nerve terminals.

In the United States, clinical signs are restricted to dogs. Cats are also susceptible to the effects of *Ixodes* neurotoxin in Australia and have similar clinical signs. In most cases, rear limb weakness begins 5 to 7 days after tick attachment. This is rapidly followed by generalized weakness and eventually complete flaccid paralysis and areflexia within 24 to 72 hours. Cranial nerves, especially the facial nerve, may be mildly affected by the *Dermacentor* neurotoxin, but pain sensation is preserved and the animals do not appear hyperpathic. In contrast, *Ixodes* neurotoxin causes more profound signs of facial paralysis, dysphagia, and megaesophagus. Autonomic signs include mydriasis with loss of pupillary light reflex (PLR), peripheral vasoconstriction and arterial hypertension, pulmonary hypertension and edema, and either tachycardia or bradycardia. Failure to diagnose tick paralysis can result in death from respiratory paralysis within days.

Electrodiagnostic changes are similar in both forms of tick paralysis. EMG is usually normal. The evoked muscle action potential is reduced in amplitude or nonexistent, and mild slowing of both motor and sensory nerve conduction velocities occurs.[1] The diagnosis is made by exclusion of other causes of rapidly progressive generalized LMN paralysis (i.e., botulism, acute polyradiculoneuritis, myasthenia gravis [MG]) and response to tick removal. Clinical signs improve within 24 hours after *Dermacentor* tick removal, and the animals are usually normal within 48 hours. In Australia, clinical signs may progress for 24 to 48 hours after tick removal.

Table • 194-4 Toxic Neuropathies Recognized in Dogs and Cats

COMPOUND	SUCCEPTABLE SPECIES	PATHOLOGY
Vincristine	Dogs and cats	Distal axonopathy, loss of neurotubules with neurofilamentous accumulations in axons
Pyridoxine	Dogs	Neuronal loss in sensory, dorsal root ganglia, and trigeminal ganglia
Mercury	Dogs and cats	Neuronal loss in sensory, dorsal root ganglia, and trigeminal ganglia
Thallium	Dogs and cats	Gastrointestinal (GI) irritation, skin lesions, neuronal loss in cerebrum, cerebellum, and sensory ganglia
Lead	Dogs and cats	Central nervous system (CNS) signs predominate, rare megaesophagus; Schwann cell pathology in other species
Organophosphates	Cats (experimental)	Distal axonopathy with tubovesicular profiles in axons
Acrylamide	Cats and dogs (experimental)	Distal axonopathy with neurofilament accumulation in axons
Hexacarbons	Cats (experimental)	Distal axonopathy with giant neurofilamentous axonal swellings
Lasalocid	Dogs	Pathology not described; dogs recovered in 2–50 days.

Administration of canine hyperimmune serum at 0.5 to 1 mL/kg intravenously has been recommended to bind circulating neurotoxin and prevent further progression. Because the only available hyperimmune serum is derived from dogs, cats should be pretreated with 30 mg/kg hydrocortisone, and epinephrine (1 mL of a 1:10,000 solution) should be available to counteract anaphylaxis. Autonomic dysfunction may be improved by administration of a combination of phenoxybenzamine hydrochloride 1 mg/kg as a 0.1% solution administered intravenously over 15 minutes every 12 to 24 hours and acepromazine 0.05 to 0.10 mg/kg intravenously every 6 to 12 hours. Oxygen therapy and respiratory support may be necessary for severely affected cases. Dogs are susceptible to repeat bouts of tick paralysis. Even though an immune response develops against *Ixodes* neurotoxin, it has only a limited duration. Vaccines are currently unavailable, so minimizing tick infestation is the best method of prevention.

194.2.2.5 Miscellaneous Toxins

The nervous system is the target of a tremendous number of toxic compounds. The list of drugs, metals, and other environmental chemicals that have been associated with peripheral neuropathy in humans is lengthy.[1] Unfortunately the clinical significance of most of these agents in veterinary medicine is uncertain. Far fewer documented toxic peripheral neuropathies exist in dogs and cats than in human beings. Potential explanations for this observation include difficulty in identifying toxin exposure without critical historical information and difficulty in identifying subtle signs of sensory deficits, weakness, or both in veterinary patients. Without overt clinical signs, a cause-and-effect relationship between chemical exposure and disease may be difficult to ascertain. Finally, clear differences exist in species susceptibility to recognized toxins. Toxin exposure should be considered for any animal with an undiagnosed peripheral nerve disease. The National Animal Poison Control Center (1-900-680-0000) can provide valuable information regarding any suspicious exposure. Some of the recognized neurotoxicants that affect the peripheral nervous system in dogs and cats are listed in Table 194-4.

194.2.3 Inflammatory and Immune-Mediated Neuropathies

194.2.3.1 Acute Polyradiculoneuritis (Coonhound Paralysis)

Acute polyradiculoneuritis is a common neuropathy affecting primarily dogs and occasionally cats.[1] The syndrome was first described in 1954 as an acute, rapidly progressive paralysis that occurred in dogs 7 to 10 days after contact with a raccoon.[1] An identical syndrome has subsequently been described in dogs and cats with no known exposure to raccoons.[1] The syndrome was originally named *coonhound paralysis* to reflect the association between raccoons and paralysis. However, the recognition of additional cases suggests the broader term *acute polyradiculoneuritis* better reflects the full spectrum of the disease.

Clinical signs of generalized weakness typically begin in the pelvic limbs and progress in an ascending fashion to involve thoracic limbs. In severe cases, cranial nerves and respiratory muscles may be affected as well. Even animals severely affected often retain voluntary tail movement and voluntary control of urination and defecation. Sensory function is likewise preserved, and many animals seem unusually sensitive to mild stimulation indicating generalized hyperpathia. In rare cases, the thoracic limbs may be affected first or preferentially. Clinical signs may progressively worsen for up to 10 days after the onset of signs and then plateau. The severity of motor deficits once the plateau is reached varies from mild weakness to complete flaccid paralysis, areflexia, and respiratory paralysis. Remission may begin as early as 1 week after the onset of clinical signs or may be delayed for several months. Complete recovery may take several months and is often incomplete. Some animals do not improve within the period that supportive care is tenable. Unfortunately no reliable prognostic criteria exist by which clinicians can gauge the probable speed or degree of functional recovery of individual cases.

Despite the fact that polyradiculoneuritis is a well-recognized syndrome, definitive diagnosis is not always straightforward. History of raccoon exposure shortly before the onset of clinical signs is helpful, but as previously mentioned, not present in all cases. Abnormal spontaneous activity is usually detected with needle EMG 5 to 7 days after the onset of clinical signs. Motor nerve conduction is typically slowed at about the same time that EMG changes are present, and the muscle action potential is often dispersed, indicating both demyelination and axonal injury. Small motor potentials produced by orthodromic conduction of evoked motor action potentials to the cell body and then back to the muscle (F wave) are often delayed or absent, reflecting injury to ventral nerve roots.[1] Increased protein without an increase in white blood cells (WBCs) (albuminocytologic dissociation) is typically found in lumbar cerebrospinal fluid (CSF) but not fluid collected from the cisterna magna. This protein appears to be albumin rather than immunoglobulins and probably arises from transudation across the blood-brain barrier.[30]

Histologically, all regions of peripheral nerves have signs of injury, but lesions are usually concentrated in ventral roots. Demyelination and inflammatory cell infiltration is the predominant finding, with more variable degrees of axonal degeneration accompanying the inflammation. The pathogenesis of the diseases is uncertain. However, an antigenic stimulus in raccoon saliva is thought to stimulate an immune reaction against peripheral nerve myelin. The source of antigenic stimulation in animals without raccoon exposure is unknown but may be viral, toxic, or infections in origin. In an attempt to find potential triggers, serum from affected dogs was evaluated for antibody titers to a number of infectious agents. Affected dogs did have significantly higher titers to *Toxoplasma gondii* than controls, but a causal relationship is not clear.[31] Similarly, antibody titers to *Campylobacter jejuni* were not significantly different between affected and control animals. Therefore the inciting agent in cases without raccoon exposure remains to be identified. An

immune basis for this syndrome is supported by several factors. Epidemiologic evidence indicates that not all dogs bitten by the same raccoon are affected. Once affected, repeated episodes can be precipitated in the same animal by raccoon exposure or injections of raccoon saliva. These two observations indicate that disease is associated with an idiosyncratic response in some dogs. Dogs with an acute onset of clinical signs shortly after a known raccoon exposure have antibodies against an antigen in raccoon saliva.[1] Histologically, demyelination can occur in regions without inflammatory cells suggesting antibody-mediated damage in some instances. Finally, the disease shares many clinical and histopathologic features with human Guillain-Barre syndrome, an immune-mediated radicuoneuropathy.

Therapy for this disease is largely supportive. Despite the probable immune-mediated cause, immunosuppressive therapy usually increases the incidence of secondary infections and muscle atrophy. Plasmapheresis has become standard in human beings with Guillain-Barré syndrome. Unfortunately, this is not widely available for animals.

194.2.3.2 Chronic (Relapsing) Demyelinating Neuropathy and Acquired Demyelinating Neuropathy

A generalized polyneuropathy that follows a remitting and relapsing clinical course has been identified in male and female dogs and cats of various breeds.[1] Clinical signs may be acute or chronic in onset and are often asymmetrical in distribution. In most cases, an overall progressive course of generalized weakness, areflexia, and diffuse muscle atrophy is interrupted by spontaneous periods of partial remission. Cranial nerves may be affected as well.

Electrophysiologic changes consist of variable degrees of spontaneous activity in limb muscles and marked slowing of nerve conduction velocities with more variable degrees of attenuation of the evoked response. These findings are most suggestive of a demyelinating neuropathy. Cerebrospinal analysis reveals increased protein concentrations without concomitant pleocytosis (albuminocytologic dissociation). Muscle biopsies contain changes characteristic of denervation, whereas primary demyelination with remyelination is seen in peripheral nerves. Variable degrees of mononuclear cell infiltrates are found in both peripheral nerves and nerve roots. The inflammatory response varies markedly between nerves and probably varies with stage of the disease process. Macrophages, monocytes, and lymphocytes are associated with prominent primary demyelination and remyelination. Redundant Schwann cell membranes form concentric layers around nerve fibers (onion bulbs are prominent in some cases, indicating repetitive cycles of demyelination and remyelination). Lesser degrees of axonal necrosis are also present in peripheral nerves, suggesting that axonal injury occurred as a consequence of the inflammatory reaction against peripheral nerve myelin. Immunosuppressive doses of prednisolone (2 mg/kg orally every 12 hours) resulted in reversal of clinical signs in some cases within weeks of therapy.[1,32] Prednisolone may be tapered after 6 or 8 months, but some cases require additional cycles of therapy. Rare cases are resistant to therapy and follow a progressive course.[1] The pathogenesis of the neuropathy in all cases remains unknown. Based on histologic appearance of an inflammatory response against peripheral nerve myelin and the response to immunosuppressive therapy, an immune-mediated cause is likely.

194.2.3.3 Brachial Plexus Neuritis

Brachial plexus neuritis is an inflammatory neuritis involving primarily the ventral branches of spinal nerves that give rise to the brachial plexus. This rare condition has been reported in two unrelated dogs and a single cat.[1] Clinical signs consisted of an acute onset of flaccid paralysis in the thoracic limbs only, with

diminished or absent spinal reflexes. Sensory nerves may be affected as well, causing anesthesia of the distal limb. Electrophysiologic changes were confined to the affected limbs. Spontaneous activity suggested denervation in limb muscles, whereas nerve conduction studies were mildly slowed with a reduced or small nerve action potential. CSF was evaluated only in the dogs and was normal. Clinical recovery occurred in the cat and one dog between 4 days and 4 months respectively.[1] No improvement was noted in the remaining dog 45 days after the onset of clinical signs.[1] In the dog that was euthanized, axonal degeneration appeared concentrated in ventral branches of spinal nerves with wallerian degeneration and mast cell infiltration present in most peripheral nerves in the thoracic limbs. More proximal portions of axons in ventral nerve roots were spared, and the disease process appeared mildly asymmetrical between left and right brachial plexi. Retrograde sensory degeneration and chromatolysis in motor and sensory neurons was the only change noted in the CNS. The cause of the condition is unknown.

194.2.3.4 Sensory Ganglioneuritis

Sensory ganglioneuritis is a poorly defined sensory neuropathy that has been reported in young adult dogs of various breeds.[1,33] The onset of clinical signs maybe subacute, acute, or chronic, with an equally variable rate of progression. Initial signs consist of rear limb ataxia that progresses over weeks or months to generalized ataxia. Facial hypalgesia, dysphagia, and regurgitation secondary to megaesophagus have been seen in some cases. A characteristic feature of the syndrome is preservation of limb muscle mass, strength, and tone, but diminished to absent proprioception and tendon reflexes. Withdrawal reflex is usually intact and most have some preservation of nocioception. Less frequent findings in some of these dogs include self-mutilation and masticatory muscle atrophy.

Electrophysiologically, needle EMG and motor conduction velocity is either normal or only mildly abnormal. However, sensory nerve conduction is usually not recordable. CSF is typically normal or may show mild increases in protein and WBC count. Axonal atrophy of large-diameter fibers is found in biopsy material from a mixed or sensory nerve.

The pathology of this syndrome is characterized by a nonsuppurative inflammation of dorsal root ganglia and cranial sensory ganglia with loss of sensory neuronal cell bodies. A concomitant loss occurs of larger-diameter fibers corresponding to sensory axons involved in proprioception and stretch reflexes in both peripheral nerves and sensory tracts in the spinal cord. The masticatory muscle atrophy reported in a few dogs was attributed to the loss of motor fibers as they coursed through the trigeminal ganglion. The cause is unknown, but immune-mediated, toxic, and viral causes have been considered. Similar clinical and pathologic changes can be produced by number of toxins including mercury intoxication, pyridoxine (vitamin B_6) excess, and doxorubicin. No treatment exists for the condition, and recovery has not been reported.

194.2.3.5 Myasthenia Gravis

MG is a disorder characterized by inefficient neuromuscular transmission secondary to a reduction in acetylcholine receptors on the postsynaptic muscle membrane. Two forms of the disease are recognized in dogs and cats: (1) congenital and (2) acquired. In congenital MG, the deficiency in acetylcholine receptors has been attributed to reduced or imperfect synthesis, probably secondary to a genetic defect. In acquired myasthenia, antibodies, usually immunoglobulin G (IgG), are generated against acetylcholine receptors. These autoantibodies block neuromuscular transmission either by directly interfering with the actions of

acetylcholine on receptors, accelerating the normal turnover rate of receptors, or activation of compliment-mediated lysis of the postsynaptic membrane.[1]

Acquired MG is the most common form of the disease. An increased risk has been identified in Akitas, various terriers, German shorthaired pointers, and Chihuahuas, whereas rottweilers, Doberman pinschers, dalmatians, and Jack Russell terriers have lower relative risks compared with mixed-breed dogs. Despite these statistics, German shepherds, and Labrador and golden retrievers are the breeds most commonly diagnosed with the disease.[1] Abyssinians and Somalis appear over-represented in cats.[34] Two age groups appear most susceptible in dogs (2 to 3 years of age; >9 years of age). Cats can be affected at any age.

Myasthenia involves a spectrum of clinical signs that vary in both distribution and severity of muscle involvement. Three major categories have been identified in dogs: (1) focal, (2) chronic generalized, and (3) acute fulminant generalized.[1] The focal form occurs in approximately 36% of recognized cases and consists of variable degrees of facial, pharyngeal, laryngeal, and esophageal dysfunction. Subclinical evidence of appendicular muscle involvement has been demonstrated in some focal myasthenics. The two generalized forms are distinguished primarily by the rate with which clinical signs develop. Twenty-five percent of dogs with generalized neuromuscular weakness have acute, fulminate clinical signs that result in nonambulatory tetraparesis and severe dyspnea within 72 hours, whereas the remaining 39% will exhibit a more chronic onset and gradual progression of clinical signs. Studies indicate that not all dogs with generalized weakness worsen with exercise, and weakness may appear concentrated in pelvic limbs. It is important to note that about 90% of dogs with generalized myasthenia also have megaesophagus.[1] Chronic regurgitation and aspiration pneumonia is a common complication. The incidence of megaesophagus is lower in cats, most likely because of the different distributions of skeletal muscle in the feline versus the canine esophagus. However, both generalized and focal forms are present in cats.[34] Thymomas are much more common in feline myasthenics, and methimazole treatment appears to be a predisposing factor.

Currently the primary criteria for diagnosis of all forms of acquired myasthenia in both dogs and cats is demonstrating serum antibodies that react with α-bungarotoxin extracted acetylcholine receptors.[35] This test is readily available and appears to be specific for MG. Sensitivity of this test is difficult to evaluate; however, approximately 15% of suspected myasthenics are seronegative for acetylcholine receptor antibodies, yet they have immune complexes localized to endplates in their muscle biopsy samples or antibodies in the serum that bind the postsynaptic membrane of normal muscle.[1] Explanations for these apparent false-negative serum tests are speculative but may be caused by the production of high-affinity antibodies that are largely bound and not free in serum. Alternatively, antibodies may be directed to additional antigens on muscle membranes other than those recognized by α-bungarotoxin. Antibodies to the muscle protein titin and a calcium channel receptor ryanodine (RyR) have recently been identified in myasthenic dogs, and these may also play a significant role in the severity of muscle weakness seen in some cases.[36]

Additional supportive evidence for the diagnosis of myasthenia can be made by the demonstration of increased muscle strength after administration of the short-acting acetylcholinesterase agent edrophonium chloride (Tensilon) or by finding a decrementing evoked muscle response after repetitive nerve stimulation. Recommended doses of Tensilon are 0.1 to 0.2 mg/kg intravenously and should cause temporary improvement in clinical signs within minutes. Esophageal musculature does not respond to Tensilon, limiting the usefulness of this test in focal myasthenics. Similarly, a large percentage of myasthenics will have a decrementing response after repetitive motor nerve stimulation that will be blocked by Tensilon administration. Both false-positive and false-negative results occur with both of these tests, so they should be

used for supportive evidence only. Recently the canine nicotinic acetylcholine receptor alpha subunit gene has been cloned and an ELISA developed to identify dogs with circulating antibodies to this receptor.[37] Sensitivity and specificity of this test is not yet known.

Treatment is directed toward amelioration of generalized muscle weakness with longer-acting anticholinesterase agents that prolong the interaction of acetylcholine with any available receptors. Pyridostigmine bromide (Mesthinon, Roche Laboratories) may be given at 1 to 3 mg/kg every 8 to 12 hours in dogs and cats. Therapy should begin at the low end of the scale and gradually increase to desired effect. Alternatively, injectable neostigmine (Prostigmin, Roche Laboratories) has been recommended at a dose of 0.04 mg/kg every 6 hours intramuscularly to bypass the problem of oral administration of medication in regurgitating pets. Esophageal motility is minimally affected by anticholinesterase therapy. Immunosuppressive therapy is controversial. Many animals can be adequately controlled with anticholinesterases, lessening potential complications of immunosuppression in pets with aspiration pneumonia. In a recent review, 47 of 53 dogs treated only with anticholinesterase therapy developed spontaneous remissions within an average of 6.4 months.[38] However, immunosuppressive therapy increased the probability of patient survival in one study and has been used successfully to shorten the course of disease in others.[1] The best advice is to tailor drug therapy to each individual patient while providing supportive care. If corticosteroids are used, current recommendations are to begin with an anti-inflammatory dose and gradually increase to an immunosuppressive dose over 3 to 4 weeks.

Most myasthenics die from aspiration pneumonia. Clinicians and owners can reduce the risk of aspiration pneumonia by feeding in an upright position and holding the animals in an elevated position for 5 to 10 minutes after feeding. Percutaneous gastrostomy has been recommended for alimentary support but will not prevent the occurrence of aspiration pneumonia. Pneumonia may require additional therapy such as antibiotics and oxygen supplementation. Several drugs (e.g., aminoglycoside antibiotics, antiarrhythmic agents, phenothiazines, methoxyflurane, and magnesium) may reduce the efficiency of neuromuscular transmission and worsen clinical signs in myasthenics. Therefore additional drugs should be used with caution.

A simple correlation between acetylcholine receptor antibody and severity and distribution of clinical signs does not exist in dogs with MG. However, clinicians can monitor the course of the disease by evaluating serum acetylcholine receptor antibodies. Spontaneous remission occurs and the antibody titer will decrease as the animal goes into remission. Duration of the disease varies from months to years, and recurrence is possible.[35] One of the most important, yet unanswered questions about myasthenia is what initiates the immune response to acetylcholine receptors. An association has been made between the occurrence of thymomas and myasthenia in both dogs and cats.[1] This is probably related to antigenic similarity between neoplastic thymocytes and acetylcholine receptors. A less direct association has been made between myasthenia and other forms of neoplasia.[1] More recent association with immune-mediated endocrinopathies such as hypothyroidism and hypoadrenocorticism, myocarditis with third-degree atrioventicular (AV) block, myositis, and other immune-mediated diseases suggests that a generalized immune dysfunction may occur in many patients.[1]

A congenital form of MG has been reported as an autosomal recessive condition in Jack Russell terriers, smooth-haired fox terriers, and English Springer spaniels.[1] It has also been reported in Siamese and domestic shorthaired cats.[1] Clinical signs are similar to generalized acquired MG, with the exception that megaesophagus has only been infrequently reported in smooth-haired fox terriers. Remissions have not been reported. Instead, clinical signs are chronically progressive usually resulting in paralysis despite treatment

with pyridostigmine bromide. Circulating autoantibodies are not present in congenital MG. Instead the diagnosis is based on response to anticholinesterase agents, decrementing response on repetitive stimulation, and demonstration of reduced concentrations of acetylcholine receptors in skeletal muscle.

194.2.3.6 Neoplastic Neuropathies

Neoplastic processes can affect the peripheral nervous system in at least three different ways. The most common clinical manifestation is the development of primary neural tumors that arise from the neoplastic transformation of cells intrinsic to the peripheral nervous system. Less commonly, secondary peripheral nerve tumors develop as peripheral nerves are invaded by neoplastic hemolymphatic cells or entrapped by nearby carcinomas or sarcomas. Finally, the peripheral nervous system can be the target of paraneoplastic processes. Both clinical and subclinical neuropathies have been attributed to the remote effects of a wide number of neoplastic process.

194.2.4 Primary Peripheral Nerve Tumors

The peripheral nervous system is composed of neurons and their cell processes surrounded by fibroblasts, Schwann cells, and perineural cells. Each of these cell types is capable of becoming neoplastically transformed.

Neuroblastomas, ganglioneuroblastomas, and ganglioneuromas are primary neural tumors that develop in the peripheral nervous system. These are rare tumors that arise from neural crest cells, usually in adrenal medulla or sympathetic ganglia, and are distinguished primarily by the degree of differentiation of the neoplastic cells. These tumors typically occur in young dogs in retroperitoneal or mediastinal locations.[1] Occasionally, tumors are reported in the GI tract, olfactory mucosa, and peripheral sympathetic ganglia.[1] A single case of a kitten with an intestinal ganglioneuroma has been reported.[1] Clinical signs vary with location of the tumor, with vomiting, diarrhea, and dyspnea being most common. Neurologic signs occur after metastasis to the brain or spinal cord.[1]

Primary tumors that develop from the neoplastic transformation of supporting cells in the peripheral nervous system are more common. Considerable controversy exists over the nomenclature of these tumors. They have been referred to as *schwannomas*, *neurinomas*, *neurilemmomas*, *neurofibromas*, and *neurofibrosarcomas*. Much of the controversy stems from difficulty in determining the primary cell of origin. Most canine primary nerve sheath tumors are poorly differentiated, pleomorphic neoplasms in which the cell of origin is difficult to identify.[1] Therefore the term *malignant nerve sheath tumor* is preferred by most authors. Malignant nerve sheath tumors may arise along the course of any peripheral nerve, including cranial nerves and spinal nerve roots. They typically are slow-growing tumors that extend by local invasion along the peripheral nerve and its branches. They rarely invade surrounding tissue, and metastasis is rare.[1] Neurologic signs are created by compression of peripheral axons, spinal cord, or brain stem by the expanding neoplastic mass. Although any peripheral nerve may be affected, over 80% of the reported cases have occurred in the brachial plexus or its nerve roots. The remaining 20% of cases occur in the pelvic plexus, thoracolumbar nerve roots, and cranial nerves.[1] Of the cranial nerves, the trigeminal nerve is most commonly affected.

Clinical signs typically begin in mature dogs with only rare examples of the disease in cats. No breed or sex predisposition has been identified. Clinical signs vary with area affected, but they begin as a chronic, progressive forelimb lameness. Muscle atrophy, pain in the axillary area, and a palpable mass may be present. Horner's syndrome and loss of the ipsilateral panniculus response reflects loss of the first two thoracic nerve roots that contain preganglionic sympathetic fibers that supply the face and give rise to the lateral thoracic

nerve. Ipsilateral hemiparesis that progresses to paraparesis occurs with extension of neoplastic tissue and secondary spinal cord compression. In cases that involve the cranial nerves, multiple cranial nerve deficits are accompanied by ipsilateral hemiparesis secondary to brain stem compression.

Diagnostically, EMG reveals denervation in muscles innervated by affected nerves. Survey radiographs may show enlarged intervertebral foramen, and myelography may show an intradural extramedullary mass if neoplastic cells have invaded nerve roots. Computed tomography (CT) has been helpful at identifying tumors in peripheral nerves.[1] Surgical exploration and biopsy of nerve or plexus may be necessary to confirm the diagnosis.

Surgical excision has been curative in a few cases.[1] Unfortunately, inability to completely resect all neoplastic tissue usually results in tumor recurrence. In one study, median survival interval after diagnosis in dogs with tumors of the brachial plexus or nerve roots was 12 and 5 months respectively.[1] Radiation therapy has been proposed as a potential treatment for malignant nerve sheath tumors, but results have not been reported.

194.2.5 Secondary Peripheral Nerve Tumors

Peripheral nerve involvement by non-neural tumors is rare. However, infiltration of cranial and spinal nerves by neoplastic lymphocytes has been reported in cats and dogs with lymphosarcoma.[1,39] More recently, two dogs with myelomonocytic neoplasia and infiltration of multiple cranial nerves and spinal nerve roots has been reported.[1] Both dogs had an acute onset of “dropped jaw” and facial hyperesthesia secondary to bilateral trigeminal neuropathy. One dog also had Horner's syndrome, whereas the other had clinical signs of optic nerve and hypoglossal nerve involvement. Antemortem diagnosis was made in one dog by identification of blast cells in lymph nodes and peripheral blood. In both cases neoplastic myeloid cells were found infiltrating cranial nerves and spinal nerve roots on postmortem examination.

194.2.6 Paraneoplastic Neuropathies

Although paraneoplastic diseases can affect a variety of tissues, neurologic involvement can be quite disabling. The incidence of paraneoplastic peripheral neuropathy in veterinary patients is uncertain but probably varies with tumor type. Most cases with clinically significant neuropathies have been associated with insulinomas.[1,40] A total of 6 dogs with histologically confirmed insulinomas have been described that had tetraparesis. All had generalized muscle atrophy, diminished spinal reflexes, and electrophysiologic changes compatible with diffuse axonal degeneration. Angular atrophy of both type I and type II myofibers seen in muscle biopsy suggested denervation and axonal degeneration was apparent in peripheral nerve sections. The association between clinically significant neuropathies and other tumor types in animals is more tenuous.

In an effort to identify the subclinical incidence of peripheral nerve changes in dogs with cancer, Braund and colleagues evaluated peripheral nerves from a series of 21 dogs with malignant tumors.[1] All of the dogs examined with bronchogenic carcinoma, insulinoma, malignant melanoma, osteosarcoma, thyroid adenocarcinoma, mammary adenocarcinoma, and one dog with a mast cell tumor had significantly more degenerative changes than age-matched controls. A combination of demyelination, remyelination, and axonal necrosis was present in every case. The number of dogs with each tumor type was relatively small, and no correlation between duration of the tumor and degree of neuropathic change was attempted. Additional studies are needed to better define the true incidence of peripheral nerve changes in animals with cancer.

Several hypotheses have been proposed regarding the pathogenesis of paraneoplastic diseases. The most widely investigated include elaboration of a neurotoxic substance by the neoplastic cells, secondary nutritional deficiencies caused by competition between the tumor and the host for an essential metabolite, cancer-associated immunosuppression may predispose affected individuals to opportunistic infections, and finally an immune-mediated disorder in which autoantibodies are produced against antigens shared by the tumor and the nervous system. To date, most evidence supports an immune-mediated disorder. Antibodies that recognize specific neuronal populations have been found in humans with a variety of paraneoplastic neurologic syndromes including Eaton-Lambert myasthenic syndrome, cerebellar degeneration, subacute sensory neuropathy, retinal degeneration, and others.[1] Although probably responsible for the neurologic signs, identification of these antibodies has also proven useful as a serologic marker for neoplasia. In many instances neurologic signs may antedate the diagnosis of cancer, and identification of these specific antibodies in serum provides presumptive evidence of occult neoplasia.

Treatment for paraneoplastic neuropathies has been unrewarding in animals. A single case with insulinoma-associated neuropathy improved with corticosteroid therapy, whereas another case regained motor function after removal of mammary carcinomas.[1,40]

194.2.7 Traumatic Neuropathies

Research into peripheral nerve trauma suggests that at least five different classifications exist for the types of injury that can occur.[1] Class 1 is referred to as *neurapraxia* and describes the response to mild or moderated focal compression. Nerve conduction is reversibly blocked. Histologically, either no lesions or mild segmental demyelination occurs. Complete recovery may occur within hours; however, with more severe compression, it may be delayed for up to 6 weeks. Class 2 injuries or axonotmesis usually occur with crush or percussion injuries. Axons are interrupted, but the supporting connective tissue remains intact. Wallerian degeneration usually occurs distal to the site of injury, but regeneration is usually effective because regenerating axons can be guided back to the appropriate targets. Class 3, 4, and 5 injuries refer to varying degrees of neurotmesis. Class 3 injuries result in disruption of axons and endoneurium, but fascicular orientation is preserved by an intact perineurium. Class 4 injuries also disrupt the perineurium, whereas the entire peripheral nerve is severed in class 5 injuries. With increasing degrees of damage to supporting structures, the ability of regenerating axons to successfully bridge the gap and reinnervate original structures is lessened.

All five classes of injury exist in animals, and more than one class can occur simultaneously. Unless the peripheral nerve is completely severed, most surgeons wait several weeks before attempting repair to assess how much functional return will occur. Surgical repair of transected nerves has been attempted either using direct end-to-end anastomosis or using a nerve graft to bridge the defect. Autologous sensory nerves may be harvested to be used as a graft, or a non-neural conduit can be used. Experimentally, application of nerve growth factors to synthetic conduits has aided peripheral nerve regeneration after complete resection and may be clinically useful in the future.[1] Axonal regrowth occurs at a rate of approximately 1 to 2 mm/day. Therefore the prognosis for functional return depends not only on class of injury or precision of surgical repair but also on the distance the axon must travel to reach its end organ.

Individual peripheral nerves can be injured in a number of ways. Injection injuries, trauma from bone fracture and repair, lacerations from dog fights, and automobile accidents are some of the more common sources in dogs and cats. Motor and sensory deficits associated with individual peripheral and cranial nerves are outlined in Tables 194-1 and 194-2. Diagnosis is usually based on clinical signs of motor and sensory deficits. EMG will

reveal denervation, and peripheral nerve conduction should fail 5 to 7 days after the injury. Recently, ultrasonography has shown promise at imaging transected nerve stumps.[1]

194.2.7.1 Brachial Plexus Avulsion

The brachial plexus is typically formed from the sixth cervical through the second thoracic spinal nerve roots. Because nerve roots lack a perineurium, traction of the forelimb or severe abduction of the scapula frequently results in avulsion of these nerve roots, usually within the dura. Depending on the direction and extent of forelimb traction, all or only part of the brachial plexus may be involved. The caudal portion of the plexus is more commonly involved in partial injuries.[1]

Clinical signs are characterized by an acute, nonprogressive monoparesis usually precipitated by an automobile accident or a fall. The resulting motor and sensory dysfunction in the limb varies with the extent of the avulsion. Avulsion of C8, T1, and T2 nerve roots injures the radial, median, and ulnar nerves. The limb may be carried in a flexed position because the musculocutaneous, axillary, and suprascapular nerves are intact, but weight bearing is impossible without the ability to extend the elbow and carpus. Injury to C8, T1, and T2 spinal nerve roots also results in Horner's syndrome and loss of the ipsilateral cutaneous trunci (panniculus) reflex due to damage to the origins of the presynaptic sympathetic innervation to the face and lateral thoracic nerve respectively. More rostral nerve root injuries also involve the musculocutaneous nerve and prevent flexion of the elbow. Limb movement is generated by advancement of the shoulder. Injury of only proximal portions of the brachial plexus is rare. Useful limb function depends on the radial nerve; in a review of 30 cases, the radial nerve was involved in 92% of dogs with brachial plexus avulsion.[1] Like motor function, sensory deficits depend on the number and distribution of nerve roots avulsed. In some instances, dorsal roots may be spared, resulting in some preservation of sensation even though motor function was lost with avulsion of the ventral roots. Despite the potential variability in sensory deficits, most cases are analgesic distal to the elbow.[1]

Diagnosis of brachial plexus avulsion depends on history, clinical signs, and electrophysiologic evidence of denervation in limb muscles. Motor nerve conduction is usually abolished in affected nerves. A sensory nerve evoked potential may be present even in the absence of conscious perception of pain, if the dorsal nerve root is avulsed proximal to the dorsal root ganglion. Somatosensory evoked potentials produced by stimulation of a peripheral nerve and measuring the response of afferent neurons in the spinal cord and brain will be abolished if all nerve roots are avulsed. Unfortunately, somatosensory evoked potentials are less useful with partial lesions.[1]

Prognosis for functional return is hopeless if the radial nerve has been avulsed. Several salvage procedures have been described for distal radial nerve deficits, but triceps innervation is required for any useful limb movement. Neurapraxia is certainly a feature of any traumatic peripheral nerve injury. Therefore a hopeless prognosis should not be given before a minimum of 4 to 6 weeks after the injury. Unfortunately less than 12% of reported cases regained radial nerve function.[1] Limb amputation should be considered if self-mutilation or other continuous trauma occurs in desensitized areas.

194.2.8 Vascular Neuropathies

Acute obstruction of blood vessels supplying peripheral nerves is rare except in cats with aortic thromboembolism. Reports in dogs usually involve heartworm disease. Although thromboembolism of any major artery could produce clinical signs, the most common site is the terminal aorta obstructing the internal

and external iliac arteries and the median sacral artery. Both physical restriction of blood flow by the embolus and the production of vasoactive substances, including serotonin and thromboxane that limit collateral blood flow, combine to produce ischemia of the sciatic nerve and adjacent muscles. Axonal necrosis occurs in the center of nerve fascicles in the distal sciatic nerve and its branches, whereas paranodal demyelination is evident in peripheral areas.[1] Muscle damage consists of focal necrosis, with inflammatory cell infiltrates and myophagia.

Clinical signs typically consist of an acute onset of pelvic limb paralysis. The femoral pulse is usually weak or absent, the rear limbs are cold, and nail beds are ischemic and fail to bleed if cut. Rear limb musculature often feels stiff because of ischemic muscle contracture, and the cats often are painful on muscle palpation. Evidence of cardiac disease is usually present either in physical examination findings, thoracic radiographs, or echocardiography. Most cats have hypertrophic cardiomyopathy; however, other forms of cardiac disease are possible. Therapeutically, in addition to specific treatment for the cardiac disease, most cats benefit from warming the limbs and administering acepromazine 0.2 to 0.4 mg/kg subcutaneously every 8 hours to encourage vasodilatation and collateral blood flow. Heparin sodium (100 to 200 IU/kg intravenously initially, followed by 50 to 100 IU/kg every 6 to 8 hours) is recommended to prevent further thrombus formation, and analgesics such as butorphanol (02. to 0.4 mg/kg every 6 to 12 hours) should be used to control pain. Specific therapy to remove the clot has been attempted both surgically and medically using thrombolytic agents.

194.2.9 Idiopathic Neuropathies

194.2.9.1 Distal Denervating Disease

Distal denervating disease is considered the most common neuropathy in dogs in the United Kingdom.[1] Dogs of all ages, breeds, and both sexes are affected. The onset of clinical signs is variable, ranging from days to a month or more. Quadriparesis to quadriplegia is accompanied by neck weakness, loss of bark, diminished spinal reflexes, and muscle atrophy (especially prominent in proximal limb muscles). Voluntary control of tail movement, urination, and defecation is maintained, and pain sensation is preserved. EMG reveals diffuse spontaneous activity in all muscles. Motor nerve conduction velocity is modestly reduced, but the evoked muscle action potential is usually small and dispersed. These electrophysiologic changes are most compatible with primary axonal loss with little demyelination. Sensory nerve conduction is normal. Muscle and nerve biopsy confirms a distal axonopathy with denervation atrophy of muscle. Most cases spontaneously resolve without treatment, with complete recovery occurring 4 to 6 weeks after clinical signs plateau.[1] Pathologic changes are restricted to the distal motor axon. No changes have been reported in the CNS, nerve roots, or main portions of peripheral nerves. Intramuscular branches are reported to show extensive collateral axonal sprouting, with early cases also exhibiting modest degrees of terminal axonal degeneration. The cause is unknown, but an unidentified toxin is considered likely.

194.2.9.2 Distal Symmetrical Polyneuropathy

Numerous adult, large breeds of dogs have been described with a distal sensorimotor polyneuropathy, which have been collectively referred to as *distal symmetrical polyneuropathy*.[1] A remarkable similarity exists to the developmental and congenital axonopathy "polyneuropathy in rottweiler dogs." Clinical signs are insidious in onset and gradually progressive over 1 to 2 months. Pelvic limb paresis is the initial presenting sign, but tetraparesis with atrophy of distal limb muscles and muscles of mastication eventually develops. Diffuse spontaneous activity is prominent with needle EMG. Motor nerve conduction velocities are usually normal or slightly slowed, but the amplitude and duration of the evoked muscle action potential is small and

prolonged, suggesting axonal injury. Muscle and nerve biopsy confirms a distal axonopathy with denervation atrophy of skeletal muscles. No other abnormalities have been reported in peripheral blood or CSF. Histologically, lesions are confined to the distal regions of motor nerves. Degeneration of large-diameter motor axons is prominent in distal limb nerves and the recurrent laryngeal nerve. Variable degrees of demyelination are present as well but appear secondary to axonal loss. Sensory and autonomic nerves may be affected as well but to a lesser degree. No lesions are found in the CNS. The cause is obscure, but metabolic, toxic, and paraneoplastic neuropathies may appear similarly. Prognosis is poor because the disease is chronic and progressive in nature and has not previously responded to treatment. However, preliminary results from a multicenter trial involving the use of Prosaptide™ TX14(A), a neurotropic peptide, in large breed dogs with idiopathic distal symmetrical peripheral neuropathy showed promising results.[41] Of the seven dogs that completed the trial, three showed improvement in neurologic function.

194.2.9.3 Dancing Doberman Disease

Dancing Doberman disease is an unusual neuromuscular disorder that presently appears restricted to adult Doberman pinschers of both sexes.[1] Clinical signs begin between 6 months and 7 years of age and are gradually progressive over several years. Affected dogs have a characteristic habit of holding one or both pelvic limbs flexed while standing. The condition may begin in one limb and then spread to the alternate limb within 3 to 6 months. When both pelvic limbs are affected, the condition may appear as shifting rear limb lameness with an increased tendency for the dogs to sit rather than stand. Conscious proprioceptive deficits have been reported in two dogs 5 and 6 years respectively after the disease was diagnosed. Exaggerated pelvic limb reflexes and atrophy of the gastrocnemius muscle are also common.

Electrophysiologic abnormalities suggest a mixture of mild myopathic and neuropathic changes. EMG shows spontaneous activity in affected muscles, but motor and sensory nerve conduction velocities are usually normal. Pathologic changes are confusing. Some dogs have multifocal pelvic limb muscular atrophy and hypertrophy, fibertype grouping, focal necrosis, and endomysial and perimysial fibrosis suggestive of a form of myotonic myopathy.[1] Other dogs have peripheral nerve changes suggestive of a primary axonopathy. Evidence of axonal degeneration in sensory and autonomic fibers has been reported, suggesting that dysesthesias caused by pressure on the feet may be responsible for the unusual clinical signs.[42]

No treatment has proven beneficial to date. Although the syndrome is slowly progressive, affected animals remain functional pets for many years. Without definitive diagnostic criteria, the syndrome can only be diagnosed by ruling out other diseases such as lumbosacral stenosis, intervertebral disk disease, or nerve root tumors that might initially appear with rear limb paraesthesias without obvious motor impairment.

194.2.9.4 Dysautonomia

Dysautonomia is a general term for dysfunction of the autonomic nervous system. A syndrome characterized by diffuse autonomic dysfunction was first reported in cats in 1982 by Key and Gaskell.[1] Over the next 2 years this previously undiagnosed disease was reported in epidemic proportions throughout the United Kingdom and later in Europe and the United States. The incidence of the disease has since markedly declined in cats. The first case of dysautonomia was reported in dogs in 1983, again in the United Kingdom.[1] Only sporadic reports of canine cases appeared until recently when 11 dogs were identified in Missouri over a 7-year period.[1] Although additional dogs have subsequently been described, all cases appear confined to the Midwest.[43,44]

Animals between 6 weeks and 11 years have developed dysautonomia, but both dogs and cats less than 3 years of age appear to be more susceptible. Both males and females are equally affected. The onset is acute in most cases, with clinical signs developing over 2 to 3 days. Rarely the onset is more insidious, lasting a week or more. Initial clinical signs are usually nonspecific and consist of lethargy, anorexia, and depression. GI signs including regurgitation and vomiting, constipation or diarrhea follow. Dysuria with a distended urinary bladder, myasis with depressed PLRs, dry mucus membranes, prolapsed third eyelids, dysphagia, and weight loss are also commonly seen. More inconsistent features include loss of anal tone and mild postural reaction deficits. Many pets also have bradycardia with heart rates less than 120 beats per minute that do not change with stress or exercise.

No consistent abnormalities have been detected in peripheral blood or CSF. Radiographically most animals have evidence of decreased peristaltic activity throughout the GI tract including megaesophagus, delayed gastric emptying, and generalized ileus. Electrodiagnostic testing is usually normal, with the exception of occasional spontaneous activity in limb muscles. Pharmacologic testing has been used to confirm parasympathetic and sympathetic nervous system dysfunction. Specifically, denervation of the iris muscle results in supersensitivity to cholinergic drugs. Instillation of 0.05% pilocarpine ophthalmic solution should cause rapid constriction of the pupils. It usually takes at least 30 minutes for miosis to occur in normal dogs, and no effect should be seen in cases where parasympathetic signs are due to atropine or a similar toxin.[44]

Histologically, sympathetic and parasympathetic ganglia are affected. Because the degree of involvement of any one ganglia can be quite variable, multiple samples are recommended. Depletion of neuronal cell bodies is the more prominent change, with many remaining neurons containing atypical homogenous cytoplasm, dissolution of Nissl substance, and an eccentric pyknotic nucleus. Axonal degeneration is present in autonomic nerves. Peripheral nerves are relatively spared, although occasionally smaller neurons in dorsal root ganglia and cranial nerve ganglia may show chromatoylitic changes. A percentage of neurons in cranial nerve nuclei, ventral horn cells, and cells in the intermediolateral gray matter of the spinal cord may also show characteristic changes. Unusual ultrastructural changes consist of derangement of rough endoplasmic reticulum with existing cisternae denuded of ribosomes and distended with electron-dense flocculent material.[1] No normal Golgi bodies are found, but instead stacks of smooth membranous profiles are seen. Membranous dense bodies and autophagic vacuoles are common in some neurons.

Treatment is largely supportive. Pilocarpine (1%) eye drops may improve mydriasis and stimulate lacrimation and salivation. Bethanechol (2.5 to 7.5 mg every 8 hours) should facilitate evacuation of the bladder at least temporarily. Metoclopramide will enhance the actions of any available acetylcholine on muscarinic receptors in the GI tract and enhance gastric emptying. Unfortunately the prognosis is poor. Less than 25% of affected cats survive, and recovery often takes over a year. The cause of the disease remains a mystery, despite numerous efforts identify an infectious or toxic agent. The clustering of cases in the United Kingdom and more recently Missouri suggests an environmental agent; however, none have been identified. Recently, autoantibodies against ganglionic acetylcholine receptors were demonstrated in dogs with dysautonomia.[45] It is not yet clear whether this represents a cause or an effect of the disease process.

194.2.9.5 Idiopathic Trigeminal Neuritis

The trigeminal nerve is most commonly injured by inflammatory or neoplastic intracranial diseases. Rarely, the trigeminal nerve is directly infiltrated by neoplastic cells (as previously described with peripheral nerve neoplasia). The trigeminal nerves are also the target of an idiopathic, inflammatory condition referred to as *trigeminal neuritis*. Clinical signs are characterized by an acute onset of bilateral trigeminal motor paralysis

causing inability to close the mouth ("jaw drop").[1,46] Facial sensation is usually preserved. Occasionally, Horner's syndrome may accompany trigeminal neuritis, presumably because the postganglionic sympathetic axons course with the ophthalmic branch of the trigeminal nerve.[46,47]

Biopsy of the muscles of mastication reveals denervation atrophy. CSF may be normal or may have mild increases in protein concentration. Rarely, a lymphocytic pleocytosis is described.[46] Histology has been limited, but nonsuppurative neuritis in all portions of the trigeminal nerve and ganglion has been described.[1,47] The brain stem is spared. Spontaneous recovery usually occurs within 2 to 3 weeks but may take months to completely resolve. Steroid therapy does not appear to alter the course of the disease.[46] Maintenance of hydration and alimentation is critical during this time. Percutaneous gastrostomy has been helpful in this regard.

194.2.9.6 Idiopathic Facial Neuritis

Because of its anatomic proximity to the inner and middle ear, the facial nerve is commonly injured in otitis media and interna. The facial nerve also has a superficial location after emerging from the stylomastoid foramen and is therefore easily susceptible to traumatic injury. The facial nerve is often affected in generalized peripheral nerve diseases including polyradiculoneuritis, tick paralysis, and botulism. Less frequently, facial nerve paralysis results from no identifiable cause and has been referred to as *idiopathic facial neuritis*.[1]

Clinical signs of facial paralysis are characterized by inability to move the lip, ear, and eyelids. Ptyalism and inability to blink are the most common admitting complaints. The facial nerve also provides parasympathetic innervation to lacrimal glands, and proximal injury may result in keratoconjunctivitis sicca. Xerostomia, focal hypalgesia to the pinna, and partial loss of taste may also occur with facial nerve paralysis, but these are difficult to appreciate clinically. Both dogs and cats have been reported with idiopathic facial neuritis.[1] The syndrome tends to occur in mature animals, and Cocker Spaniels have been identified in two studies as being predisposed.[1] Clinical signs typically appear acutely and in the absence of any other systemic illness. One or both facial nerves may be initially affected. In cases with unilateral facial neuritis, the other side may become affected later. Electrophysiologically, spontaneous activity suggestive of denervation appears in superficial facial muscles. Stimulation of the facial nerve failed to evoke an action potential in one report.[1] Fascicular biopsy of the ventral buccal branch of the facial nerve in two dogs showed axonal degeneration.[1]

The cause of this condition is unknown. A casual link has been made, with hypothyroidism. Statistically the relationship with hypothyroidism has been difficult to prove.[1] However, numerous cases have concurrent hypothyroidism and clinically improve with thyroid supplementation.[1] Other theories that are also unproved include herpes viral neuritis or swelling of the facial nerve causing compression in the bony facial canal traversing the petrous temporal bone.

The prognosis for idiopathic facial neuritis is poor. Steroid therapy has been recommended, but its efficacy is uncertain. Cases may improve within weeks or months. However, the facial nerve remains permanently paralyzed in a significant number of cases. Exposure keratitis, especially if compounded by decreased lacrimation, is the most significant complication.

194.2.9.7 Idiopathic Peripheral Vestibular Disease

An idiopathic vestibular dysfunction has been identified in old dogs and cats of all ages.[1] Clinical signs are acute in onset and consist of head tilt, nystagmus, falling, rolling, and ataxia. Postural reactions remain intact, and spinal reflexes are normal. Facial nerve deficits and Horner's syndrome are common features of otitis media and interna are conspicuously absent in idiopathic vestibular disease. In cats an unusually high frequency of cases occurs in July and August.[1] The reason for this seasonal incidence is unknown. The diagnosis is based on clinical signs and failure to identify other causes of vestibular dysfunction including trauma, otitis media and interna, or toxins. Aminoglycoside antibiotics, especially streptomycin in cats, can damage vestibular and auditory receptors and result in vestibular dysfunction. The prognosis for idiopathic vestibular dysfunction is excellent. Most cases spontaneously improve within weeks. Some cases have a residual head tilt. An association between idiopathic peripheral vestibular disease and hypothyroidism has been noted.[1] Other inner and middle ear diseases are covered more thoroughly in Chapter 209.

195 CHAPTER • 195 Disorders of the Skeletal Muscles—Canine*

Stéphane Blot

Striated muscle, which accounts for approximately 50% of the body mass, is an intricate machine designed to convert chemical energy into mechanical energy. The component processes include excitation-contraction coupling, the contractile mechanism itself, various structural components, and the energy system that supports the activity and integrity of the other systems. Proper function of striated muscle, therefore, depends on the integrity of all organs of the body. This chapter focuses on primary defects involved in skeletal muscle diseases (primary myopathies), but numerous secondary myopathies are encountered as a result of defects in other organs. Disorders of the neuromuscular junction are discussed elsewhere.

195.1 ANATOMY AND PHYSIOLOGY

Skeletal muscles are composed of fusiform, multinucleated cells, called *myofibers,* as well as connective tissue, vessels, and nerves.[1–3] During myogenesis, myofibers are produced by the fusion of *myogenic cells,* the myoblasts that stem from the same mesodermal embryonic tissue that provides bone, cartilage, and connective tissue. However, all muscles do not derive from the same origin, which explains the immunologic differences between groups of muscles and therefore may account for specific topographic muscle lesions. Some multinucleated myogenic cells, called *satellite cells,* do not merge, but rather lie beneath the basement membrane of mature muscle fibers. When a muscle is damaged and necrosis occurs, the satellite cells develop and merge to form new muscle fibers.

On transverse section of normal muscle, myofibers are all polygonal, roughly of equal size with peripheral nuclei; however, different types of myofibers are identified based on physiologic and histochemical criteria (Table 195-1). *Slow contraction fibers (type 1)* withstand fatigue and use oxidative metabolism, whereas *fast contraction fibers* extract energy from the glycolytic pathway. Most skeletal muscles are made up of a mixture of these functional types, the proportion of each type being stable for a given muscle in each species.[4] In specific muscles, one type appears largely predominant. The functional type of each myofiber is actually determined by the neuronal cell body innervating the cell.[5,6] All myofibers innervated by the same motor neuron define a motor unit, the size of which varies; muscles with fine movement are composed of small motor units (e.g., extraocular muscles), and antigravity muscles are composed of large units.

Perimysial connective tissue defines fascicles that enclose several motor units. All motor units are closely intermingled, producing a particular mosaic-like or checkerboard pattern. Each muscle fiber is surrounded by a thin layer of connective tissue (the *endomysium*), and the entire muscle is encased in epimysial connective tissue. Each myofiber is composed of hundreds of myofibrils made of thin and thick contractile filaments separated by an intermyofibrillar network containing aqueous sarcoplasm, mitochondria, glycogen, and the sarcoplasmic reticulum (calcium reservoir) with the associated transverse tubular system. The protein myosin is the main component of the thick filaments, and actin, troponin, and tropomyosin constitute the thin contractile filaments.

Ultrastructurally, the regular spatial distribution of the contractile filaments presents a characteristic striated appearance that is the result of the repetition of a transverse pattern. This repetitive pattern, called the *sarcomere,* contains an electron-dense area (the *A band*), which is produced by the overlapping of thick and thin filaments, and an electron-lucent area (the *I band*), which contains thin filaments alone. In the middle of the A band is an area in which the absence of thin filament produces an additional electron-lucent band, the *H zone*. The *transverse*

M line in the H zone is composed of cross-linked thick filaments, and the *transverse Z line* in the I band is made up of protein-anchoring adjacent thin filament. The sarcomere thus is the structural unit defined by two successive Z lines.

Molecular studies yield constant enlightenment about the components of the cytoskeletal, sarcolemmal, or contractile apparatus, leading to the discovery of molecular defects involved in degenerative myopathies. The muscle fiber converts a biochemical signal (i.e., the release of acetylcholine from the nerve terminal after arrival of a nerve action potential at the neuromuscular junction) into a mechanical force produced by the coordinated contraction of several thousand sarcomeric units. To achieve this complex process, known as *excitation-contraction coupling,* several elementary phases are required, comprising depolarization of the sarcolemma, transverse tubules, and sarcoplasmic reticulum. Depolarization leads to the release of calcium into the sarcoplasm. At rest, tropomyosin (a regulating protein) blocks the active site of actin and prevents the myosin-actin interaction. Binding of the calcium to troponin moves tropomyosin, which then promotes formation of several cross-bridges between actin and myosin molecules. With the availability of energy (adenosine triphosphatase [ATPase] from myosin catalyzes hydrolysis of adenosine triphosphate [ATP], which comes from the phosphocreatine stock—the myofiber's battery—or from oxidative phosphorylation metabolism or glycogenolysis), the thin filaments move on the thick myofilaments, leading to the shortening of the myofibrils. Dissociation of the cross-bridges, which produces relaxation time, also requires energy.

* At the author's request, this chapter (with feline referencing deleted) has been reprinted from the last edition.

195.2 GENERAL CLINICAL FEATURES

The main sign of a disease affecting the appendicular musculature is weakness. Weakness induced by skeletal muscle disorders usually is persistent but may become more pronounced after exercise (increased fatigability). In rare cases weakness disappears with exercise, and the signs are exacerbated by rest (myotonia). Weakness may be discrete, manifesting as a stiff gait; tremors; an abnormal posture, such as neck ventroflexion (more pronounced in cats owing to the absence of a nuchal ligament); palmigrade or plantigrade stance; splaying of digits; bunny hopping gait; or difficulty negotiating simple motions, such as jumping over steps or climbing into the car. Weakness may also be extreme, mimicking a neurogenic disease. Muscle atrophy is common; however, hypertrophy can occur in some instances. In most cases hypotony with normal tendon reflexes is encountered, although hypertonic muscles are also observed (polymyositis, myotonia). Absent tendon reflexes are sometimes observed in congenital myopathies or later in the course of degenerative myopathies. Muscular fibrosis and contracture, causing reduced range of articular movement, is a frequent feature in severe inflammatory or degenerative myopathies. Muscle pain *(myalgia)* occasionally may be identified in inflammatory conditions. The normal muscular response to percussion is a barely visible transient contraction of the myofibers. It disappears prematurely in primary muscle diseases, in contrast to the conservation of tendon reflexes. However, mechanical excitability is exaggerated in neurogenic muscular atrophies. In the myotonic syndrome, the myotonic dimple persists for several seconds. Signs affect the appendicular musculature and several other striated muscles, such as the masticatory, extraocular, cardiac, digestive, and respiratory musculature. Therefore disorders of striated muscle should be suspected as one cause of the condition in dogs with regurgitation, vomiting, dysphagia, dysphonia, or ophthalmoplegia.

Table • 195-1 Characteristics of Mammalian Myofiber Types

PROPERTIES	TYPE 1	TYPE 2m*	TYPE 2a	TYPE 2b†	TYPE 2c‡
Histochemistry Staining Intensity

* Masticatory myofiber type.

† Type 2B myofiber does not exist in the canine.82

‡ Type 2C myofiber is a primitive myofiber that may be a precursor of types 2A and 2B.

Because weakness is a nonspecific sign frequently encountered in other nonmuscular diseases, ancillary tools must be used to confirm the presence of a myopathy.

195.3 GENERAL DIAGNOSTIC FEATURES

Several serum enzymes, such as creatine kinase (CK), lactate dehydrogenase, aldolase, and aspartate aminotransferase, may be elevated in muscle diseases.[3] In particular, owing to the short half-life of creatine kinase (about 6 hours), the level of serum CK is the best indication of a recent muscle lesion.[7] However, tremendous variability occurs, based on age (the younger the animal, the higher the value), breed (the smaller the dog, the higher the value), motor activity (exercise produces a higher value), recent intramuscular injections, and sampling methods. Although some myopathies are associated with dramatic persistent elevations (i.e., muscular dystrophies, polymyositis), numerous myopathies cause little, transient, or no elevation at all. Therefore a normal CK level should not exclude a muscle disease from the differential diagnosis.

Electrophysiologic tests (electromyography, nerve conduction studies, and repetitive stimulation) are more valuable in the evaluation of peripheral neuropathies than in myopathies.[8] If contractile activity is recorded, myopathies are classically associated with smaller, shorter, and sometimes polyphasic motor unit potentials. Spontaneous abnormal activity (fibrillation potentials, positive waves, high-frequency discharges, and complex repetitive discharges) may be recorded in numerous myopathies, but no activities are specific for certain myopathies except the myotonic burst that is pathognomonic for myotonia. If a muscle biopsy is planned, that muscle site should not be electrophysiologically tested, to avoid iatrogenic changes.

When muscle disease is suspected, a muscle biopsy is indicated to confirm the diagnosis. The sampling is a relatively innocuous procedure, but certain guidelines must be followed if maximum information is to be gained.[9] Blood for serum muscle enzyme analysis should be collected before the biopsy is performed. Selection of the muscle for biopsy is guided by electromyography or, failing that, atrophic or hypertrophic muscles are chosen. Although a single muscle biopsy is usually satisfactory, the chances of identifying characteristic lesions are considerably enhanced if several muscles are sampled (generally at least one muscle biopsy each from the pelvic and thoracic limbs). The biopsy specimen is taken at the center of the muscle belly by parallel incisions along the longitudinal axis of the myofibers. A section 4 to 5 mm wide and 2 cm long is satisfactory for routine light microscopic evaluation. Tools for reducing the shortening of the muscle sample may be used (muscle biopsy clamp or a sterile applicator stick). 902 903

The muscle sample should be divided into two fragments; one is fixed in 10% buffered formalin, and the other is submitted prior to fixation, in a refrigerated gauze sponge, within 24 hours, so that histochemical stains can be applied. Such stains are the only satisfactory method for analyzing degenerative myopathies. When muscle atrophy is of nervous origin, it is characterized by variability in fiber diameter, the presence of angular, atrophied fibers, and alteration of the normal checkerboard pattern.

Myopathies can be categorized as inflammatory or degenerative (Box 195-1). The inflammatory conditions are either infectious or immune mediated, whereas degenerative myopathies are acquired or inherited. This discussion focuses on the main myopathies in dogs.

Mitochondrial myopathy

Lipidic myopathy

Malignant hyperthermia

Centronuclear myopathy (Labrador retriever)

195.4 INFLAMMATORY MYOPATHIES

A classic distinction is made between infectious myositis conditions and those that are immune mediated. In cases of infectious myositis, bacteria (*Leptospira* or *Clostridium* spp.) or parasites (*Toxoplasma* or *Neospora* spp.) are

directly responsible. Some agents are capable of triggering noninfectious myositis by modifying muscle immunogenicity (leishmaniasis or ehrlichiosis).

195.4.1 Infectious Bacterial Myositis

Bacterial myositis is a rare disorder in carnivores; it occurs more frequently in food animals.[10] A distinction can be made between polymyositis and focal myositis. The manifestation of the latter disorder is lameness accompanied by pain and muscle enlargement. This type of myopathy occurs with bacterial spread from a distant site of infection via the blood or after bacterial inoculation through external trauma, such as a bite, a sting, or contamination of surgical wounds.[11–14] Staphylococci and streptococci are often involved in canine traumatic infectious myositis. Clostridial myositis (caused by *Clostridium perfringens*) is rarely found in domestic carnivores. *Leptospira icterohaemorrhagiae* is responsible for serious myositis. However, the severe nature of the general signs masks the muscle damage. The treatment consists of lancing the wounds and draining any abscesses. In the case of secondary bacterial myositis, the first step consists of identifying the primary site. The antibiotic is selected by the results of sensitivity testing. Clindamycin (5 mg/lb given orally twice a day) is the anti-biotic of choice for anaerobic bacterial myositis.[12,15,16]

195.4.2 Parasitic Myositis

195.4.2.1 Toxoplasmosis (Toxoplasma gondii)

Toxoplasmosis develops clinically only in young animals (less than 1 year old) and often arises when another disease occurs. The muscular signs are characterized by abnormal gait, muscle pain, and muscle atrophy. In some cases myositis with subsequent fibrosis evolves quickly.[17]

195.4.2.2 Neosporosis (Neospora caninum)

Neurologic damage dominates the clinical presentation of neosporosis, and pups that are affected rapidly show hyper-extension of the hindlimbs. Transplacental transmission mimics a hereditary disease. Clindamycin (5 mg/lb twice daily) or trimethoprim combined with sulfadiazine (7 mg/lb twice per day) is the drug of choice; however, pelvic limb extensor rigidity does not respond to therapy.[18–20]

195.4.2.3 Other Parasites

Trichinella spiralis, Ancylostoma caninum, and *Sarcocystis* spp. may infect the muscle and only rarely produce clinical signs. Generally, they are discovered purely by chance.[17,18,21,22]

195.4.3 Immune-Mediated Myositis

195.4.3.1 Myositis of the Masticatory Muscles

The muscle fibers of the masticator muscles have a distinct embryologic origin, which explains the presence of a particular type of fiber called *type 2M*. These fibers enclose a specific myosin, which is specifically involved in this immune-mediated reaction. Type 1 fibers are spared. This myopathy affects all dogs regardless of age, gender, or breed, but the German shepherd seems to have a predisposition.[23–26]

In the acute form, hypertrophy of the temporal and masseter muscles is observed with myalgia. The animal is reluctant to open its mouth. It has difficulty eating and may dribble saliva. Sometimes the jaws remain open because complete closing is impossible. Fever, inflammation of the tonsils, and local adenitis may also be found. In most cases myositis of the masticatory muscles is a chronic condition with severe, progressive muscular atrophy accompanied by fibrosis, resulting in a reduced ability to open the mouth and trismus (lockjaw).

903
904

The disorder generally is bilateral. Exophthalmos linked to enlargement of the temporal muscles sometimes can be the cause of an optic neuritis and can result in vision disorders. Biochemical examinations are not specific, but the serum CK level may be increased, and leukocytosis is sometimes found. Electromyography (EMG) reveals abnormal spontaneous activity. Muscle biopsy shows sites of necrosis and phagocytosis of type 2M fibers, with perivascular infiltration of mononucleate cells. In the serum of affected dogs, type 2M antitype antibodies are identified.

Administration of immunosuppressive doses of cortico-steroids is the only advisable therapy. Clinical recovery is usually rapid and complete if treatment is begun early. A dosage of 0.5 to 1 mg/lb twice a day is maintained for 15 days, after which the dose is gradually reduced. Should a relapse occur, the maximum dose should be administered again. Sometimes a prolonged course of treatment is required, with small doses administered on alternate days. Therapy is ineffective if administered to an animal that has already experienced several inflammatory episodes that have resulted in extensive fibrosis.

195.4.3.2 Polymyositis

Polymyositis is an inflammatory polymyopathy with an immune-mediated etiology. It is sometimes associated with other immune-mediated diseases, such as systemic lupus erythematosus. Polymyositis may also be caused by parasitic disorders (toxoplasmosis and ehrlichiosis) or various forms of cancer (paraneoplastic syndrome).[26] In most cases the etiology is unknown. Polymyositis affects all skeletal muscles of the limbs, although occasionally there are reports of focal damage, such as the extraocular muscles.[27]

Large adult dogs are most commonly affected. Signs include muscle weakness, which is sometimes exacerbated by exercise, and myalgia, pyrexia, amyotrophy, and muscle stiffness are sometimes noted. Dysphagia and regurgitation caused by mega-esophagus are less common. Pneumonia is a frequent complication. Generally, an increase in the CK level is observed. EMG abnormalities are similar to those seen in myopathy of the masticator muscles. The muscle biopsy reveals perivascular infiltrations of mononucleate cells, and necrosis and regeneration are also noted. Therapy is based on immunosuppressive doses of corticosteroids. The prognosis is guarded, especially when pneumonias arise. The combination of prednisolone and azathioprine is effective in certain cases that prove refractory to the administration of corticosteroids only.

Dermatomyositis is an inherited disorder in which myositis is associated with dermatitis. It has been reported in the collie, the Shetland sheepdog, and the Welsh corgi.[28–34] The manifestations of the nonpruritic cutaneous disorder are erythema, alopecia, and ulceration. The signs appear in 3-to 11-week-old pups, and the disease appears to wax and wane. The myopathic signs of weakness are usually observed within a few months. Myositis, especially involving the temporal muscles, is seen histologically.

195.5 DEGENERATIVE MYOPATHIES

195.5.1 Endocrine Myopathy

Both myopathy and peripheral neuropathy have been associated with hypothyroidism.[35] These conditions may occur simultaneously. The EMG examination may record high-frequency discharges. In most cases the muscle biopsy result is normal, and if any lesions are present, they are not specific (glycogenic inclusions, type 2 atrophy, necrotic fibers, and centralized nuclei). Moderate signs can be resolved through hormone supplementation. Abnormal serum electrolytes, particularly with regard to potassium, can cause a myopathic syndrome.[35]

Myopathy has been reported in spontaneous and iatrogenic hypercorticism in dogs.[36] Clinical forms vary from muscle weakness to a myotonic form. Myotonia causes limb stiffness and seems to affect the poodle in particular. In some cases, it is even associated with muscular hypertrophy. EMG shows bursts of pseudomyotonic potentials. Muscle biopsy demonstrates disorganized muscle fibers with an abnormal accumulation of mitochondria (ragged red fibers). Treatment of the underlying disease leads to improvement of the neuromuscular signs, except in the pseudomyotonic form.

195.5.2 Hyperkalemia

Hyperkalemic periodic paralysis is an inherited myopathy characterized by frequent episodes of weakness, during which serum potassium is elevated. A myotonic syndrome may often accompany this myopathy, and the fits of weakness can be triggered by oral administration of potassium. Only one report of this has been documented, in a 7-month-old female American pit bull. Administration of acetazolamide and fludrocortisone led to clinical improvement in the patient's condition.

195.6 FIBROTIC AND OSSIFYING MYOPATHIES

Ossifying myopathy is generally described as a progressive ossifying myositis. It may occur in both localized and generalized forms. Clinically, the animal refuses to move. Upon radiographic investigation, intramuscular zones can be seen, and their density is close to that of bone. Histologically, a progressive ossification of the connecting intramuscular tissue is seen in which isolated patches of trabecular bone and cartilage are found, in addition to perivascular lymphocytic infiltrates, which gave rise to the term, myositis, used for this disorder. However, the term *fibrodysplasia* is preferable, because neither the optical microscope nor the electron microscope shows any lesions confirming primary damage to the muscle fibers.[37,38]

The appearance of a permanent focal contracture with muscle fibrosis (infraspinous, femoral quadriceps) causes lameness. The cause is often obscure; congenital malformation, *Neospora caninum* infection, and trauma have been proposed.[18,39,40]

195.7 INHERITED MYOPATHIES

195.7.1 Muscular Dystrophies

Muscular dystrophies are a group of inherited myopathies clinically defined by a muscular weakness and histologically characterized by chronic degeneration and regeneration of muscle fibers accompanied by progressive fibrosis. Among these conditions, the best known is X-linked muscular dystrophy.

195.7.2 X-Linked Muscular Dystrophy

X-linked muscular dystrophy results from an alteration of the gene dystrophin, as is the case in Duchenne muscular dystrophy in humans. The absence of dystrophin or production of abnormal dystrophin leads to degeneration of the muscle fibers. The gene is carried by the X chromosome, and in a natural environment, only males are affected. The canine disease was initially identified in the golden retriever,[41,42] in which the mutation was cloned.[43] Since then, the disease has been detected in the rottweiler, Samoyed,[44] Groenendaeler shepherd,[45] and miniature schnauzer.[46] The clinical signs appear at about 8 weeks of age and manifest as muscular weakness, stiffness in gait, and reduced opening of the mouth. Within a few weeks, exercise intolerance appears and the muscles become atrophic. Hypertrophy of the esophageal muscle, the tongue, and the diaphragm can lead to severe digestive signs. The dog's gait becomes peculiar; abduction of the elbows, adduction of the hocks, and lordosis occurs in older animals. The signs usually stabilize by about 6 months of age, and movement becomes restricted with the onset of muscular fibrosis. There is no neurologic deficiency. Life expectancy depends on the severity of the signs. Death may occur within the first few days, caused by severe diaphragmatic necrosis,[47] or the animal may survive for several years and die after progressive deterioration of its general condition and because of difficulty eating. The onset of dilated cardiomyopathy is gradual, and this condition is considered a major cause of mortality.[48] The CK levels vary (10,000 to 30,000 IU/L). EMG reveals high-frequency and pseudomyotonic discharges.

904

905

Muscle biopsy reveals necrosis with an influx of macrophages and phagocytosis, muscle regeneration, and sites of intracellular calcification.[49] Some muscles, such as the sartorius, the extensor carpi radialis, the deltoid, and the cranial tibial muscle, are affected earlier and more severely. Fiber size varies with the centralized nuclei.

195.8 OTHER MUSCULAR DYSTROPHIES

Several cases of canine muscular dystrophies without dystrophin deficiency have been reported.[50,51]

195.8.1 Labrador Retriever Myopathy

Labrador retriever myopathy is an autosomal recessive myopathy that has been reported in the United States, Australia, Great Britain, and France. It has been initially described as a dystrophic disease affecting type 2 muscle fibers.[28] The cause of the disease remains unknown. Muscle biopsy specimens display a mixture of denervation and primary myopathies.

Clinical signs appear by 8 weeks to 11 months of age, the peak being around 4 months.[52,53] General weakness is seen with muscle atrophy, most visibly in the temporal muscles. Neck ventroflexion and a bunny hopping

gait are also noted. Fatigability is variable. The animal has a very slender profile, in contrast to the muscular stature of a healthy Labrador. Tendon reflexes are absent or reduced. Some dogs have kyphosis or megaesophagus. Clinical signs stabilize after 8 months of age, and the disease is not lethal. The CK level is normal, and EMG reveals early fibrillation potentials, slow positive waves, and repetitive complex discharges that disappear in aged dogs. Muscle biopsy shows a marked diameter difference, with small angular or round fibers and large fibers with centralized nuclei. Later in the course of the disease, most fibers display centrally placed nuclei.[54] Necrosis is visible on rare occasions.[28]

195.8.2 Myotonia

Nondystrophic myotonia is caused by dysfunction of one or several ionic sarcolemmal channels, mainly the chloride and sodium channels. Myotonic or pseudomyotonic syndrome may be continuous or transient and can be drug induced.

In the chow chow, myotonia is inherited with an autosomal recessive trait. Nonetheless, certain descendants may exhibit autosomal dominant transmission with incomplete penetrance. Clinical signs are visible at 10 to 12 weeks of age.[55,56] These dogs have excess muscle mass. Immediately after rest the gait is stiff, and animals may frequently fall forward with the forelimbs spread out. Dyspnea and hypoxia are common because the respiratory muscles are unable to respond to the rise in metabolic requirements. A myotonic dimple persists several seconds after percussion on the surface of a muscle. Myopathy stabilizes after a few months, but because myotonia occurs in young animals, bone or articular deformations may appear. The CK level is normal or only moderately increased, and myotonic discharges are seen on EMG. Muscle biopsy is not specific; it displays mild abnormalities, mainly hypertrophy of the muscle fibers with some centralized nuclei. No satisfactory therapy is available, although the disease itself is not life-threatening. A possible dystrophic myotonia in boxers was recently described.[57]

195.8.3 Metabolic Myopathy

Glycogenoses are storage diseases caused by an enzymatic deficiency in glycolytic metabolism that leads to the accumulation of glycogen in cells. Signs are nonspecific. Muscular weakness, fatigability, syncope, rhabdomyolysis, and convulsions caused by hypoglycemia after a period of fasting or moderate exercise are clinical hallmarks. Seven types have been identified in humans, but only three have been identified in dogs. Type II glycogenosis, or Pompe's disease, is caused by a deficiency in alpha-glucosidase (acid maltase). This disease has been described in the spitz.[41] The mode of transmission is autosomal recessive. Clinical signs are usually observed by 6 months of age, and the animal usually dies in its second year.[58–60] Type III glycogenosis, or Cori's disease, is caused by a deficiency in amylo-1,6-glucosidase. In the German shepherd, clinical signs appear during the second month, and the disease is rapidly fatal.[61] Type VII glycogenosis, which is caused by a phosphofructokinase deficiency, has been identified in a colony of springer spaniels[62] and in an American cocker spaniel.[63] The animals show exercise intolerance and suffer from muscle cramps and hemolytic anemia. Mitochondrial myopathies are characterized by a functional abnormality (an enzymatic deficiency) or a structural abnormality of the mitochondria (membrane transporter deficiency). An enzymatic deficiency in pyruvate dehydrogenase has been identified in the clumber spaniel and the Sussex spaniel.[35] In these dogs, exercise leads to collapse and severe metabolic acidosis. Another mitochondrial myopathy is suspected in the Old English sheepdog, but the biochemical substrate remains unknown.[64]

Lipid storage has been noted in muscle in dogs with myopathies.[35,65] Clinically, once the dogs reach adulthood, they show muscle weakness and muscle pain. Tremors, stiffness, and fatigability may well be encountered.

196 CHAPTER • 196 Feline Myopathies

Frédéric P. Gaschen

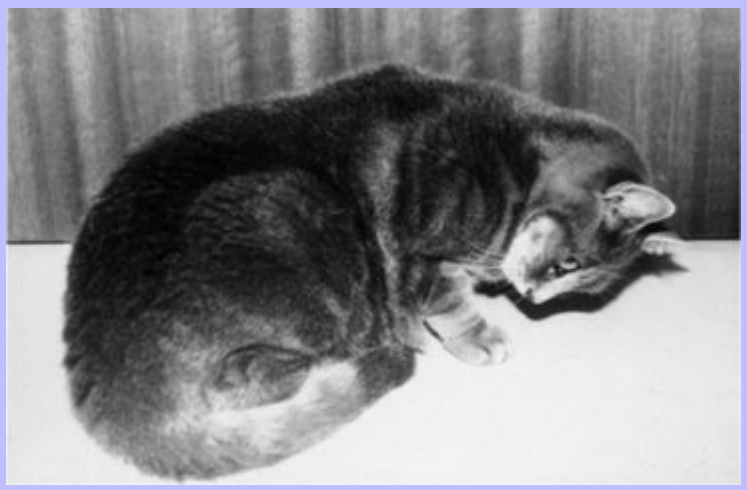
Boyd R. Jones

Although muscle and neuromuscular junction diseases occur relatively rarely in cats, a number of congenital and acquired feline myopathies have been described over the last 20 years.[1] Muscle weakness is a common clinical sign and may cause a stiff, stilted gait. Weak cats are more prone to show cervical ventroflexion than other species with muscle disease because they lack a nuchal ligament (Figure 196-1). Other clinical signs include mild lower motor neuron (LMN) deficits, tiredness, and changes in muscle size (swelling, hypertrophy, atrophy), possibly accompanied by pain in some diseases. Cats with acquired myopathies may additionally show clinical signs involving other organ systems.

The clinical investigation of cats with suspected muscle diseases is similar to that described for muscle disease in the dog. The special techniques for investigation, including electromyography (EMG), muscle biopsy, and histologic and histochemical analysis, are described elsewhere in this text. Specific feline serologic tests such as testing for the retroviruses, feline immunodeficiency virus (FIV) or feline leukemia virus (FeLV), and for the protozoan *Toxoplasma gondii* may be required.

In spite of the relative rarity of muscle diseases in cats, it is important for clinicians who regularly examine feline patients to recognize and identify the specific feline disorders in a timely way. A good knowledge of these diseases and their features is necessary to enable a diagnosis to be made and prognosis to be given. Treatment of individual cats and advice to breeders that may help them to eliminate an hereditary trait from their breeding lines both depend on an accurate diagnosis. The congenital myopathies described in the cat are shown in Table 196-1.

Figure 196-1 Adult cat with severe weakness and cervical ventroflexion.



196.1 CONGENITAL MYOTONIA

Primary congenital myotonia has been reported in a variety of species but only recently in the cat.[2,3] The clinical features of myotonia in cats described by Hickford and colleagues[2] and Toll and colleagues[3] are very similar. The affected cats walk with a stiff, awkward gait. The limbs are abducted when walking due to poor flexion of proximal appendicular joints. Widespread hypertrophy of muscle groups occurs. The stiffness is worse on awakening and in cold weather, but it improves with exercise. When affected kittens are startled, they may stiffen and fall into lateral recumbency with legs extended. Spasm of the eyelids and facial muscles frequently occur when the cats are startled (Figure 196-2). Their jaws cannot be opened fully, and mild dysphagia sometimes occurs. Clinical chemistry, including serum (CK) activity is normal.

The presence of a dimple on percussion of muscle (tongue or skeletal muscle) and the occurrence of spontaneous high-frequency discharges that wax and wane on EMG after insertion of a needle electrode and the "dive bomber" sound are features of all affected cats (Figure 196-3).

Histologic section of muscle shows a variation in fiber size, central nuclei, and proliferation of sarcolemmal nuclei.[2,3] The reports of myotonia in cats neither described treatment nor emphasized that medical treatment was required.

196.2 DYSTROPHIN-DEFICIENT MYOPATHY

Feline dystrophin deficiency, like that in other species, is due to a mutation in the dystrophin gene—a very large gene located on the X chromosome—and is transmitted according to an X-linked recessive inheritance pattern.[4] In cats the most prominent sign is severe hypertrophy of the axial and proximal appendicular skeletal muscles (Figure 196-4). The tongue and diaphragm also show massive hypertrophy in some individuals, and this can result in potentially lethal complications, such as esophageal compression, insufficient water intake, and severe hyperosmolality due to dehydration.[4]

Dystrophin-deficient kittens cannot be differentiated from normal kittens at birth, although they are slow to grow. Appendicular muscular hypertrophy is first seen around 10 weeks of age, followed by axial muscle hypertrophy, especially of the cervical muscles. Dystrophin deficiency causes a disease often called *hypertrophic feline muscular dystrophy* (HFMD). These animals have a stilted gait, and they tend to "bunny hop" when they run. Occasionally, they show marked stiffness and reluctance to move.

Dystrophin-deficient cats develop a subclinical cardiomyopathy with myocardial hypertrophy from 6 to 9 months of age.[5] Fractional shortening of the left ventricle is usually normal, suggesting normal left ventricular contractility. These cats infrequently develop clinical signs of heart failure, but some older cats have died from cardiomyopathy (Gaschen, unpublished observations).

Table • 196-1 Congenital Myopathies

DISEASE	AFFECTED BREEDS AND GEOGRAPHIC PROVENIENCE	MODE OF INHERITANCE	UNDERLYING DEFECT	CLINICAL SIGNS	PROGNOSIS
Congenital myotonia	DSH (NZ, USA)	Autosomal recessive	Probable defect in chloride channels	Stiff gait; hyperactivity of selected muscle groups when startled; percussion dimple	Fair to good (nonprogressive condition, cats enjoy a normal quality of life)
Devon Rex myopathy	Devon Rex (AUS, GB)	Autosomal recessive	Unknown	Cervical ventroflexion; generalized muscle weakness; abnormal gait; megaloesophagus	Poor (many cats die of asphyxiation)
Dystrophin-deficient myopathy	DSH (USA, NL, CH)	X-linked recessive	Dystrophin deficiency	Skeletal muscle hypertrophy with possible complications; sensitivity to stress; stiff gait	Guarded to fair (cats can have almost normal quality of life but may require more frequent veterinary visits)
Glycogen storage disease type IV	Norwegian forest cats (USA, Europe)	Autosomal recessive	Glycogen branching enzyme (GBE) deficiency	Stillbirth; muscle tremor; muscle atrophy; cardiomyopathy	Poor (all cats eventually die)
Hypokalemic myopathy	Burmese (AUS, NZ, GB, NL)	Probably autosomal recessive	Unknown	Transient, paroxysmal clinical signs with generalized muscle weakness, cervical ventroflexion	Good response to potassium supplementation
Malignant hyperthermia	DSH	Unknown	Unknown	Severe hyperthermia during anesthesia (halothane)	Poor (the two reported cats died)
Merosin-deficient myopathy	DSH, Siamese (USA)	Unknown	Merosin (laminin α2) deficiency	Hindlimb weakness from 6 months old, worsening to muscle atrophy and contractures at 1 year old	Poor (both cats were euthanized before 2 years of age)
Myasthenia gravis (MG)	DSH	Unknown	Lack of acetylcholine receptors	Generalized muscle weakness	Fair, generally good response to therapy
Nemaline myopathy	DSH (USA)	Possibly autosomal recessive	Unknown	Progressive weakness (6–18 months); rapid, choppy, hypermetric gait; tremor, exercise intolerance	Poor (all five reported cats died or were euthanized)

AUS, Australia; *CH,* Switzerland; *GB,* Great Britain; *NL,* Netherlands; *NZ,* New Zealand; *USA,* United States of America.
From Gaschen F et al: Congenital diseases of feline muscle and neuromuscular junction, *J Feline Med Surg*, 2003 (in press).

EMG findings include myotonic discharges, fibrillation potentials, prolonged insertional activities, complex repetitive discharges, and positive sharp waves.

In young and adult cats, serum (CK) activity is increased, but serum CK concentrations do not allow a differentiation of dystrophin-deficient kittens from normal littermates at birth. Serum aspartate transaminase (AST) and alanine aminotransferase (ALT) are also increased.

Histopathologic changes in dystrophin-deficient skeletal muscle include variation in myofiber diameter, with large myofibers showing splitting, foci of degeneration and regeneration, with minimal mononuclear infiltration and absence of endomysial or perimysial fibrosis. Severe dystrophic calcification can be present. A definitive diagnosis is made when immunohistochemistry (IHC) staining confirms a lack of dystrophin at the sarcolemma.

The prognosis for HFMD is fair; no specific treatment is available. Many cats enjoy a nearly normal quality of life. However, stress, intense physical activity, and inhalant anesthesia should be avoided if possible because they may elicit acute rhabdomyolysis.[6]

907

908

Figure 196-2 An affected kitten showing flattening of the ears and retraction of the lip after receiving a fright. (From Hickford FH et al: Congenital myotonia in related kittens, *J Small Anim Prac* 39:281, 1998, with permission.)

196.3 MYOPATHY OF DEVON REX CATS

This myopathy has been reported in many countries: Australia, New Zealand, the United Kingdom, and the United States.[7]

The most obvious and consistent clinical sign is passive ventroflexion of the head and neck. Ventroflexion is frequently accentuated when walking, during micturition and defecation. Typically the animal has a high-stepping forelimb gait, head bobbing, and dorsal protrusion of the scapulae. Due to weakness of the shoulder girdle musculature with exertion, they tire easily and eventually collapse in sternal recumbency.

Myopathic Devon Rex cats frequently rest in a characteristic “dog-begging” position, with their front paws on a supporting object (Figure 196-5). One of the significant features of the disease is the difficulty affected cats have prehending food and swallowing. They can choke and asphyxiate due to the accumulation of ingesta in the pharynx. The severity of signs often fluctuate from day to day. Stress, concurrent illness, exertion, and cold all tend to accentuate weakness.

Figure 196-3 Electromyography (EMG) recording from the biceps muscle of an affected kitten showing waxing and waning, high-frequency discharges after needle insertion. (From Hickford FH et al: Congenital myotonia in related kittens, *J Small Anim Prac* 39:281, 1998, with permission.)

Figure 196-4 Adult dystrophin–deficient cat with appendicular muscle hypertrophy and hypertrophy of the tongue.

The age of onset is variable, and less seriously affected kittens may go unnoticed for several months. Breeders normally recognize the affected kittens at about the time they start to walk. The disease is inherited as an autosomal recessive trait.

In the one detailed study by Malik and colleagues[7] of four cats with this muscle disorder, esophageal hypomotility and megaesophagus were identified in all animals. Hematologic and serum biochemistry values including electrolytes and CK are within reference ranges.[7] Sparse fibrillation potentials and positive sharp wave activity may be detected on EMG of the upper limb and cervical muscles.

Skeletal muscles appear grossly normal, but histologic changes are best identified in dorsal cervical and proximal forelimb muscles. The severity of the changes correlates with both the severity of signs and the age of the cat.[7] In muscle biopsies, the significant lesions are variation in cross-sectional area, more rounded fibers, occasional degenerating fibers, some fiber segmentation, and increased subsarcolemmal nuclei. Lesions do not affect one fiber type in particular, and dystrophin is present. No specific treatment is available, but feeding from a raised platform can help ingestion of food and prevent choking.

908
909

Figure 196-5 Young Devon Rex kitten showing the characteristic posture when resting. (Published with permission of Manon publishing.)

196.4 NEMALINE ROD MYOPATHY

Affected cats are normal until 6 to 18 months of age; then they develop muscle atrophy and weakness, and their gait becomes wobbly. They show a fast, jerky, and hypermetric gait and a crouched stance with an exaggerated hip and tarsal flexion. These cats become quickly exhausted and pant after exertion. The clinical course is slowly progressive. CK activity in serum is increased, but no changes are seen on EMG examination. Myofibers contain nemaline rods. The prognosis is poor, and most affected cats are euthanized for humane reasons.[1]

196.5 LAMININ α2 (MEROSIN) DEFICIENCY

Laminin 2, also called *merosin*, is a glycoprotein indirectly anchoring the cell membrane and the basal lamina and is present in skeletal muscle and Schwann cells. O'Brien and colleagues have described two merosin-deficient cats.[8] Hindlimb weakness starts at 6 months of age and is followed by generalized muscle atrophy by 12 months of age. Hindlimb muscle contractures are present. Serum CK is increased, and the motor nerve conduction velocity is markedly decreased. Myofiber necrosis, variation in fiber size, and lipid accumulation are present in muscle, and axonal demyelination is present in peripheral nerves. IHC stains show a lack or decrease of laminin α2 in skeletal muscle.

196.6 GLYCOGEN STORAGE DISEASE TYPE IV

A myopathy associated with glycogen storage disease type IV has been reported in Norwegian forest cats.[9] Many affected cats are stillborn or die within the first few days of life. The surviving cats are often normal until they reach 5 to 7 months of age. They may show clinical signs of persistently increased body temperature, generalized muscle tremors, intermittent listlessness and a “bunny hopping” gait, muscle weakness, atrophy, and contracture. Most affected cats die by 10 to 14 months of age.

The disease is due to a lack of the glycogen branching enzyme (GBE) and is characterized by accumulation of abnormal glycogen in several tissues including skeletal muscle. Hereditary transmission occurs according to an autosomal recessive pattern. Affected cats are homozygous for a deletion in the GBE gene causing instability of mRNA.

Serum CK and ALT are increased. Fibrillation potentials and bizarre high-frequency discharges are present in the EMG. Cytoplasmic inclusions containing periodic acid-Schiff (PAS) and toluidine blue–positive material are present in many organs.

Diagnosis of the disease in an affected kitten unequivocally identifies the parents as carriers of the mutation, which should have direct implications for their use in any breeding program. A DNA-based carrier test is available in selected laboratories to screen problem breeding families.

196.7 MYASTHENIA GRAVIS

Acquired myasthenia gravis (MG) is a rare disease, but sporadic reports and a published series of 20 cases exist.[10] Congenital MG has been described in two cats.[11] Acquired feline MG is an immune-mediated disease as evidenced by the presence of serum acetylcholine receptor antibodies. The main clinical sign is muscle weakness. Ducote and colleagues described three distinct forms.[10] Cats with focal MG have signs isolated to the esophageal, pharyngeal, laryngeal, or facial muscles. Generalized MG is characterized by appendicular muscle weakness with or without esophageal, pharyngeal, laryngeal, or facial muscle involvement. Acute fulminating MG is a severe acute onset form of generalized MG with a rapid progression of muscle weakness often associated with respiratory muscle paresis or paralysis.

The diagnosis of MG in the cat is similar to the dog and includes an increase in muscle strength after intravenous edrophonium hydrochloride administration, decremental evoked muscle action potential response to repetitive nerve stimulation, and an increase in serum ach-receptor antibody concentration. MG in cats may be associated with a thymic mass (thymoma) and concurrent immune-mediated myositis. Thoracic radiography and muscle

biopsy may be indicated in selected cases. Treatment of feline MG patients includes administration of anticholinergics (pyridostigmine 0.25 to 1 mg/kg every 12 hours) with the dose titered to the clinical response. An immunosuppressive dose of prednisone (2 to 4 mg/kg every 24 hours) is indicated if aspiration pneumonia is absent.

196.8 HYPOKALEMIC POLYMYOPATHY

A polymyopathy associated with total body potassium depletion has been recognized in cats of all breeds, ages, and both sexes.[12] Some cats with chronic renal failure and cats eating acidifying diets are affected. Cats with polyuria or polydipsia secondary to hyperthyroidism and cats with anorexia from any cause may also be at risk. Severe total body depletion of potassium occurs secondary to decreased dietary intake or increased urinary excretion of potassium.[12]

Burmese kittens develop hypokalemia associated with disturbances of the intracellular and extracellular balance of potassium.[12] The condition has a familial and inherited basis (putative autosomal recessive), with affected kittens being produced in specific lines of this breed.[12,13]

The significant clinical sign in these cats is weakness characterized by persistent ventroflexion of the neck; a stiff, stilted gait; and reluctance to move. Muscle pain may be elicited on palpation, but the neurologic examination is normal. Clinical signs may have an acute onset and may be episodic. Serum CK activity is often high (>50,000) and the serum potassium concentration is decreased (<3.0 nmol/L), and increased fractional urinary excretion of potassium can be measured (>10% to 15%). No evidence exists for reduced potassium intake or urinary potassium loss in affected Burmese kittens. Many affected cats have renal disease; urea and creatinine concentrations are elevated. Hypokalemia can result in decreased glomerular filtration, which can alter urine-concentrating mechanisms; therefore a low urine specific gravity is not a good guide to renal function.

Mild diffuse EMG changes, including increased insertional activity, positive sharp waves, fibrillation potentials, and high-frequency discharges have been recorded in affected cats. Muscle biopsies show mild myonecrosis or are normal.[13]

Signs of hypokalemic polymyopathy usually resolve after parenteral or oral supplementation of potassium. Oral treatment with potassium gluconate is recommended for mildly affected cats (Kaon Elixir, Adria Laboratories, Columbus, OH; Tumil K, Daniels Pharmaceuticals) at a dose of 2 to 4 nmol/cat twice a day for 2 days, then once daily. The dose administered is adjusted based on the response and the serum potassium concentration. Cats with more dramatic hypokalemia (<2.5 nmol/L) or those with severe muscular weakness will initially require parenteral administration of intravenous saline or lactated ringers with supplemented potassium chloride. Intravenous infusion of potassium should not exceed 0.5 nmol/kg/hour. Oral supplementation with potassium gluconate should be continued and potassium concentration measured at regular intervals.

196.9 HYPERTHYROIDISM

Hyperthyroidism is one of the most common endocrinopathies affecting older cats. Mild muscle weakness is a relatively frequent accompanying sign. However, severe muscle disease only affects a low percentage of hyperthyroid cats.[15] The pathogenesis of hyperthyroid myopathy is unknown. In humans, depletion of energy-rich molecules in the striated muscle and intracellular displacements of potassium have been suspected.[15] In cats, hyperthyroidism may be associated with hypokalemia and hypokalemic myopathy.[16] Increased renal losses of

potassium may occur without evidence of azotemia because hyperthyroidism generally leads to an increase in renal plasma flow and may mask the presence of renal insufficiency. In such cats, renal disease may only become obvious after onset of treatment.

Generalized muscle weakness with abnormal gait and exercise intolerance occur relatively frequently. Sometimes, cervical ventroflexion can occur before hyperthyroidism is diagnosed. In addition to the typical laboratory finding observed in hyperthyroidism, serum activity of CK can be increased. The prognosis is good: signs of muscle weakness usually disappear after hyperthyroidism has been successfully treated. In treated cats developing overt renal failure, regular monitoring of serum potassium concentration and oral potassium supplementation (see previous discussion) are essential for a successful outcome in addition to adequate management of chronic renal failure.

196.10 PARASITIC POLYMYOSITIS

The cat is the definitive host of the protozoal parasite *Toxoplasma gondii*. Although the parasite mainly undergoes an enteroepithelial cycle in this species, it can also occasionally lead to the formation of tissue cysts and cause clinical signs. The prevalence of antibodies against *Toxoplasma* spp. in cats varies from 30% to more than 65%, depending on the geographic area. Prevalence increases with age due to the higher risk of contact with *Toxoplasma*. However, only a small fraction of seropositive cats develop clinical toxoplasmosis.[17]

Typical clinical signs include poor general condition with anorexia, lethargy, and fever. Toxoplasmosis affects different organs such as the lungs, CNS (brain, spinal cord), liver, pancreas, heart, and eyes. In contrast to dogs, myositis is only rarely observed in cats.[17] However, if muscle weakness, exercise intolerance, and myalgia are present, toxoplasmosis should be considered as a differential diagnosis. Positive immunoglobulin M (IgM) titers and increasing immunoglobulin G (IgG) titers can help confirm the diagnosis. Immunodeficiency (e.g., after retroviral infections) can increase the risk of new infections or reactivate chronic *Toxoplasma* infections.[17] (Treatment and prognosis of feline toxoplasmosis are described in detail in the section on infectious diseases.)

196.11 OTHER FORMS OF POLYMYOSITIS

Polymyositis may occur in association with various diseases. Adult cats experimentally infected with FIV show histologic and occasionally EMG changes in skeletal muscle in the absence of clinical signs of muscle disease.[18] Some cats with thymoma can develop a paraneoplastic polymyositis that is sometimes associated with dysphagia.[19] Idiopathic polymyositis is an inflammatory muscle disease for which no specific cause can be found, and an immune-mediated pathogenesis is suspected.[19–21]

The clinical signs are muscle weakness of varying severity; cervical ventroflexion is occasionally observed. Affected cats may show dysphagia, especially with paraneoplastic or idiopathic polymyositis. The serum concentration of CK is significantly increased. Nonspecific EMG changes are present with normal nerve conduction velocities. Multifocal inflammatory infiltrates with mononuclear cells[18,19] are observed histologically.

Idiopathic polymyositis is treated with immunosuppressive doses of glucocorticoids (prednisolone 2 mg/kg twice a day). The prognosis is guarded to good for idiopathic polymyositis, but dysphagia or the presence of megaesophagus are poor prognostic signs.[20,21]

196.12 ISCHEMIC NEUROMYOPATHIES

196.12.1 Arterial Thromboembolism Associated with Cardiomyopathy

Arterial thromboembolism is a significant complication of feline cardiomyopathies and occurs most frequently in the distal aorta. It may also rarely occur secondary to neoplasia in cats without cardiovascular disease.[22] Recently, 271 cats with feline arterial thromboembolism (FATE) were described in three large retrospective studies.[22–24] The main features of these cases are summarized in Table 196-2.

The high proportion of male cats may reflect the high prevalence of hypertrophic cardiomyopathy in male cats.[20] Frequently, cats with FATE have no previous history of cardiac disease. Affected animals most often experience acute to peracute onset of bilateral hind limb paralysis. However, unilateral hind limb or front limb involvement can be observed. Paralysis or paresis is often accompanied by painful swelling of all involved muscles. In the affected hind limbs, the femoral pulse is absent or, with partial embolism, it is weaker. Cyanosis of the unpigmented nail beds and foot pads is observed when compared with the unaffected limbs. The cardiovascular signs of cats with FATE are discussed elsewhere in this text.

In the published case studies, laboratory changes included increases in serum activities of CK, ALT, and AST in most cats and azotemia in up to one half of the cases.[22] Bilateral embolism of the hind limbs and absence of motor function in the affected limbs were negative prognostic factors.[22] Cats that survived the FATE episodes had higher body temperature (mean 99° F [37.7° C] versus 96.5° F [35.8° C] and higher heart rates (median 210 versus 188 beats per minute). The diagnosis of congestive heart failure (CHF) did not appear to significantly influence the prognosis.[22]

Management of FATE includes supportive treatment, including intravenous fluids and oxygen supplementation. Analgesia with opiates (buprenorphine, oxymorphone, or fentanyl) is essential, because most signs of distress are due to pain and abate once the pain is controlled. The use of anti-coagulant and antithrombogenic drugs is controversial. Aspirin is often administered as an antithrombogenic drug, but efficacy data is lacking. No differences in outcome were noticed between cats with FATE receiving anti-inflammatory (81 mg/cat every 72 hours) and low (5 mg/cat every 72 hours) doses of aspirin.[22] Thrombolytic therapy with streptokinase, an activator of fibrinolysis, was studied in 46 cats with FATE. The survival rate did not significantly differ from that of cats receiving no streptokinase in other retrospective studies; however, the authors claim that their study population was more severely affected than cats in other studies.[26] The underlying cardiomyopathy must be treated according to the recommendations given elsewhere in this text.

Table • 196-2 Diagnostic Features of Feline Arterial Thromboembolism

PARAMETER	LASTE ET AL, 1995	SHOEMAN, 1999	SMITH ET AL, 2003
Number of cats	100	44	127
Prevalence in hospital population	N/A	N/A	0.57%
Signalment:			
Mean age (years)	7.7	8.7	8.6
Gender distribution in % (M:F)	67:33	75:25	67:33
History:			
No previous diagnosis of cardiac disease	89%	77%	93.0%
Vomiting shortly before thromboembolic episode	N/A	6.8%	15.7%
Physical examination:			
One limb affected	N/A	N/A	24.8%
Two or more limbs affected	N/A	N/A	75.2%
Partial thromboembolism	20%	31%	N/A
Hypothermia	35%	N/A	65.5%
Tachypnea	26%	N/A	90.8%
Cardiac parameters:			
Cardiac murmur	35%	N/A	30.7%
Gallop rhythm	20%	N/A	24.4%
Arrhythmia	19%	N/A	15.7%
Mod to severe LA enlargement	71.2% (n=63)	66% (n=9)	91.0% (n=78)
Congestive heart failure (CHF)	66.3% (n=80)	51% (n=25)	44% (n=125)
Laboratory parameters:			
Increased CK	N/A	80% (n=5)	100% (n=87)
Increased ALT	88.7% (n=53)	N/A	72.8% (n=87)
Increased AST	84.9% (n=53)	N/A	98.6% (n=87)
Increased BUN	54.7% (n=53)	N/A	41.3% (n=87)
Increased creatinine	56.6% (n=53)	N/A	26.3% (n=87)

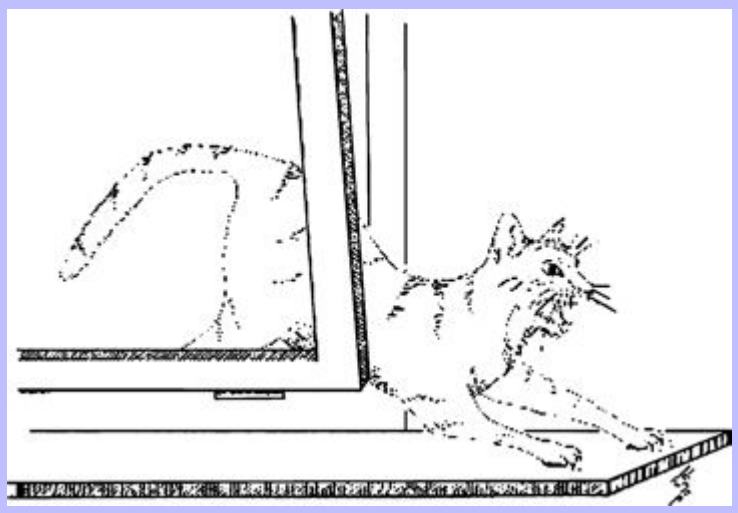
In recent retrospective studies, 35% to 39% of cats survived episodes of FATE, 28% died during the initial hospitalization, and 33% to 35% were euthanized.[22–24] In one study, survival rate was better during the last 10 months of the study (up to 75% survivors) than during the 9 earlier years (less than 30% survivors).[22] Among cats for which treatment was initiated, 45% survived to be discharged.[22] Depending on the study, median survival time (MST) was between 117 days and 6 months. Re-embolization occurred in 24% to 50% of discharged cats. These results confirm that FATE is associated with a poor prognosis. The underlying cardiomyopathy represents a clear risk for new thromboembolic events and contributes to the unfavorable prognosis. Rapid identification of cats with more favorable prognosis is important to allow owners to make an informed decision to treat or not. Cats that recover may have permanent ischemic muscle or nerve damage.

196.12.2 Traumatic Ischemic Neuromyopathy Associated with Bottom-Hung Pivot Windows and Garage Doors

In Europe, bottom-hung pivot windows are common. Cats try to get in or out through these windows and get themselves wedged in between the costal arch and the pelvis (see Figure 196-6). After unsuccessful efforts to free themselves, the cats become wedged with pressure on their abdomen and in a position that can lead to traumatic lesions to muscle, internal organs, blood vessels, spine, and spinal cord. A recent report reviewed the clinical features and outcome of 30 cats trapped in bottom-hung pivot windows.[27]

The signs shown were hypothermia (19 cats); pain in the hind limbs, lumbar area, and abdomen (21 cats); swelling of the hind limb muscles (7 cats); cold hind limbs (6 cats); weak femoral pulse (10 cats); absent femoral pulse (9 cats); and paraparesis or paraplegia (17 cats), often associated with decreased spinal reflexes in the hind limbs (see Figure 196-6). Deep pain perception was decreased in two cats and absent in four.

Figure 196-6 A cat trapped in a bottom-hung pivot window.



Moderate hyperkalemia may be have been due to reperfusion injury after the cats had been freed from the window.

911

912

Serum activities of CK and AST were massively increased, with a moderate increase in ALT. Hematuria was present in some cats. Abdominal radiographs showed soft tissue density underneath the lumbar spine or in the retroperitoneal area, with a loss of contrast in the caudal abdomen. Occasionally, fractured vertebrae were present.

Medical treatment included fluid therapy, management of pain, and administration of antibiotics and high dose of corticosteroids. Physical therapy consisting of massage of the involved muscles and gentle manipulation of the hind limbs was performed once the limbs were less painful.

The prognosis was good. Eighty percent of the cats were discharged, and all but one recovered fully within 1 month.[26] The duration of the hospital stay was between 1 and 12 days.

197 CHAPTER • 197 Pathophysiology of Heart Failure

Helio Autran de Morais

Denise Saretta Schwartz

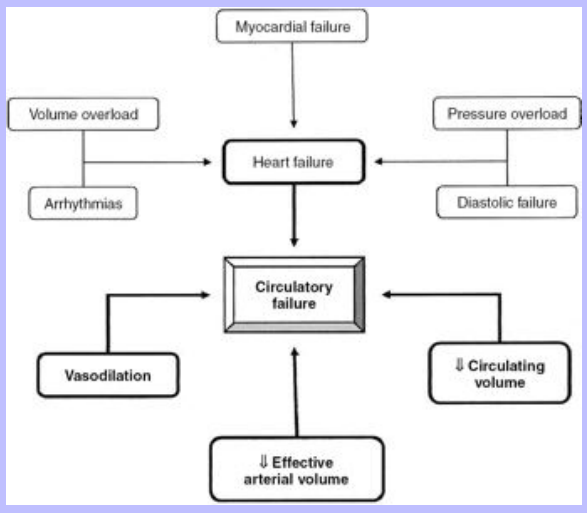
The heart, consequently, is the beginning of life; the sun of the microcosm, even as the sun in his turn might well be designated the heart of the world; for it is the heart by whose virtue and pulse the blood is moved, perfected, and made nutrient, and is preserved from corruption and coagulation; it is the household divinity which, discharging its function, nourishes, cherishes, quickens the whole body, and is indeed the foundation of life, the source of all action.

William Harvey (1628)

197.1 WHAT IS HEART FAILURE?

Heart failure is a clinical syndrome in which impaired pumping decreases ventricular ejection and impedes venous return. During heart failure the heart cannot pump blood at a rate adequate to maintain metabolizing tissue requirements, or it can do so only with elevated filling pressures.[1] However, this definition is not complete because it does not mention that heart failure is a progressive disease.[2] The hemodynamic abnormalities associated with heart failure are in many cases complicated by depressed myocardial contractility and relaxation, caused by biochemical and biophysical disorders in the myocardial cells. These cellular disorders, in turn, are partly the result of molecular abnormalities that not only impair the heart's performance, but also accelerate deterioration of the myocardium and hasten myocardial cell death.[3] *Circulatory failure* is a decrease in cardiac output caused by abnormalities in one or more components of the circulation (i.e., heart, blood volume, oxyhemoglobin concentration, vasculature). Heart failure therefore is one of the many causes of circulatory failure (Figure 197-1).

Figure 197-1 Causes of circulatory and heart failure.



The heart, like any pump, has only two ways to fail: It either cannot pump enough blood into the aorta or pulmonary artery to maintain arterial pressure (low-output heart failure), or it cannot adequately empty the venous reservoirs (congestive heart failure [CHF]). Heart failure therefore can be recognized clinically by signs of low cardiac output (e.g., depression, lethargy, hypotension) or congestion (e.g., ascites, pleural effusion, pulmonary edema). Heart failure can also be classified, based on the side that is failing, as right, left, or bilateral heart failure. Right-sided heart failure is associated with signs of congestion in the systemic circulation (ascites, peripheral edema), whereas left-sided heart failure causes signs of congestion in the pulmonary circulation (pulmonary edema, dyspnea). Bilateral heart failure presents a combination of left-and right-side signs. In small animal practice, pleural effusion is usually associated with bilateral CHF. Both left-and right-sided heart failure can be associated with low-output signs.

914

915

197.2 WHY DO HEARTS FAIL?

Heart failure may result from inability by the heart to eject blood properly (systolic failure), from inadequate ventricular filling (diastolic failure), or both. The final result in all three cases is a reduction in stroke volume, leading to a decrease in cardiac output and a tendency toward decreased arterial pressure. Patients with severe heart failure have reduced or inadequate cardiac output even at rest, whereas patients with mild heart failure or diastolic failure have an inadequate increase in cardiac output with perturbation (e.g., exercise or stress).

197.2.1 Systolic Function and Dysfunction

Systemic arterial blood pressure (ABP) is a result of the interplay between the arterial system and the heart. Any pressure can be estimated as the product of flow × resistance. In the cardiovascular system, cardiac output (CO), or the amount of blood pumped at a given time, is the flow, and the aortic input impedance (Z), the opposition that the vasculature offers to the ejection of blood by the heart, is the resistance factor:

$$ABP \approx CO \times Z$$

Cardiac output (CO) is the product of the left ventricular stroke volume (SV) and the heart rate (HR):

$$CO = SV \times HR$$

The higher the stroke volume, the higher the cardiac output. Increases in the heart rate increase cardiac output linearly until a plateau is reached, at which point further increases in the heart rate do not affect cardiac output. This latter effect occurs because there is less diastolic time for ventricular filling, and increases in the heart rate are balanced by decreases in the stroke volume. With further increases in the heart rate, cardiac output starts to fall. Stroke volume is primarily determined by an intrinsic property of the myocardial cell, contractility, and two coupling factors, preload and afterload. Preload and afterload are considered coupling factors because they depend on vascular changes. Stroke volume increases with increases in preload and contractility and decreases in afterload. *Preload* is the force acting to stretch the ventricular fibers at the end of diastole and to determine the maximal resting length of the sarcomeres.[4] It reflects the degree of ventricular filling just before contraction. Clinically, preload is estimated as being the end-diastolic volume or, less precisely, the end-diastolic pressure. Substitution of pressure for volume in the estimation of preload is not accurate in all clinical situations (e.g., noncompliant or stiff ventricles). *Afterload* is the force opposing ventricular ejection. This opposition is presented by the vasculature to the ejecting ventricle and is best described by the aortic input impedance.[5–7] An increase in afterload communicates itself to the ventricles during systole by increasing wall stress. The end-systolic wall stress, therefore, can be used as an index of the afterload.[7] *Contractility* is a change

in the heart's ability to do work when the preload, afterload, and heart rate are kept constant.[3,7] Stroke volume is also affected by ventricular filling during diastole, ventricular wall motion abnormalities, space-occupying lesions, and arrhythmias. All determinants of cardiac output are intertwined. Therefore as physiologic compensatory and reflex mechanisms affect one component, the other components may also change (Box 197-1).

197.2.1.1

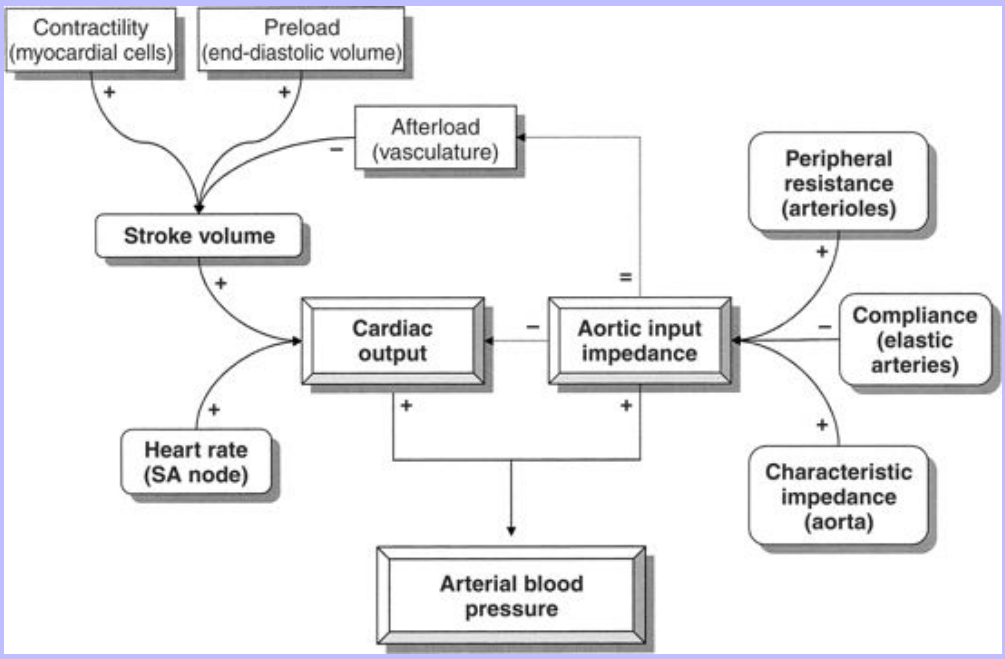
Box • 197-1 Interrelation between Determinants of Cardiac Performance and Properties of the Heart

- **Preload and contractility** → Increases in the preload lead to increases in contractility as a result of optimum myocardial fiber length and greater interaction between actin and myosin.
- **Heart rate and preload** → Ventricular filling depends on the duration of the diastolic period. Decreases in the heart rate may increase preload by lengthening diastole. Excessive increases in the heart rate interfere with ventricular filling, decreasing preload.
- **Heart rate and contractility** → Excessive increases in the heart rate decrease the diastolic period, leading to a decrease in myocardial oxygen delivery, and might negatively affect contractility. Increases in the heart rate can also decrease contractility by decreasing preload.
- **Heart rate and myocardial relaxation (lusitropism)** → Decreased diastolic myocardial oxygen delivery during fast heart rates negatively affects relaxation, an energy-dependent process. Ventricular suction capacity is impaired, and ventricular compliance is decreased because of increased stiffness.
- **Heart rate and automatism** → Increases in the heart rate decrease oxygen offer to myocardial cells, changing membrane potential and favoring the development of arrhythmias.
- **Preload and afterload** → Excessive increases in preload increase wall tension. Increases in wall tension increase afterload, leading to increased myocardial oxygen consumption.

In the estimation of blood pressure, the resistance factor is best represented by the arterial impedance, which is the aortic pressure divided by aortic flow at a given time. The properties of the arterial system can be described by the total arterial compliance, the peripheral resistance, and the characteristic impedance.[8] *Total arterial compliance* is the change in volume that results from a given change in pressure in the elastic arteries. *Peripheral resistance* is largely determined by small arteries and arterioles and represents the resistance to the steady (nonpulsatile) flow. *Aortic characteristic impedance,* the opposition to pulsatile flow, accounts for the elastic wall and blood mass properties in the proximal aorta.[8] Increases in peripheral resistance and characteristic impedance and decreases in compliance increase left ventricular afterload. With a decrease in compliance, the ventricle ejects into a stiff vasculature, increasing both the energetic cost to maintain blood flow and myocardial oxygen consumption (MVO_2). With decreased compliance, ventricles expend more energy to distend less compliant elastic arteries, making less energy available for tissue perfusion.[9,10] Characteristic impedance, a property of the proximal aorta, increases whenever the stiffness of the aorta increases or its radius becomes smaller. Increases in peripheral resistance (caused by decreases in the cross-sectional area of the arterioles) increase the mean aortic pressure and decrease the left ventricular stroke work and stroke volume.[11–13] Peripheral resistance has a greater effect on ventricular performance than does characteristic impedance or compliance.[9] However, it should be remembered that the left ventricle ejects blood into the

proximal aorta and not into the arterioles. The principal factors involved in the determination of arterial pressure are shown in Figure 197-2.

Figure 197-2 Determinants of arterial blood pressure. Arterial blood pressure is a function of cardiac output and arterial impedance. Contractility, preload, and afterload determine the stroke volume, which, multiplied by the heart rate, yields the cardiac output. Changes in arterioles, elastic arteries, and the aorta all influence the aortic input impedance (afterload). Increases in afterload increase arterial blood pressure but decrease cardiac output. (+), Increases in the parameter increase aortic input impedance, stroke volume, cardiac output, or arterial blood pressure; (–), increases in the parameter decrease aortic input impedance or stroke volume; (=), afterload and aortic input impedance are synonymous.



Systolic failure is characterized by normal filling of the ventricle and a decrease in the forward stroke volume. The decrease in SV may stem from a decrease in contractility *(myocardial failure)* or from a primary increase in ventricular pressure *(pressure overload)* or volume *(volume overload)* (Box 197-2). Increases in volume are usually caused by a leaking valve or an abnormal communication between the systemic and pulmonary circulations.

197.2.1.2 Myocardial Failure

Myocardial failure may be primary (e.g., dilated cardiomyopathy) or may occur secondary to chronic volume or pressure overload. In patients with myocardial failure, a decrease in contractility lowers the stroke volume, cardiac output, and arterial blood pressure. Myocardial failure depresses the heart's ability to compensate for the decrease in cardiac output (Figure 197-3).

197.2.1.3 Pressure Overload

The most common reasons for pressure overload in small animal medicine are subaortic stenosis and systemic arterial hypertension on the left side of the heart and heartworm disease and pulmonic stenosis on the right side. In pressure overload states, the ventricles must overcome the increase in resistance to eject blood. The first response is to dilate, increasing the sarcomere length to the point where overlap between myofilaments is optimum (approximately 2.2 μm). Dilatation increases ventricular contractility and pressure through a length-dependent activation of contractility, which helps overcome the increased resistance and maintain stroke volume. However, this adaptation increases ventricular wall stress and consequently MVO_2.

Left ventricular wall stress can be approximated as the product of intraventricular pressure times the left ventricular radius divided by twice the left ventricular wall thickness (Figure 197-4). During the initial dilatation, the ventricular radius increases and wall thickness decreases; both of these factors increase ventricular wall stress. With a sustained pressure overload, the ventricular muscle adapts by undergoing concentric hypertrophy (Figure 197-5). In this type of hypertrophy, an increase in wall thickness occurs at the expense of a decrease in chamber size (decrease in ventricular radius), returning ventricular wall stress toward normal and increasing contractility.

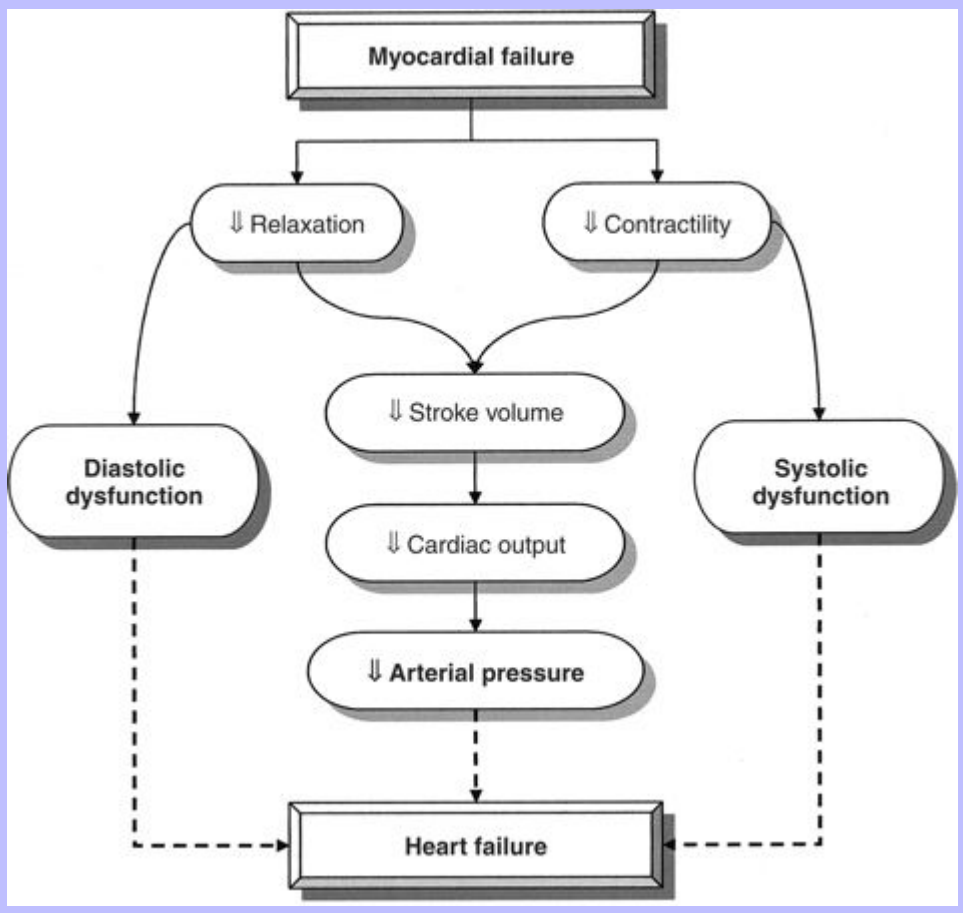
Heartworm disease

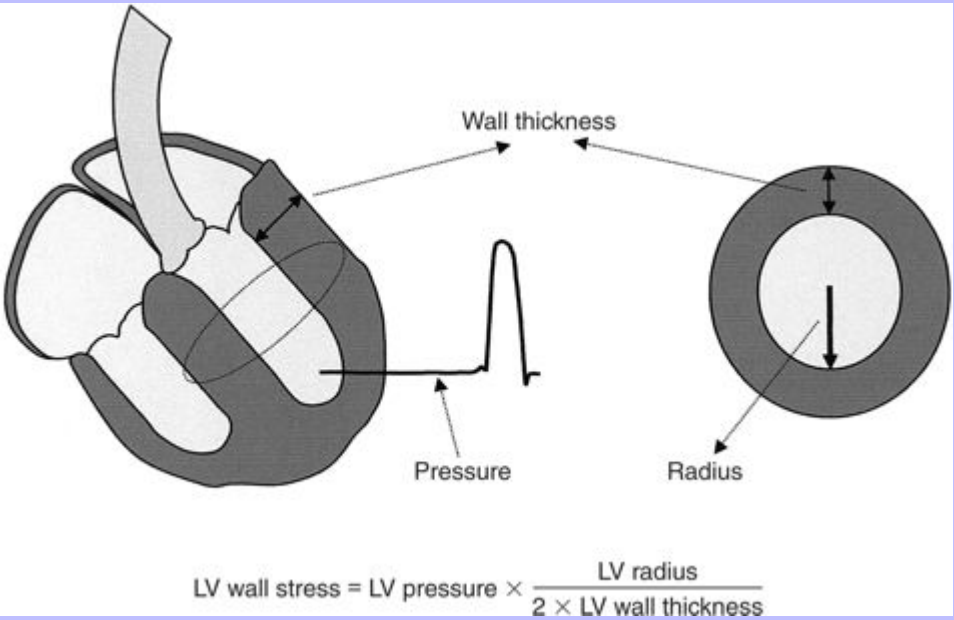
* Many disease are also associated with diastolic dysfunction.

Figure 197-3 Progression from myocardial failure to heart failure.



Myocardium that undergoes hypertrophy secondary to pressure overload is not normal. A close link exists between hypertrophy and systolic dysfunction. The hypertrophied ventricle is also prone to ischemia, which leads to fibrosis and an increase in collagen content. The early increase in collagen helps maintain systolic function, but it interferes with diastolic function. With progression of the myocardial hypertrophy, perimuscular fibrosis impairs both systolic and diastolic function.[1] As secondary myocardial failure settles in, the ventricle again dilates. The sequence of events in heart failure secondary to pressure overload is shown in Figure 197-6.

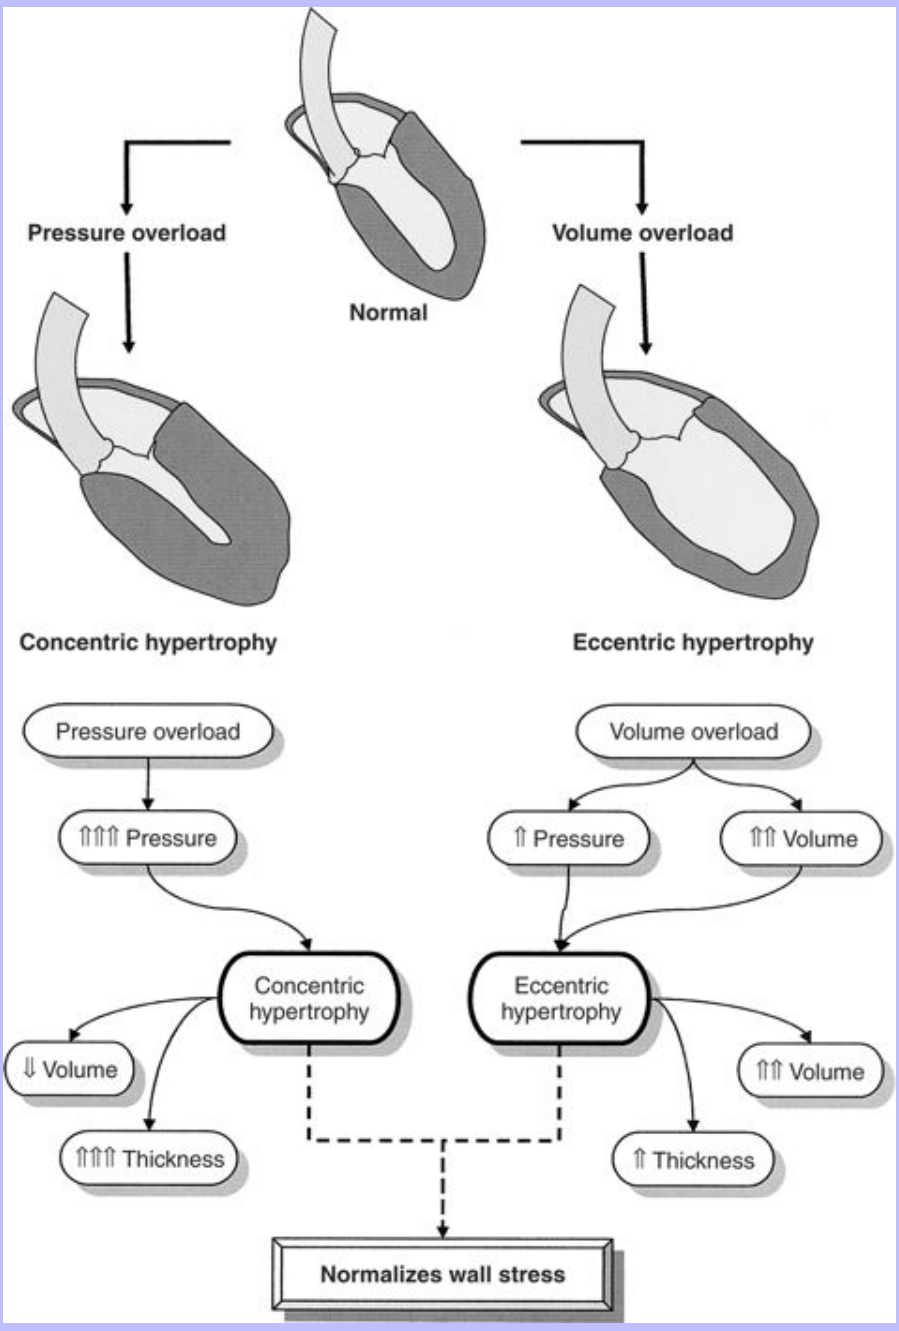
Figure 197-4 Determinants of left ventricular wall stress. *LV*, Left ventricle.



197.2.1.4 Volume Overload

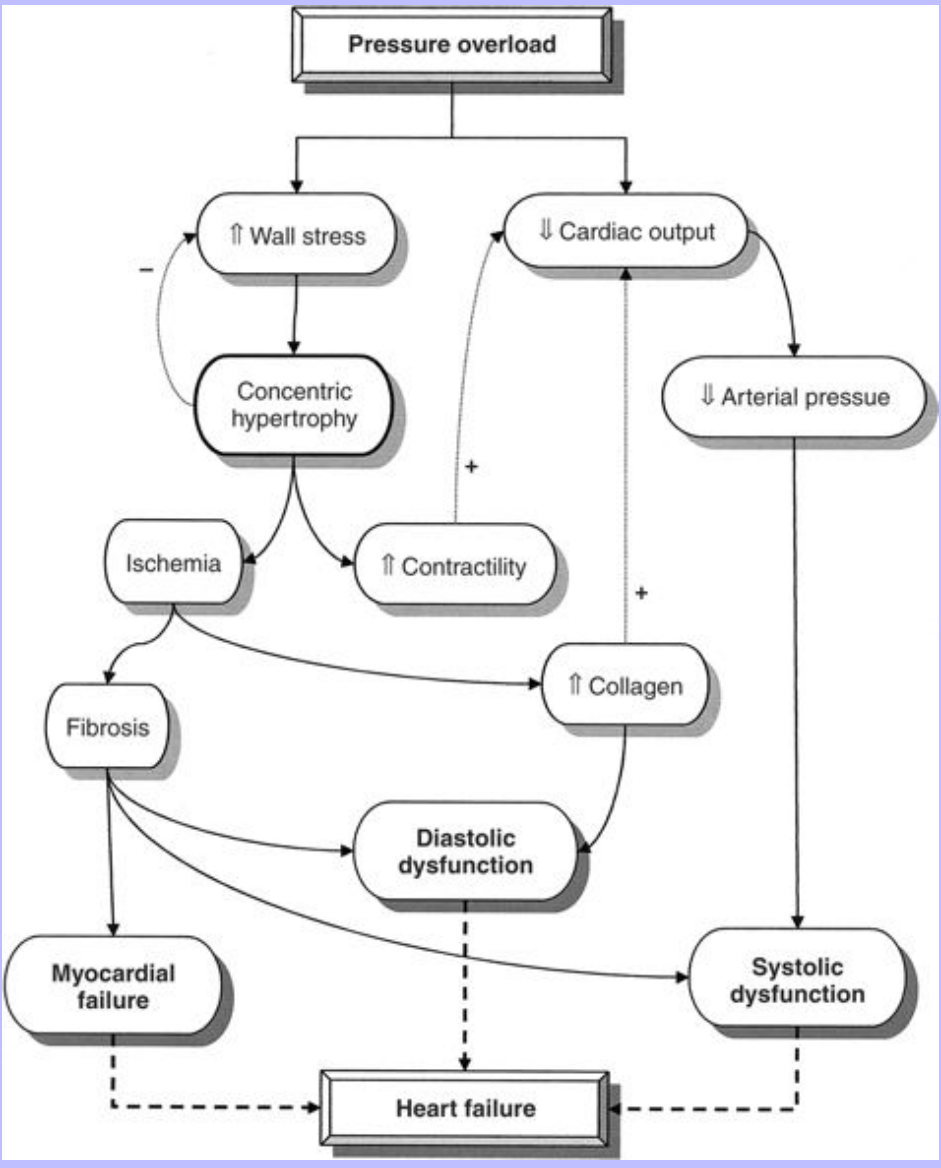
Volume overload may occur with valvular insufficiency, abnormal communications (e.g., patent ductus arteriosus, septal defects), and high-output states (e.g., hyperthyroidism). The initial event, an increase in chamber size, occurs as a result of the need to accommodate a large ventricular end-diastolic volume; this increases the sarcomere length to the optimal 2.2 μm. Again, dilatation leads to an increase in wall stress, which in turn causes ventricular hypertrophy and normalizes wall stress. Volume overload is marked by an eccentric hypertrophy, with a mild increase in wall thickness and an increase in radius (see Figure 197-6). The degree of hypertrophy is not as severe as in pressure overload states because the primary event now is an increase in volume, which causes only a mild increase in ventricular pressure. The performance of each unit of myocardium in a chronically volume-overloaded heart is normal or near normal, allowing a greater than normal stroke volume. The ventricle responds to a volume overload situation by increasing size and also by changing its geometry. Contrary to what happens in the pressure-overloaded myocardium, collagen formation is not a problem in the early stages of volume overload. In fact, a loss of myocardial collagen occurs in volume-overloaded hearts. The loss of collagen causes the ventricle to dilate and increases ventricular compliance. Left ventricular dilatation and increased compliance do not occur in volume-overloaded hearts when collagenase stimulation caused by mast cell degranulation is blocked.[14]

Figure 197-5 Types of ventricular hyper-trophy. Increases in pressure lead to concentric hypertrophy (parallel addition of new sarcomeres), whereas increases in volume lead to eccentric hypertrophy (in-line addition of new sarcomeres).



With progression of the disease, ventricular end-diastolic pressure again rises above the normal range, increasing resting tension and compromising the endocardial perfusion pressure.[15] The increase in tension that occurs in this setting is the result of slippage of fibers, with an excessive increase in chamber size. The mechanism for fiber slippage is poorly understood, but it is probably related to a disruption in normal collagen-myocyte interaction. If collagen fibers fail to support the myocytes, increases in intracavitary pressure may push the myocytes apart by means of fiber slippage.[16] Fiber slippage helps maintain stroke volume by an unknown mechanism, probably by improving diastolic function. The stretched collagen and the longer fiber length act in the diastole in the opposite way that hypertrophied myocardium does, thereby increasing diastolic compliance. Fiber slippage, on the other hand, sets the stage for progressive disease. The increase in chamber size increases wall stress and MVO_2, changes the ventricular geometry, and may cause pressure hypertrophy and fibrosis. Stretch also stimulates the production of tumor necrosis factor alpha (TNF-alpha) in cardiac fibroblasts,[17] increasing protein synthesis and stimulating hypertrophy.[18] With progression of the disease, secondary myocardial failure may ensue, and the ventricle will undergo further dilatation. The sequence of events in heart failure secondary to volume overload is shown in Figure 197-7.

Figure 197-6 Progression from pressure overload to heart failure. Pressure overload states increase wall stress, leading to concentric hypertrophy. Hypertrophy increases contractility and decreases wall stress. Unfortunately, pressure hypertrophy leads to ischemia, fibrosis, and increased collagen formation. The end result is myocardial failure and diastolic dysfunction, leading to heart failure. (–), Decreases wall stress; (+), increases cardiac output.



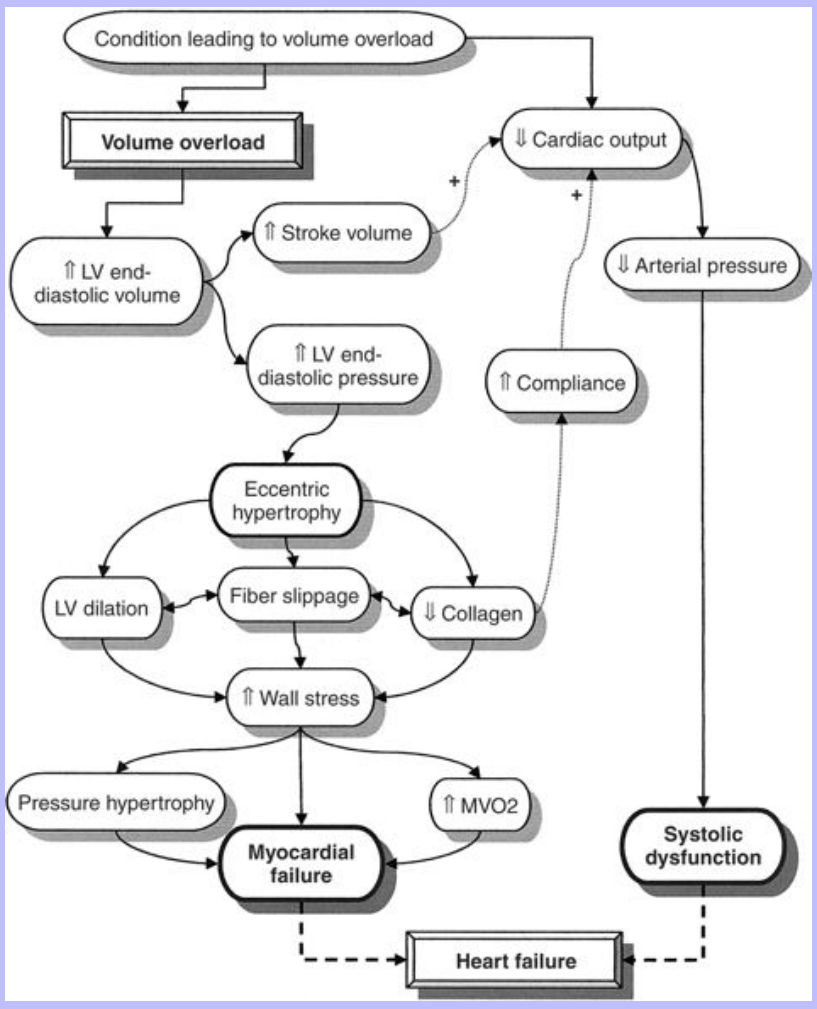
197.2.2 Diastolic Function and Dysfunction

Diastolic dysfunction results from impairment in ventricular filling. Diastolic heart failure exists when pulmonary venous congestion and resultant clinical signs occur in the presence of normal or near normal left ventricular (LV) systolic function.[19] Approximately one third of human patients with heart failure have diastolic failure, another one third have systolic failure, and the remaining one third have impairment of both systolic and diastolic function.[15] Mechanisms that lead to diastolic heart failure are listed in Box 197-3. Diastolic failure may result from abnormal relaxation (early diastole), abnormal compliance (early to late diastole), or external constraint by the pericardium. If diastole is defined as starting at the time of aortic valve closure (there are other definitions), it can be divided into four phases: (1) isovolumic relaxation (aortic valve closure to mitral valve opening); (2) rapid early mitral inflow (or the rapid filling phase, during which most of ventricular filling occurs); (3) diastasis (or the slow filling phase, during which little change occurs in ventricular volume and pressure); and (4) atrial contraction (atrial systole and its contribution to ventricular filling). The second through fourth phases of diastole represent ventricular filling.

Relaxation is a dynamic, energy-dependent process that begins at the end of contraction and lasts throughout isovolumic relaxation and early ventricular filling. Beta-adrenergic stimulation improves relaxation, whereas ischemia, asynchrony of relaxation, an increase in afterload, ventricular hypertrophy, and abnormal calcium fluxes in the myocardial cells delay relaxation. Ventricular *compliance* is the ability of the heart to fill passively, and it is usually measured at the end of diastole, when the heart is relaxed. It is determined by volume, geometry, and the tissue characteristics of the ventricular wall. Compliance is an expression of the distensibility of a fluid-filled organ. The higher the compliance, the lower the pressure at a given volume. Ventricular compliance decreases with increases in filling pressures and intrinsic myocardial stiffness (e.g., infiltrative diseases, fibrosis, ischemia) and with hypertrophy and cardiac tamponade. *Lusitropy*, a measure of the global diastolic performance of the heart, comprises the relaxation and filling phases.[20]

Ventricular filling may be affected by several factors, including the atrioventricular pressure gradient, isovolumic relaxation rate, synchronized atrial kick and ventricular relaxation, and compliance. The driving force for ventricular filling is the pressure gradient between the left atrium and ventricle when the mitral valve opens. This gradient is affected mostly by the intravascular volume and the degree of vasodilatation. The isovolumic relaxation rate is also an important determinant of early ventricular filling. Adrenergic stimulation increases the rate of relaxation, improving relaxation to a greater extent than it improves contractility. This makes evolutionary sense because during faster heart rates, diastole is shortened to a greater extent than is systole. Tachycardia shortens the duration of the diastasis. Incremental increases in the heart rate up to 180 beats/min in dogs progressively increase the rate of relaxation, improve left ventricular contractility, and decrease left ventricular end-diastolic pressure.[21,22] These changes allow increases in early filling when higher heart rates are needed (e.g., during exercise). Patients with ventricular hypertrophy that are ischemic, however, show a decrease in left ventricular distensibility with increases in the heart rate.

Figure 197-7 Progression from volume overload to heart failure. Volume overload states decrease forward stroke volume, leading to systolic dysfunction and an increased end-diastolic volume. The increase in the end-diastolic volume increases the stroke volume but also the end-diastolic pressure, leading to eccentric hypertrophy. Eccentric hypertrophy leads to a decrease in collagen content that helps diastolic function, but it also causes fiber slippage, thereby increasing wall stress and ultimately leading to myocardial failure. Patients with volume-overloaded hearts usually develop congestive heart failure (CHF) secondary to a decrease in forward stroke volume, but in some patients CHF may occur secondary to myocardial failure. (+), Increases cardiac output.



197.2.2.1

Box • 197-3 Mechanisms Leading to Diastolic Heart Failure

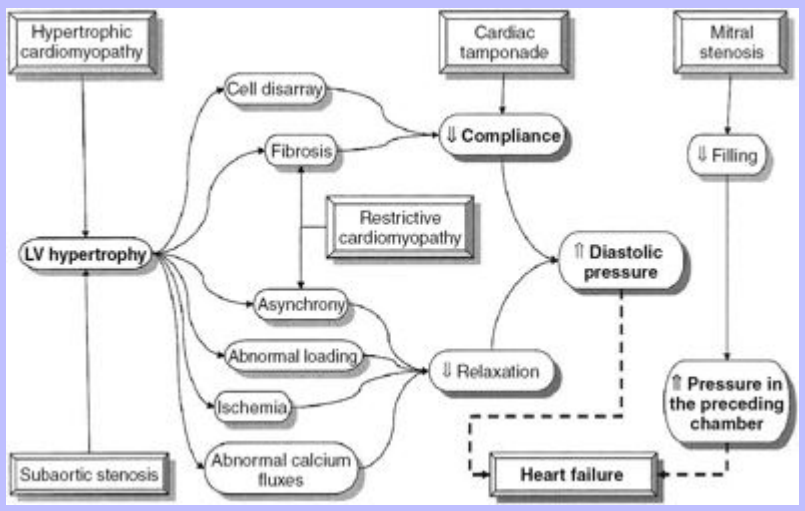
  - Intracardiac neoplasia causing intracardiac obstruction
  - Cor triatriatum
- Pericardial abnormalities
  - Constrictive disease

Cardiac tamponade

Normal diastolic filling also depends on synchronized contraction between the left ventricle and left atrium.[19] Loss of atrial contraction is one reason why dogs with dilated cardiomyopathy or mitral endocardiosis develop heart failure when the atria start to fibrillate. Asynchronous relaxation of the left ventricle may be observed in cats with restrictive cardiomyopathy. A decrease in the uniformity of relaxation reduces ventricular filling and may contribute to development of heart failure in these patients. Left ventricular compliance also affects ventricular filling. Patients with left ventricular hypertrophy have decreased left ventricular compliance and poor diastolic function as a result of the increases in cardiomyocyte size, collagen formation, and wall thickness.[19] The pericardium may also restrict ventricular filling in constrictive pericardial disease or cardiac tamponade. In these situations ventricular filling is abruptly halted in mid-diastole by the abnormal pericardium, which imposes its mechanical properties on those of the ventricle during the final phases of diastole. The mechanisms that lead to the development of congestive heart failure during diastolic dysfunction are shown schematically in Figure 197-8.

920 921

Figure 197-8 Sequence of events leading to diastolic heart failure. Most mechanisms leading to diastolic failure decrease lusitropy by reducing compliance (thus increasing stiffness) or relaxation, or both. Mitral stenosis leads to diastolic heart failure through interference with left ventricular filling.



197.3 HOW DOES THE BODY REACT TO HEART FAILURE?

Many conditions and different heart diseases can progress into heart failure. Regardless of the cause, there is an initial fall in cardiac output that lowers arterial pressure. Clinical signs observed in heart failure are mainly the result of chronic activation of compensatory mechanisms to restore and maintain blood pressure. The cardiovascular system is part of a biologic control system that works in co-operation with the central nervous,

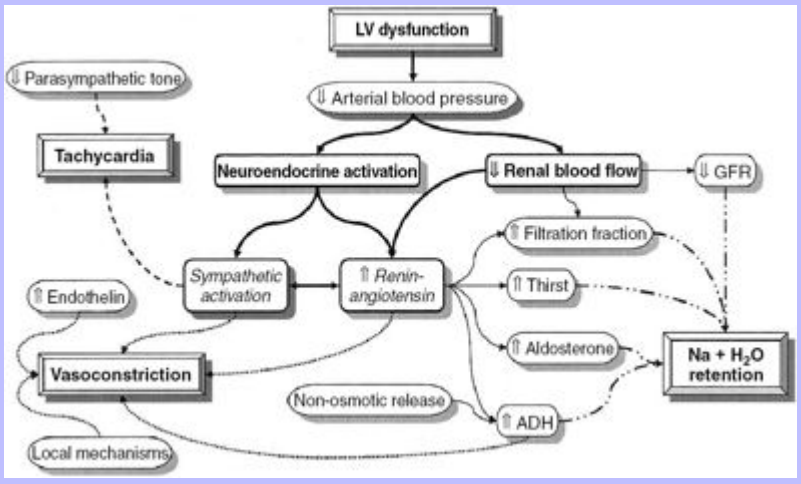
renal, and endocrine systems to keep cardiovascular variables at physiologic levels. Maintenance of arterial blood pressure and effective plasma volume are the main priorities of this integrated system. Changes are sensed by high-pressure baroreceptors in the aortic arch and carotid sinus, by mechanoreceptors in the ventricular myocardium, by volume receptors in the atria and great veins, and by the juxtaglomerular apparatus in the kidneys. During episodes of low blood pressure, a reactive neuroendocrine activation occurs to re-establish normal blood pressure. The immediate response is a decrease in parasympathetic drive and an increase in sympathetic drive, causing vasoconstriction (increasing arterial impedance) and tachycardia (increasing cardiac output). Vagal responses tend to be immediate and short-lived, whereas sympathetic responses are slower but last longer. A decrease in renal blood flow causes the release of renin and activation of the renin-angiotensin-aldosterone system (RAS), contributing to vasoconstriction and causing sodium and water retention, which increases the circulating volume. Compensatory mechanisms are acute responses that evolved to maintain an animal's life during and immediately after an episode of bleeding. During heart failure, however, compensatory mechanisms are chronically activated (Figure 197-9). In an effort to maintain blood pressure, the cardiovascular system allows the venous pressure to increase and redistributes cardiac output, maintaining blood flow mostly to essential organs (Figure 197-10).

Compensation cannot be viewed as an isolated response of the circulation. The heart and the myocardial cells undergo changes to adapt to ventricular dysfunction. A common characteristic of all compensatory responses is that the short-term effects are helpful, but the long-term effects are deleterious. In acute injuries to the heart, cardiac output decreases and acute heart failure may occur; this phase, known as *transient breakdown*, initiates activation of the compensatory mechanisms.[23] In small animals, heart failure is usually a chronic problem, and the transient breakdown phase merges with the following phase. As compensation occurs, cardiac output and clinical signs steadily improve, because the heart and circulation are performing extra work; this compensated phase is known as *stable hyperfunction*. Chronic hyperfunction leads to progression of left ventricular dysfunction, myocardial cell death, the development of clinical signs, and death, the *exhaustion and progressive cardiosclerosis* phase. The chronic effects of the compensatory mechanisms that lead to progression of left ventricular dysfunction are shown in Figure 197-11.

197.3.1 Neuroendocrine Activation

Neuroendocrine activation in CHF is a result of the decrease in cardiac output and atrial hypertension. Neuroendocrine mechanisms include vasoconstrictive/sodium-retaining systems and vasodilator/natriuretic systems (Box 197-4). All neuroendocrine mechanisms are operating fully during severe CHF. The exact point at which each neuroendocrine mechanism is activated is the subject of debate. In a tachycardia-induced heart failure model, increases in neurohormones were detected within 3 weeks of pacing at 180 beats/min during early myocardial dysfunction, when the animals were still asymptomatic.[24] Clinical data are still lacking in small animals with naturally occurring CHF. The underlying cause of the ventricular dysfunction appears to play a role in the determination of when activation of a particular neuroendocrine mechanism starts. The net effect of neuroendocrine activation is vasoconstriction, sodium and water retention, and LV hypertrophy, leading to ventricular and peripheral vessel remodeling.

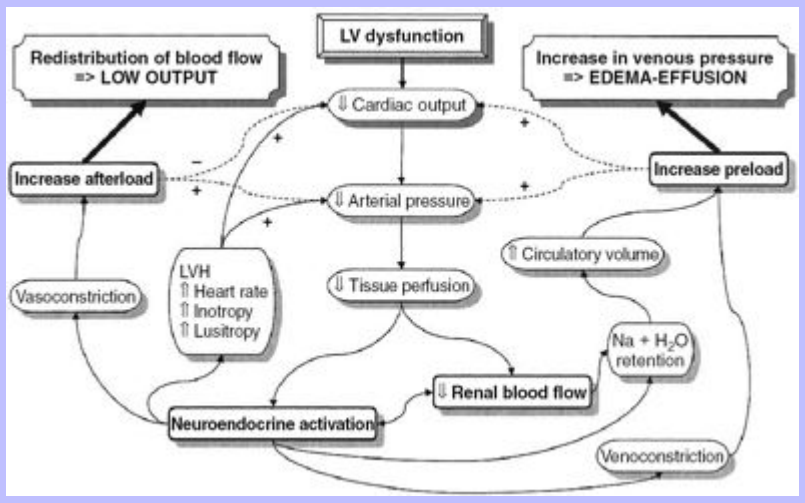
Figure 197-9 Compensation in congestive heart failure. Left ventricular (LV) dysfunction decreases cardiac output and arterial blood pressure. The decrease in renal blood flow and concomitant neuroendocrine activation set in motion compensatory mechanisms designed to restore blood pressure: sodium and water retention *(dash-and-dot line)*; vasoconstriction *(dotted line)*; and tachycardia *(dashed line)*. *ADH*, Vasopressin; *GFR*, glomerular filtration rate.



197.3.1.1 Autonomic Nervous System

CHF is accompanied by a generalized increase in sympathetic nerve activity and attenuation of parasympathetic tone. Dogs with naturally occurring CHF caused by dilated cardiomyopathy and mitral regurgitation have increased nor-epinephrine concentrations, a finding that correlates positively with the clinical severity of the CHF.[25] The increase in nor-epinephrine, however, does not correlate with the degree of myocardial dysfunction.[25,26] The norepinephrine concentration correlates with cardiac death in human patients with CHF. Increased release of norepinephrine from adrenergic endings and its "spillover" into plasma, as well as decreased uptake by adrenergic nerve endings, are responsible for the observed increase in the norepinephrine concentration during CHF. The decrease in left ventricular function leads to relative hypotension, which stimulates the baroreceptors to activate the sympathetic nervous system.[27] However, the precise mechanisms responsible for the persistent sympathetic overactivity and blunted baroreflex control seen in CHF remain obscure and cannot be explained solely by chronic withdrawal of baroreflex inhibition.[28] Augmented peripheral chemosensitivity also has been demonstrated in CHF.[29] A link between increased peripheral chemosensitivity and impaired autonomic control, including baroreflex inhibition, has been demonstrated in human patients with CHF.[30] Overactivity of muscle metaboreceptors (ergoreceptors) may also contribute to the autonomic imbalance,[31] because ergoreflexes from the ailing skeletal muscle may further promote adrenergic and RAS activation.[32]

Figure 197-10 Compensation and clinical signs of congestive heart failure. The compensatory mechanisms activated to restore arterial blood pressure during heart failure are ultimately responsible for the clinical signs of the disorder. Retention of sodium and water leads to the formation of edema and effusions, and an increased afterload decreases cardiac output. (+), Increases arterial pressure or cardiac output; (–), decreases cardiac output; *ADH,* vasopressin; *LV,* left ventricle; *LVH,* left ventricular hypertrophy.



Despite the increase in the plasma concentration of norepinephrine, patients with CHF have depletion of nor-epinephrine from the atria and ventricles, which blunts the response to sympathetic activation. Increased levels of norepinephrine in the vicinity of beta adrenoreceptors leads to downregulation of these receptors. Downregulation of beta adrenoreceptors occurs in patients with severe cardiomyopathy and correlates with the severity of the heart disease. In normal hearts, the ratio of $beta_1$ to $beta_2$ receptors is approximately 80:20, whereas in failing hearts, it approaches 60:40.[33] In patients with dilated cardiomyopathy, downregulation is consistently shown in $beta_1$ adrenoreceptors but not in $beta_2$ adrenoreceptors, whereas in mitral disease and in ischemic cardiomyopathy, both subsets of beta adrenoreceptors are downregulated. The selective downregulation of $beta_1$ adrenoreceptors may occur because myocardial $beta_1$ adrenoreceptors are innervated and therefore are exposed to the increased norepinephrine released from the nerve endings, whereas myocardial $beta_2$ adrenoreceptors are not innervated. Postadrenoreceptor changes in the beta adrenoreceptor–adenylate cyclase complex can contribute to changes in adrenergic responsiveness.

Figure 197-11 Compensation process and progression of left ventricular dysfunction. The compensatory mechanisms activated to restore arterial blood pressure during heart failure are ultimately responsible for progression of the disease. Increased afterload and increased cardiac activity increase myocardial oxygen consumption (MVO_2); left ventricular (LV) hypertrophy is associated with fibrosis. (+), Causes further left ventricular dysfunction.

* $Beta_2$-adrenergic stimulation causes vasodilatation and may be antiapoptotic and cardioprotective.

The increase in sympathetic activity is partly responsible for the vasoconstriction and sodium and water retention, whereas the decrease in norepinephrine stores and the changes in adrenoreceptors lead to a decrease in the contractile response of the myocardial cells and in the chronotropic response of the sinoatrial node cells during exercise. Chronic adrenergic stimulation also leads to increases in afterload and MVO_2, as well as to ventricular arrhythmias, and it favors progression of left ventricular dysfunction (Figure 197-12). Remodeling of the heart and peripheral vessels, also stimulated by chronic sympathetic activation, further favors progression of left ventricular dysfunction. It is interesting to note that $beta_2$-adrenergic stimulation leads to vasodilatation and may be antiapoptotic and cardioprotective.[32]

Baroreflex control is altered during CHF, a circumstance that is partly responsible for the increased sympathetic activity and the blunted tachycardic response during exercise or hypotension. Abnormal baroreflexes also contribute to sodium and water retention. Normally, increases in atrial pressure stimulate atrial stretch receptors, inhibiting the release of antidiuretic hormone (ADH), decreasing sympathetic activity, and increasing renal blood flow and the glomerular filtration rate. During CHF atrial and arterial receptors show a decreased response to stimulation, and baroreceptor function is impaired. The mechanisms are not clear but appear to be related to increases in sodium-potassium adenosine triphosphatase (Na^+-K^+ATPase) activity in the baroreceptors. The decrease in parasympathetic activity in CHF decreases the restraint of the sinoatrial (SA) node. The net result is a higher heart rate for a given arterial pressure and a decrease in heart rate variability. Decreases in heart rate variability have been observed in dogs with naturally occurring[34] and experimentally induced [35,36] heart failure (Figure 197-13). Impairment of the heart rate response to postural changes is an early finding in experimental heart failure progression in dogs,[37] which suggests that parasympathetic activity is reduced in the initial phases of heart failure (Figure 197-14). A decrease in parasympathetic tone in CHF carries a poor prognosis.

197.3.1.2 Renin-Angiotensin-Aldosterone System

Low cardiac output during CHF stimulates renin release through direct beta adrenoreceptor stimulation and a decrease in renal flow in the juxtaglomerular apparatus of the kidneys. Renin increases angiotension II concentration. An array of effects of angiotensin II initially brings the blood pressure toward the normal range, but perpetuation of its effects leads to a vicious cycle that contributes to further declines in ventricular function. Angiotensin II is a potent vasoconstrictor. Vasoconstriction increases arteriolar resistance, which helps to normalize blood pressure but also increases afterload. The higher afterload increases MVO_2 and negatively affects cardiac output. On the venous side, angiotensin-induced venoconstriction decreases venous capacity, increasing venous return to the heart and cardiac output. Angiotensin II also stimulates the release of ADH and aldosterone. ADH causes vasoconstriction and stimulates water resorption in the renal distal tubules, whereas aldosterone causes sodium and water retention and contributes to baroreceptor dysfunction. Aldosterone increases total body water and may contribute to increased tissue water content, increasing stiffness and decreasing compliance of the arterial system.[38] Aldosterone also increases potassium and magnesium excretion. Even in the absence of a low serum magnesium level, aldosterone decreases the cytosolic magnesium concentration by decreasing $alpha_1$ antiproteinase activity, a marker of oxidative stress.[39] Increases in plasma aldosterone are associated with an inflammatory response with evidence of oxidative stress and may lead to intramural coronary artery remodeling and fibrosis.[39] Angiotensin II also enhances sympathetic activity, constricts the efferent renal artery, and stimulates thirst.[38] Thus activation of the RAS contributes to vasoconstriction with sodium and water retention during CHF. Sympathetic activation usually precedes RAS activation, although some of the sympathetic activation during CHF is caused by the increased activity of the RAS.

Figure 197-12 Beneficial and detrimental effects of sympathetic activation. Short-term sympathetic effects are beneficial, whereas chronic activation favors progression of left ventricular dysfunction. Dashed lines indicate long-term effects. (+), Causes further left ventricular dysfunction; *CO,* cardiac output; *ABP,* arterial blood pressure; *HR,* heart rate; *AL,* afterload; *NE,* norepinephrine; *Imp,* arterial impedance; *PL,* preload.

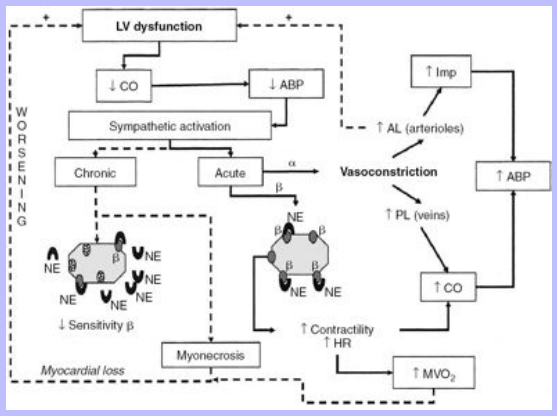

Figure 197-13 Heart rate variability over 1 minute in a dog before and after induction of progressive congestive heart failure. Heart rate variability is shown over time *(x axis)* as heart rate *(y axis)* fluctuation above and below the mean heart rate per minute *(horizontal line)*. With progression of the disease, the heart rate increases and heart rate variability decreases. (From Schwatrz DS: *Studies on baroreceptor function in dogs*, doctoral dissertation, Columbus, Ohio, 2000, Ohio State University.)

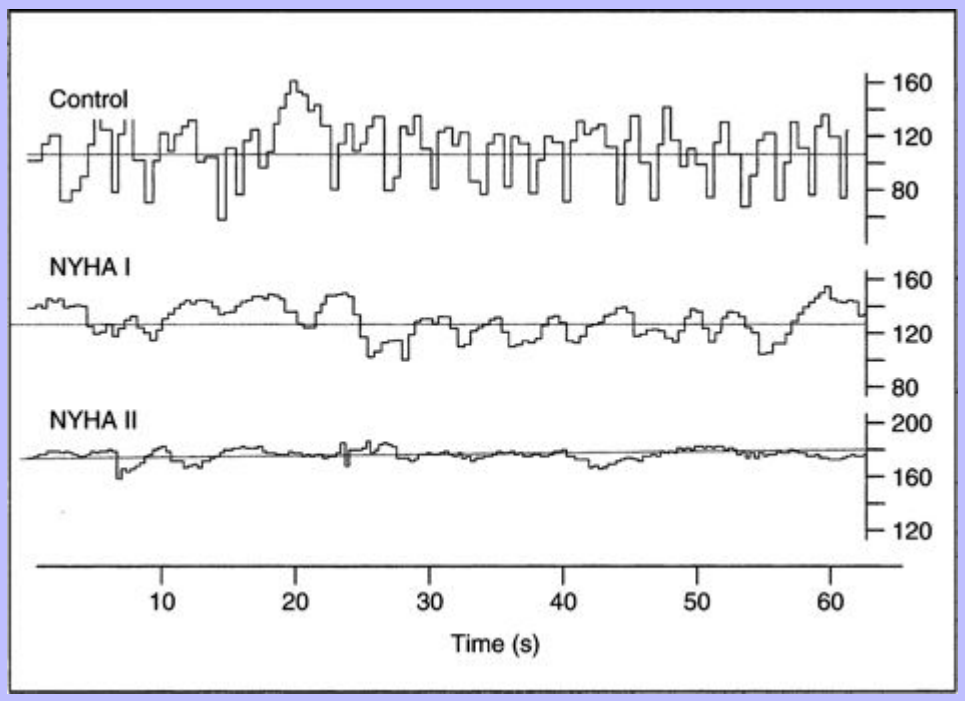

Figure 197-14 Lack of heart rate response to postural change (active head-up tilt, HU) in a dog with rapid pacing-induced heart failure (New York Heart Association [NYHA] class II) *(lower figure)*. Note that before induction of heart failure *(baseline)*, a rapid increase in the heart rate and large heart rate variability immediately after postural change are seen. (From Schwatrz DS: *Studies on baroreceptor function in dogs*, doctoral dissertation, Columbus, Ohio, 2000, Ohio State University.)

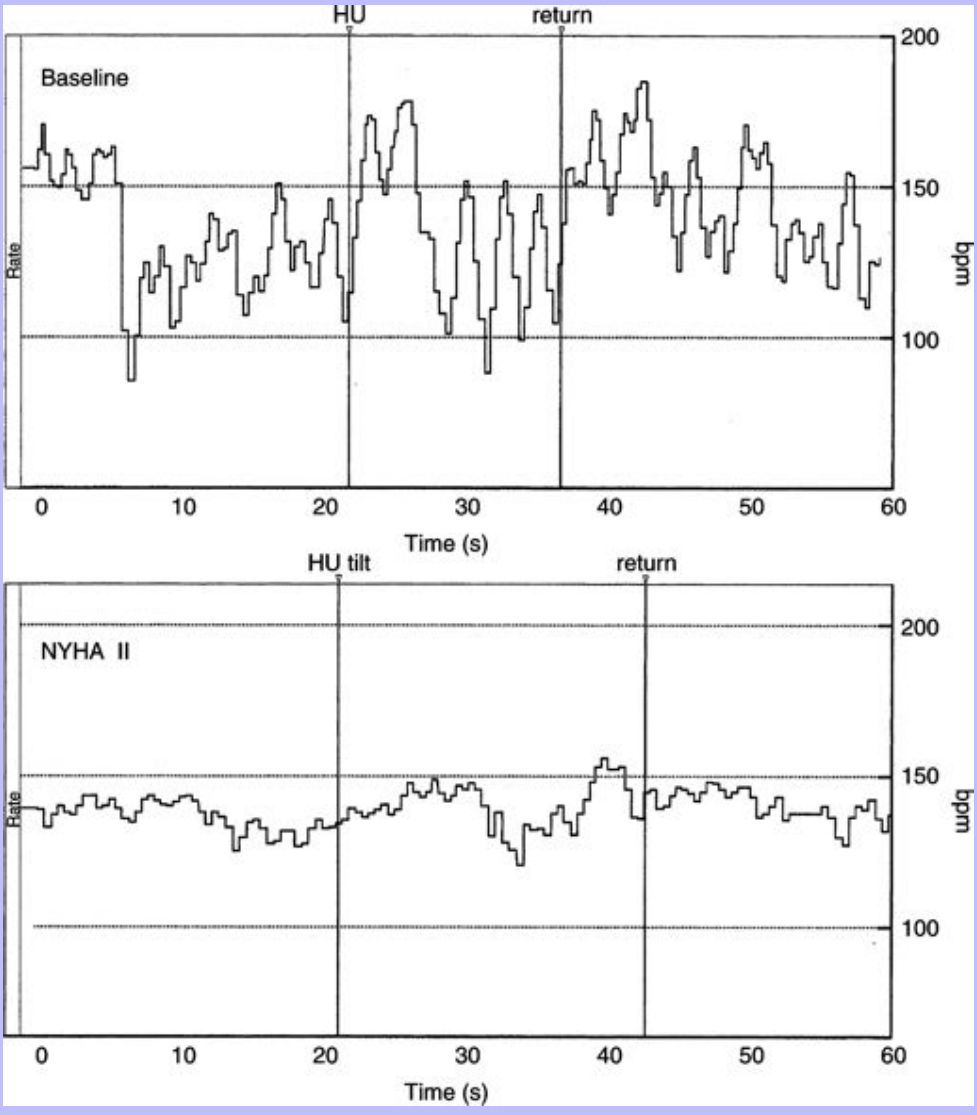


Angiotensin II stimulates growth factors, promoting remodeling in the vessels and myocardium. It may also stimulate vessel remodeling by reducing nitric oxide synthesis or by increasing local angiotensin-converting enzyme (ACE) breakdown of bradykinin. Vascular remodeling causes structural changes that further decrease the compliance of the arterial system. Angiotensin II stimulates smooth muscle cell growth, leading to cellular hyperplasia, hypertrophy, and apoptosis (programmed cell death).[38] An increased level of angiotensin II is associated with superoxide formation (oxidative stress), endothelin secretion, plasminogen activation, TNF-alpha production (inflammation), fibroblast hypertrophy, and increased production of collagen. The final result is myocyte and vascular wall fibrosis. Angiotensin II plays a key role in the development of pathologic hypertrophy, exerting cytotoxic effects on the myocardium, causing myocyte necrosis, and contributing to myocardial loss.[40] Stimulation of angiotensin receptors (AT_1) is responsible for altered gene expression and gene reprogramming of cardiac myocytes and fibroblasts, leading to increases in skeletal alpha actin, atrial natriuretic peptide, and beta myosin heavy chain, as well as increases in fibronectin, impairing diastolic and systolic function.[40] The beneficial and detrimental effects of angiotensin II during heart failure are presented in Figure 197-15.

Activation of the RAS contributes to vasoconstriction, increasing afterload and MVO_2 and causing the kidneys to retain sodium and water. Remodeling of the heart and peripheral vessels is also stimulated by the RAAS, conditions that favor progression of left ventricular dysfunction. Angiotensin II induces cardiac myocyte necrosis associated with increased apoptosis and contributes to myocardial loss, perpetuating the progression of left ventricular dysfunction.

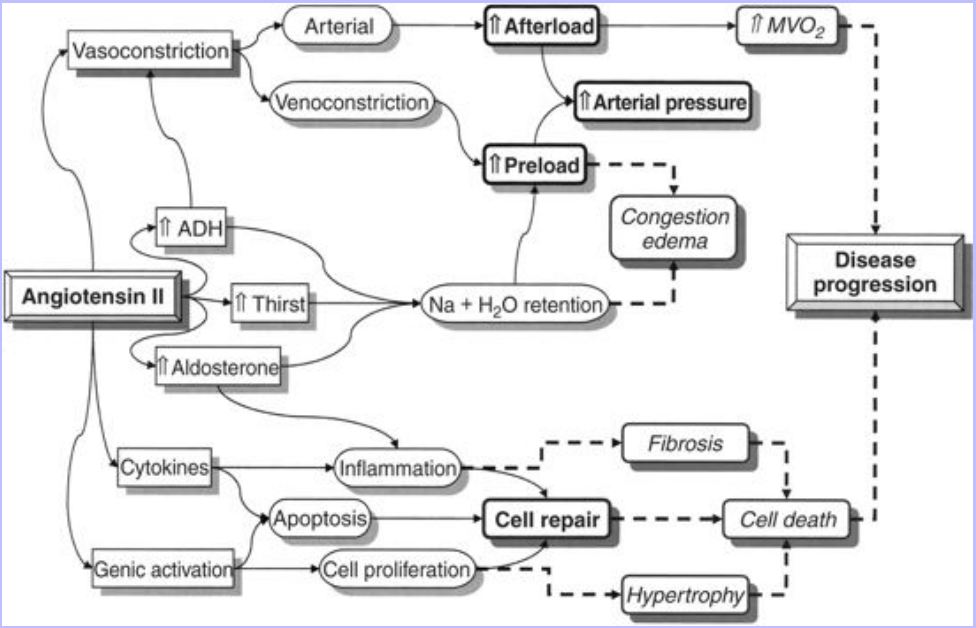
197.3.1.3 Other Vasoconstrictive Agents

ADH levels are increased in patients with heart failure as a result of nonosmotic release, impairment in baroreceptor-mediated inhibition of brain stem centers, and an increase in circulating angiotensin II. ADH synthesis is substantially and chronically elevated in patients with heart failure despite the volume overload and reductions in plasma osmolality often observed in these patients. ADH levels may be increased even in patients with asymptomatic left ventricular dysfunction. The release of ADH leads to vasoconstriction and water resorption and favors the development of hyponatremia. ADH also appears to affect hemodynamics and cardiac remodeling adversely while potentiating the effects of norepinephrine and angiotensin II. Chronic ADH receptor blockade did not attenuate ventricular remodeling in at least one model of left ventricular dysfunction.[41] ADH, therefore, may not play a major role in the structural progression of heart failure.

Endothelin is the most potent vasoconstrictor known for vascular smooth muscle cells. It is elevated in a canine pacing model of heart failure, and the increase correlates well with the right atrial or pulmonary capillary wedge pressure.[42] The increase in endothelin during heart failure is likely due to increased production and not decreased clearance.[43] It has been shown that cardiac overexpression of endothelin-1 (ET-1) is sufficient to increase inflammatory cytokines and cause an inflammatory cardiomyopathy that leads to heart failure and death.[44] Activation of myocardial and plasma ET-1 precedes activation of myocardial and plasma RAS in a canine model of CHF,[45] but angiotensin II further increases the ET-1 concentration. Endothelin plays an important role in the maintenance of blood pressure and blood flow during CHF.[46] Chronic blockage of endothelin receptors may prevent the progression of experimental heart failure in dogs,[47] and an endothelin-converting enzyme prevented vascular remodeling during experimental

heart failure.[48] Unfortunately, clinical trials with chronic ET-receptor antagonism showed worsening of CHF symptoms.

Figure 197-15 Beneficial *(bold)* and detrimental *(italics)* effects of angiotensin II during heart failure. The short-term effects of angiotensin II are beneficial, whereas chronic activation favors the appearance of clinical signs and progression of left ventricular dysfunction. Angiotensin II also participates in sympathetic activation. Dashed lines indicate long-term effects.



197.3.1.4 Vasodilatory Agents

The natriuretic peptides are counter-regulatory hormones involved in volume homeostasis and cardiovascular remodeling. They consist of atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), dendroaspis natriuretic peptides (DNP), and urodilatin. The natriuretic peptides promote natriuresis, diuresis, peripheral vasodilatation, and inhibition of the RAS. ANP and BNP are elevated in patients with left ventricular dysfunction; the serum levels correlate with the severity of heart failure and appear to have prognostic value.[49] ANP is stored in the right atrium and released by increases in atrial distending pressures. This peptide causes arterial dilatation, venodilatation, natriuresis, and water diuresis, counteracting the effects of vasoconstrictory agents. It also inhibits renin and aldosterone secretion and reduces sympathetic vasoconstriction.[50] BNP is stored in the ventricular myocardium and also causes vasodilatation and natriuresis. Congestive heart failure is associated with an increase in ANP, and the changes are related to the fall in the ejection fraction and the increase in cardiac filling pressures. Despite the natriuretic peptides' beneficial effects during CHF, their release is over-ridden by the release of agents that cause vasoconstriction and sodium and water retention.

Nitric oxide (NO) is the major physiologic regulator of basal blood vessel tone. NO is produced by virtually all cell types that make up the myocardium, and it regulates cardiac function through both vascular-dependent and vascular-independent effects. Vascular-dependent factors include regulation of coronary vessel tone, thrombogenicity, and proliferative and inflammatory properties, and the cellular cross-talk that supports angiogenesis. Vascular-independent factors constitute the direct effects of NO on several aspects of cardiomyocyte contractility, from the fine regulation of excitation-contraction coupling to modulation of autonomic signaling and mitochondrial respiration.[51] NO also plays a very important role in the maintenance of cardiac architecture and the prevention of pathologic hypertrophy. A dissociation of stimulated and basal release of NO appears to exist in patients with heart failure. The stimulated, endothelial-dependent dilatation exerted by acetylcholine in peripheral resistance vessels is blunted during heart failure, which suggests a reduced release of NO on stimulation. This defective mechanism may be involved in the impaired vasodilator capacity in the peripheral circulation (e.g., during exercise).[52] In contrast, basal release of NO from the endothelium of resistance vessels appears to be preserved and may even be enhanced; also, it may play an important compensatory role in CHF during resting conditions by antagonizing neuroendocrine vasoconstrictive forces.[52]

197.3.2 Peripheral Compensation

Peripheral compensation occurs outside the heart and is directed at normalization of the arterial blood pressure. The main mechanisms involved in peripheral compensation are vasoconstriction in addition to sodium and water retention (see Table 197-1).

197.3.2.1 Blood Vessels and Vasoconstriction

The mechanism responsible for the increased tone of the vascular smooth muscle in CHF is multifactorial but basically results from neuroendocrine activation and the interplay of local mechanisms. Decreased blood flow to muscles causes overactivity of muscle metaboreceptors (afferents sensitive to skeletal muscle work) and peripheral chemoreceptors, which contributes to the autonomic imbalance. An increase in efferent sympathetic neuron discharge causes vasoconstriction. Dogs with paced-induced CHF show an increase in aortic stiffness (characteristic impedance) and a decrease in the compliance of large arteries before vasoconstriction of the small arterioles (increase in peripheral resistance).[53] Sympathetic activation occurs even in patients with asymptomatic left ventricular dysfunction. Further increases in plasma norepinephrine appear to occur in these patients when signs of heart failure develop. The RAS is activated by the decrease in cardiac output, further increasing vascular tone as a direct effect of angiotensin II and indirectly through the facilitative effect of angiotensin II in the alpha-adrenergic neurons. Unlike the sympathetic system, the RAS normalizes as compensation returns cardiac output to normal. Whether dogs with asymptomatic mitral regurgitation or left ventricular dysfunction show activation of the RAS is still the subject of debate.[54–57] ADH may be increased even in patients with asymptomatic left ventricular dysfunction, and this contributes to the increase in peripheral vascular resistance in patients with heart failure.

926 927 927 928

Table • 197-1 Peripheral Compensatory Mechanisms in Heart Failure

RESPONSE	MECHANISM	POTENTIAL BENEFIT	POTENTIAL HARM	MANIFESTATIONS	CORRELATES
Sympathetic activation	Decrease in arterial pressure; RAS activation	Inotropic support, tachycardia, RAS activation, vasoconstriction, venoconstriction	Increased MVO_2 and afterload, sympathetic desensitization, excessive preload	Tachycardia, arrhythmias, pale mucous membranes	Norepinephrine concentration correlates with mortality. Beta-adrenoreceptor blockade may improve survival time.
Vasoconstriction	Sympathetic and RAS activation, increase in ADH, local blood vessel mechanisms	Maintenance of arterial pressure and perfusion of "essential" organs	Increased MVO_2 and afterload, stimulation of LVH, decreased cardiac output, redirection of blood flow	Pale mucous membranes	Modulation of excessive arterial tone with vasodila-tors is beneficial during heart failure.
Activation of renin-angiotensin system	Sympathetic activation, decreased renal perfusion	Vasoconstriction, stimulation of thirst, release of ADH and aldosterone, increased sympathetic tone	Increased MVO_2 and afterload, stimulation of LVH and blood vessel remodeling, decreased cardiac output and tissue perfusion, potentiation of mitral regurgitation	Pale mucous membranes	Angiotensin-converting enzyme (ACE) blockade increases survival time in patients with heart failure
Sodium and water retention	Poor renal perfusion, increases in thirst, ADH, and aldosterone	Increased preload, improved LV function	Congestion; excessive preload, which increases wall stress; hypokalemia (aldosterone)	Edema and cavitary effusions, arrhythmias (hypokalemia)	Use of diuretics in CHF decreases sodium and water retention. Aldosterone inhibition reduces risk of hypokalemia. Aldosterone receptor blockade may improve survival time.
Venoconstriction	Sympathetic activation	Increased preload and ventricular function	Congestion; excessive preload, which increases wall stress	Edema and cavitary effusions, venous distention	Venodilators and nitrates can be used in the treatment of heart failure.

ADH, Antidiuretic hormone (vasopressin); *CHF,* congestive heart failure; *LV,* left ventricle; *LVH,* left ventricular hypertrophy; *MVO2,* myocardial oxygen consumption; *RAS,*, renin-angiotensin system.

Local vasoregulatory mechanisms are very important in the modulation of vascular tone during heart failure. In normal dogs, shear stress caused by pulsatile flow prompts the release of NO and prostacyclin and inhibits ET-1, leading to vasodilatation. During CHF, decreased shear stress secondary to decreased peripheral blood

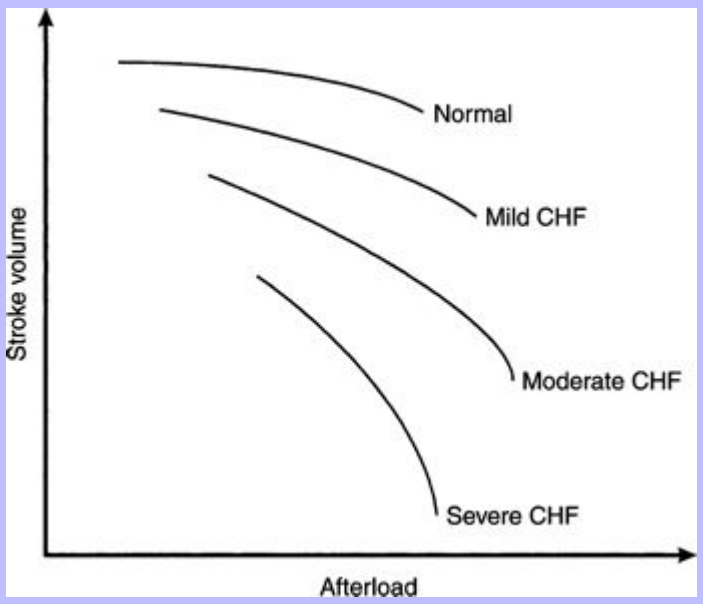
flow and neuroendocrine activation reduces the release of NO and increases ET-1, leading to vasoconstriction.[58] Endothelin is a potent vasoconstrictor that is overexpressed during CHF.

Vasoconstriction is primarily mediated by increased sympathetic tone, RAS activation, and an increased ET-1 concentration.[46,59] ADH becomes an important vasoconstrictive agent only in hyponatremic patients.[59] These mechanisms also lead to venoconstriction, which increases venous pressure and venous return to the heart. Vasoconstriction helps maintain arterial pressure, but the increase in afterload reduces the stroke volume. Failing ventricles are afterload dependent, and the stroke volume falls with any increase in afterload (Figure 197-16). When cardiac output is low, the cardiovascular system redistributes the cardiac output, reducing blood perfusion to "less essential" organs. Increases in afterload also increase MVO_2 by increasing wall stress. In patients with severe mitral regurgitation, the increase in opposition to ventricular ejection increases regurgitation; in patients with a left-to-right shunt, it increases the shunting fraction.

197.3.2.2 Skeletal Muscles

Left ventricular dysfunction leads to a decrease in blood flow to the periphery, causing vasomotor changes and muscle alterations. Mechanisms unrelated to the decrease in blood flow (e.g., decrease in activity, increase in catabolic factors, insulin resistance) also may play a role in muscle changes during CHF. Patients with CHF have substantial skeletal muscle atrophy, and the degree of atrophy correlates with muscle strength and peak oxygen consumption.[60] Skeletal muscles are morphologically and metabolically abnormal in CHF. Muscle apoptosis is observed in a high percentage of heart failure patients but not in normal subjects. The presence of collagen, indicative of fibrosis, is also detected in some heart failure patients and is more pronounced in those with cachexia.[61] Atrophy; changes in muscle fiber type and the mitochondrial ultrastructure; and a decrease in oxidative enzymatic capacity, leading to an increased reliance on anaerobic metabolism and lactate production, all have been demonstrated in patients with CHF. An increase in lactate during exercise stimulates peripheral metaboreceptors (or serves as a marker for the presence of other stimulants). Patients with CHF, therefore, have a higher metaboreceptor stimulation for a given degree of exercise than normal subjects.[28,60] Metaboreceptor stimulation increases sympathetic outflow, which adds to vasoconstriction and reduces blood flow to exercising muscles, because alpha adrenergic–mediated vasoconstriction is not impaired during CHF. In patients with mild heart failure, exercise limitation correlates well with central hemodynamic factors (e.g., cardiac output), whereas in advanced heart failure, peripheral hemodynamic factors become more important (e.g., local blood flow, vascular resistance, and venous tone).[62]

Figure 197-16 Effects of increasing afterload in left ventricular stroke volume in normal animals and in patients with congestive heart failure.



197.3.2.3 Kidneys and Sodium and Water Retention

Several mechanisms are responsible for sodium and water retention in CHF. Competing vasodilator/natriuretic and vasoconstrictive/sodium-retaining mechanisms operate. A decrease in cardiac output decreases renal blood flow and increases sympathetic drive, which causes renal vasoconstriction and further decreases in renal blood flow. Renin is released through activation of the juxtaglomerular apparatus by beta-adrenoreceptor stimulation and decreases in renal blood flow. The end result of renin release is an increase in angiotensin II and aldosterone. Angiotensin II stimulates thirst and release of ADH, leading to water retention. Aldosterone causes sodium and water retention and potassium wasting by the kidneys. Decreases in renal perfusion are countered by the release of prostaglandin E, which dilates the afferent renal arteriole and constricts the efferent renal arteriole, a response mediated by angiotensin II. These alterations combine to increase the glomerular filtration pressure and the filtration fraction (the ratio of glomerular filtration to renal plasma flow) and to maintain the glomerular filtration rate despite the reduction in renal blood flow. Sodium and water retention increases the circulating volume and preload, helping to maintain cardiac filling pressures and increasing cardiac output. Retention of sodium and water, however, leads to an excessive increase in the venous filling pressure, resulting in the development of edema and cavitary effusions. It also increases afterload and favors progression of left ventricular dysfunction.

197.3.3 Central Compensation (the Heart)

The heart participates actively in the compensation for the decrease in cardiac output. Sympathetic activation leads to an increase in the heart rate, inotropy, and lusitropy, all of which increase cardiac output. In addition,

hypertrophy helps normalize cardiac output by increasing the stroke volume. Compensatory mechanisms that act on the heart are shown in Table 197-2.

197.3.3.1 Tachycardia

During heart failure, sympathetic tone increases (increasing the heart rate) and parasympathetic tone decreases, a combination that leads to tachycardia. It is usually believed that sinus rates above 160 beats/min imply not only parasympathetic withdrawal but also sympathetic activation. The end result is an increase in the heart rate and a decrease in heart rate variability. The increase in the heart rate helps normalize arterial pressure, but at a high price: an increase in MVO_2. A decrease in heart rate variability is a negative prognostic factor for overall mortality in human patients with myocardial infarct. In dogs with chronic mitral valve disease, a decrease in heart rate variability correlates with the severity of congestive heart failure.[34] Patients with decreased heart rate variability are also less likely to respond to vasodilator infusion. The increase in the heart rate in patients with heart failure parallels sympathetic activation, which in turn correlates with the severity of the heart failure.

928

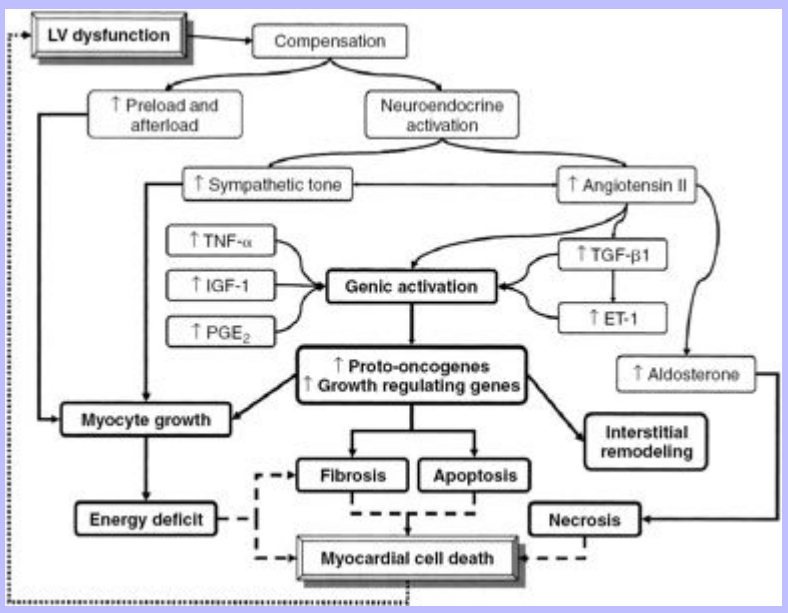
930

Table • 197-2 Central (Cardiac) Compensatory Mechanisms in Heart Failure

RESPONSE	MECHANISM	POTENTIAL BENEFIT	POTENTIAL HARM	MANIFESTATIONS	CORRELATES
Sympathetic desensitization	Downregulation of $beta_1$ adrenoreceptors, uncoupling of $beta_2$ adrenoreceptors, depletion of myocardial norepinephrine	Energy sparing	Decreased contractility	Low-output signs (e.g., depression, lethargy, hypotension)	Beta-adrenoreceptor blockade may reverse sympathetic desensitization.
Tachycardia	Sympathetic activation, parasympathetic withdrawal	Increased cardiac output	Increased MVO_2	Tachycardia, decreased heart rate variability	Decrease in heart rate variability correlates with mortality. Increase in heart rate correlates with sympathetic activation and severity of CHF.
Increased inotropy	Sympathetic activation	Increased stroke volume	Increased MVO_2	—	—
Increased relaxation	Sympathetic activation	Improved diastolic function (lusitropy)	Increased MVO_2	—	—
Appearance of slow myosin in the atria	Changes in isogene expression	Decreased cost to achieve normal tension, energy sparing, increased atrial kick	Atrial failure	—	Changes do not occur in the ventricles of dogs and cats.
Reduced myocardial ATPase activity	Unknown (altered isoenzymes?)	Facilitation of high-pressure, low-speed work; energy sparing	Slowed contraction rate, decreased contractility	Low-output signs	Myocardial ATPase activity is increased in high-output CHF (e.g., thyrotoxicosis).
Pressure overload (concentric hypertrophy)	Increased afterload, RAS activation, increased levels of TNF-alpha and other cytokines	Unloading of individual muscle fibers, decreased wall stress and MVO_2	Imbalance in energy demand and supply, focal necrosis, fibrosis, increased collagen formation, diastolic dysfunction	Cardiomegaly, increased diastolic dysfunction and venous congestion	Pressure overload induces cardiomy-opathy of overload. Growth-inhibitory drugs (e.g., ACE inhibitors, nitrates) may delay development of cardiomyopathy of overload.
Volume overload (eccentric hypertrophy)	Fiber slippage, increased tension	Increased compliance(?); increased stroke volume with same ejection fraction (dilatation)	Increased wall stress and MVO_2; pressure hypertrophy	Cardiomegaly	Increased wall stress leads to pressure hypertrophy.

ACE, Angiotensin-converting enzyme; *ATPase*, adenosine triphosphatase; *CHF*, congestive heart failure; *MVO_2*, myocardial oxygen consumption; *TNF-alpha*, tumor necrosis factor alpha.

Figure 197-17 Mechanisms that lead to myocardial hypertrophy and remodeling. Increases in the load and activation of proto-oncogenes and growth-regulating genes lead to hypertrophy (myocyte growth) and remodeling. Short-term sympathetic effects are beneficial, but chronic activation favors progression of left ventricular dysfunction. Hypertrophy is beneficial because it decreases left ventricular wall stress and increases cardiac output. Unfortunately, chronic myocardial hypertrophy and remodeling are associated with myocardial cell death. Dashed lines indicate long-term effects. *TNF-alpha*, Tumor necrosis factor alpha; *IGF-1*, insulin-like growth factor-1; *PGE_2*, prostaglandin E_2; *$TGF\text{-}beta_1$*, transforming growth factor $beta_1$; *ET-1*, endothelin-1.



197.3.3.2 Increased Inotropy and Lusitropy

Beta-adrenergic stimulation caused by increased sympathetic tone during heart failure increases calcium entry in the atrial and ventricular cells, calcium release from the sarcoplasmic reticulum, and the interaction between contractile proteins. All these actions increase contractility. Beta-adrenergic stimulation also increases lusitropy by increasing calcium efflux from the cell and calcium uptake by the sarcoplasmic reticulum.[3] The increase in calcium entry is largely responsible for the positive inotropic effect; the facilitated dissociation from troponin and increased calcium uptake by the sarcoplasmic reticulum are the

key factors in causing a positive lusitropic effect.[3] Beta-adrenergic stimulation increases cardiac output, but also increases MVO_2 and contributes to myocardial remodeling.

197.3.3.3 Myocardial Growth

Cardiac mass is increased in patients with heart failure, apparently as a result of a combination of reactive fibrosis and myocyte hypertrophy, along with alterations in the cytoskeletal structure in the myocyte. An increase in afterload and neuro-endocrine activation lead to left ventricular hypertrophy. Hypertrophy reduces the load in individual cells and increases cardiac output. Hypertrophy causes growth of myocyte and nonmyocyte cells in the extracellular matrix of the myocardium. The growth of myocytes and nonmyocyte cells occurs independent of each other. Chronic anemia and thyrotoxicoses cause myocyte growth without the involvement of fibroblasts, whereas hypertrophy secondary to pressure overload is accompanied by reactive fibrosis that is not secondary to myocyte necrosis. Increases in preload, afterload, sympathetic activation, and growth hormone induce myocardial growth, whereas activation of the RAS, prostaglandin E_2, transforming growth factor-$beta_1$ (TGF-$beta_1$), and insulin-like growth factor-1 (IGF-1) induce remodeling of the cardiac interstitium (Figure 197-17).[63] All these substances induce expression of proto-oncogenes and growth-regulating genes that play an important role in the mediation of hypertrophy. Structural remodeling of myocardial collagen matrix contributes to the progression of heart failure.

Hypertrophy in patients with CHF results in a ventricle that is not normal. Morphologic, biochemical, and genetic changes cause ventricular remodeling, leading to progression of the left ventricular dysfunction. The appearance of a “slow” myosin, a more efficient myosin that spares energy in the heart, has been detected in the atria[64] but not the ventricles[65] of dogs with CHF. Pressure-induced hypertrophy unloads the individual myocardial cells and decreases wall stress and MVO_2. However, hypertrophied ventricles have a capillary deficit and a decreased number of mitochondria, leading to a state of energy starvation.[66] The chronic energy starvation leads to necrosis, fibrosis, an increase in the collagen concentration, and diastolic dysfunction. Volume-induced hypertrophy decreases wall stress and MVO_2 and helps maintain stroke volume, probably by increasing compliance. Fiber slippage, however, causes further dilatation of the heart, again increasing wall stress and MVO_2 and favoring progression of the left ventricular dysfunction.

197.4 WHAT IS THE ROLE OF INFLAMMATION IN HEART FAILURE?

930

Cytokines are highly potent, endogenous peptides with autocrine and paracrine actions; they are produced by a variety of cell types. Unlike hormones, cytokines are not stored but are secreted in response to specific stimuli. TNF-alpha, interleukin-1-alpha (IL-1α), interleukin-1-beta (IL-1β), and interleukin-6 (IL-6) are classified as proinflammatory cytokines.[2] These cytokines initiate both primary host responses and tissue repair. Interleukin-2 (IL-2) is a potent immunostimulatory polypeptide that amplifies the immune response to antigens. Evidence suggests that proinflammatory cytokines are capable of modulating cardiovascular function through a variety of mechanisms, such as promotion of left ventricular remodeling, induction of contractile dysfunction, and uncoupling of myocardial beta-adrenergic receptors (Table 197-3).[67] Several studies have shown that CHF is associated with increased circulating levels of proinflammatory cytokines. Short-term expression of cytokines in the heart may be an adaptive response to different forms of stress, whereas long-term expression may be maladaptive by producing cardiac decompensation. The cytokine hypothesis for heart failure does not imply that cytokines cause heart failure per se. However, they are potentially involved in the genesis of this pathology, and overexpression of cytokines contributes to the progression of heart failure once ventricular dysfunction ensues.[68]

931

Chronic sympathetic activation[69] and increases in angiotensin II[70,71] and aldosterone[72] play a role in the overexpression of cytokines during CHF. Sustained hemodynamic overloading provokes a transient increase in proinflammatory cytokine and cytokine-receptor gene expression.[73]

The main stimulus for cytokine activation in CHF is not known.[74] The heart is primarily involved and could be the main source of proinflammatory cytokines, because the failing myocardium is capable of producing TNF-alpha.[75] It has also been demonstrated that pressure overload stimulates the synthesis of TNF-alpha messenger ribonucleic acid (mRNA). Myocardial stretch induces mRNA production by myocytes.[76] Another potential stimulus for an increase in the production of TNF-alpha by the failing heart is extramyocardial cytokine release caused by tissue hypoxia.[77] Tissue hypoxia and the production of free radicals are potent stimuli for the generation of cytokine release via nuclear factor-kappa-B (NF-kappa-B)–dependent pathways.[78] Cytokines are expressed in the myocardium in end-stage heart failure to a much greater degree than in patients with recent onset of symptoms. Plasma levels of TNF-alpha correlate with mRNA expression in the myocardium and thus may serve as an appropriate marker of myocardial cytokine activation. Whether the production of cytokines in the failing human heart precedes the elevation of cytokines in the plasma remains undefined.[79]

Table • 197-3 Effects of Chronic Proinflammatory Cytokine Activation in Heart Failure

EFFECT	MECHANISM	CLINICAL CORRELATE
Heart		
Myocyte hypertrophy	Generation of reactive oxygen intermediates in cardiac myocytes; activation of fetal gene programs	Cardiac hypertrophy
Left ventricular remodeling	Stimulation of production of extracellular matrix proteins and increased turnover of matrix	Cardiomyopathy of overload
Cardiomyocyte loss	Necrosis, apoptosis	Progression of heart failure
Depression of myocardial function	Nitric oxide dependent; sphingomyelinase pathway; uncoupling of beta adrenoreceptors; abnormal mitochondria energetics	Decreased contractility
Exacerbated inflammatory response	Cytokine cascade	Myocarditis
Skeletal Muscle		
Myopathy	Free radical and nitric oxide overproduction; endothelial dysfunction	Reduced blood flow in muscles, exercise intolerance
Decreased skeletal mass	Apoptosis	Cardiac cachexia
Other Effects		
Anorexia		Cardiac cachexia
Pulmonary edema		Dyspnea

The bowel could also be a source of proinflammatory cytokines during CHF. The intestinal wall edema and ischemia that occur during CHF favor bacterial translocation and may cause the release of endotoxins, with subsequent immune activation.[80] It has been shown that during acute, edematous exacerbation of CHF, endotoxin and cytokine concentrations increase but can be normalized by diuretic therapy.[81]

197.4.1 Tumor Necrosis Factor Alpha

TNF-alpha is a proinflammatory cytokine that exerts negative inotropic effects *in vivo* and *in vitro*. Acute negative inotrope results from disruption of calcium transients, whereas chronic effects are associated with

induction of inducible NO synthase (iNOS) and are due to NO-induced myofilament desensitization to calcium.[82] TNF-alpha also can produce left ventricular remodeling, hypertrophy and apoptosis, pulmonary edema, and cardiomyopathy.[83] It stimulates production of other endogenous pyrogens, such as IL-1β. The main known stimuli that prompt adult mammalian myocardial cells to produce TNF are endotoxins, hypoxia, and increased mechanical stress.[76,84] NF-kappa-B can also participate in the production of TNF-alpha. Oxidative stress activates NF-kappa-B, which binds to a TNF promoter, increasing TNF-alpha transcription.[85] Mild acute increases in TNF-alpha are an adaptive response to stress; they protect the heart during ischemia and favor remodeling during infarcts and adaptive growth during hemodynamic overload. Severe acute increases lead to myocarditis as a result of an exacerbated inflammatory response, and chronic increases are maladaptive, favoring cardiac decompensation and apoptosis.[86]

931

932

Cats with naturally occurring CHF have increased concentrations of TNF-alpha.[87] Increases in the TNF-alpha concentration have been independently associated with a poorer prognosis for CHF. TNF-alpha is produced in the heart by cardiac myocytes and resident macrophages under conditions of cardiac stress. Normal hearts do not produce TNF-alpha, but failing human hearts make abundant quantities.[83] The source of cardiac TNF-alpha appears to be at least partly attributable to production by the cardiac myocyte.[75] TNF-alpha plays an important role in the development of heart failure. Administration of TNF-alpha to experimental animals and transgenic overexpression of TNF-alpha lead to CHF. Mice that overexpress TNF-alpha recapitulate heart failure and a dilated cardiomyopathy state in other species shows (1) four-chamber dilatation, (2) myocyte hypertrophy, (3) interstitial infiltrates, (4) extracellular matrix remodeling with fibrosis, (5) diminished beta-adrenergic responsiveness, and (6) premature death.[86] Attenuation of the biologic activity of TNF-alpha abrogates the development of CHF in experimental model systems. Unfortunately, anti-TNF strategies to date have not demonstrated salutary benefits in large, multicenter, randomized and placebo-controlled clinical trials in patients with symptomatic heart failure.[88]

197.4.2 Interleukins

Interleukin-1 (IL-1) mediates immune response and the production of inflammatory responses through an increase in prostaglandins, and it may be a basal part of the overactivated cytokine cascade during CHF.[2] IL-1 appears capable of modulating myocardial function. It exerts a potent antiproliferative effect on cardiac fibroblasts but induces cardiac myocyte hypertrophy. IL-1β is increased during CHF; it decreases myocardial contractility by stimulating iNOS, and it may uncouple beta adrenoreceptors from adenylate-cyclase, one of the mechanisms of heart failure progression.[89] The negative inotropic effect of IL-1 appears to be mediated, at least partly, by production of NO or by the activation and release of interleukin-18, a member of the IL-1 family.[88] IL-1 induces synthesis by T lymphocytes of interleukin-2 (IL-2), an endogenous T-cell mitogen that enhances T-cell proliferation. IL-2 thus amplifies the immune response and stimulates the production of interferon-gamma and the release of other inflammatory factors (e.g., TNF-alpha). IL-2 levels are increased in human patients with dilated cardiomyopathy and in their relatives, with left ventricular enlargement usually being higher in patients with CHF.[90] Interleukin-6 (IL-6) is a multifunctional cytokine that mediates both immune and inflammatory responses. It is also a promoter of cardiomyocyte hypertrophy and a negative inotrope that is elevated in patients with heart failure, especially those with cardiac cachexia or severe CHF.[91] In human patients with CHF, IL-6 is a predictor of mortality independent of etiology, the sodium concentration, the severity of heart failure, and the ejection fraction.[92]

197.4.3 Nuclear Factor–Kappa-B

During CHF, oxidative stress, increased expression of TNF-alpha, and an increase in the angiotensin II concentration serve to activate NF-kappa-B. NF-kappa-B is a redox-sensitive transcription factor that is critical to initiation of the co-ordinated expression of classic components of the myocardial inflammatory response, including increased expression of proinflammatory cytokines (e.g., TNF-alpha, IL-6), NO, chemokines, and adhesion molecules.[84,88] NF-kappa-B is an important player in inflammation during heart failure. Activation of NF-kappa-B initiates gene transcription of several substances that can lead to cardiovascular injury. NF-kappa-B signaling also plays an important role in myocardial growth, and its inhibition attenuates cardiomyocyte hypertrophy.[93,94] Myocardial cells from patients with heart failure exhibit activation of NF-kappa-B and increased expression of genes it regulates (e.g., TNF-alpha, iNOS). Elevation of NF-kappa-B seems to occur independent of the etiology of heart failure but appears to be related to the severity of CHF. NF-kappa-B can activate cell death pathways, and TNF-alpha–induced apoptosis is associated with an increase in NF-kappa-B. However, blocking of NF-kappa-B in this setting paradoxically exacerbates cell death.[85] It is not known if NF-kappa-B activates antiapoptotic factors. The paradoxical effect of activating detrimental molecules while protecting cells may be related to the inflammatory program mediated by NF-kappa-B; it generates toxic molecules that can kill invading micro-organisms without damaging host cells.[85]

197.4.4 Reactive Oxygen Species

Increases in angiotensin II induce production of reactive oxygen species. An important effect of angiotensin II is activation of the NAD(P)H oxidase, a major source of reac-tive oxygen species (ROS) production by vascular cells. Reactive oxygen species are the end result of univalent reductions in oxygen that produce superoxide anion, hydrogen peroxide, and water.[95] ROS influence both normal and abnormal cellular processes, including cellular growth, hypertrophy, remodeling, lipid oxidation, modulation of vascular tone, and inflammation. The increase in cellular ROS contributes to the pathogenesis of vascular disease by altering endothelial cell function; enhancing smooth muscle cell growth and proliferation; stimulating inflammatory proteins, including macrophage chemoattractant agents, growth factors and cytokines; and modulating matrix remodelling.[96] These ROS can be released from the cardiac myocyte mitochondria, and chronic release of ROS recently was linked to the development of left ventricular hypertrophy and progression of heart failure.[97] The release of ROS is required for the normal physiologic activity of cardiac cells, but abnormal activation of nonphagocytic NAD(P)H oxidase in response to neurohormones and cytokines (angiotensin II, nor-epinephrine, TNF-alpha) has been shown to contribute to cardiac myocyte hypertrophy. The fibrosis, collagen deposition, and metalloproteinase activation involved in the remodeling of a failing myocardium depend on ROS released during the phenotypic transformation of fibroblasts to myofibroblasts that is associated with progression of end-stage heart failure.[97] Studies of genetically altered mice have shown that activation of the NAD(P)H oxidase by angiotensin II contributes to hypertension and left ventricular hypertrophy.[98,99]

The *cytokine hypothesis*[2,100] for heart failure suggests that heart failure progresses because cytokine cascades that are activated after myocardial injury exert deleterious effects on the heart and circulation. This hypothesis does not imply that cytokines cause CHF, but rather that overexpression of cytokines contributes to the progression of heart failure once left ventricular dysfunction ensues.[101] TNF-alpha and IL-6 become activated after left ventricular injury or myocardial stretch. These stress-activated cytokines can exert autocrine and paracrine effects in the myocardium by binding to specific cytokine receptors. If cytokine expression is

excessive, these molecules may produce left ventricular dysfunction and left ventricular dilatation. It is further postulated that cytokines, when overproduced, may spill over into the circulation, leading to secondary activation of the immune system, which is then capable of amplifying the cytokine signal in the periphery.[101] There is an easily recognizable overlap between the neurohormonal and cytokine hypothesis. However, there are likely to be important differences in the mechanisms that initiate overexpression of these molecules, as well as differences in the biologic effects that these molecules exert.

933

197.5 WHAT ARE THE CLINICAL MANIFESTATIONS OF HEART FAILURE?

Clinical signs in heart failure may result from accumulation of fluids, low cardiac output, or changes in the skeletal muscles (Box 197-5). Dogs with CHF are usually brought to the veterinarian because of a cough, dyspnea, exercise intolerance, abdominal enlargement, or syncope. Cats, on the other hand, are usually presented because they cannot breathe (pleural effusion or pulmonary edema) or cannot walk (aortic thrombo-embolism) properly.

Sodium and water retention increase the circulating volume and venous pressure, an effect that is potentiated by venous constriction. Venous hypertension and microcirculatory congestion lead to transudation of fluids in body cavities (effusion) or the interstitium (edema). These signs develop preferentially in the capillary beds drained by the failing ventricle. Thus elevated pulmonary venous and capillary hydrostatic pressures in small animals lead to pulmonary edema and can be manifested as dyspnea, cough, pulmonary crackles, and exercise intolerance. Systemic venous hypertension causes jugular distention, hepatic congestion, ascites, and subcutaneous edema. In dogs, ascites always precedes subcutaneous edema in patients with right-sided CHF. Cats rarely develop ascites secondary to right-sided CHF. Biventricular failure shows a combination of left-and right-side signs and is often associated with accumulation of pleural fluid. Although cats may occasionally develop pleural effusion during experimentally induced right-sided CHF,[102] almost all cats with pleural effusion from CHF have bilateral disease or a disease of the left side, with pulmonary hypertension or atrial fibrillation. Pleural effusion in small animals usually accompanies biventricular failure, not isolated right-sided failure.[103] Dogs develop pleural effusion only during experimentally induced right-sided CHF, when large volumes of crystalloid are infused, leading to severe hypoproteinemia.[104] In this setting, pleural effusion correlates better with the pulmonary capillary wedge pressure than with the right atrial pressure, which suggests that right-sided CHF was not the main cause of the development of pleural effusion.

197.5.1 Box • 197-5 Clinical Signs in Congestive Heart Failure

197.5.1.1 Low-Output Signs

Complaints → Exercise intolerance, syncope

Clinical signs → Weak arterial pulses, tachycardia, arrhythmias, cool extremities

197.5.1.2 Signs Related to Poor Skeletal Muscle Function

Complaints → Loss of weight, exercise intolerance, dyspnea*

Clinical signs → Decreased muscle bulk

197.5.1.3 Signs Related to Fluid Retention

Left side (pulmonary edema)

Complaints → Dyspnea, orthopnea, exercise intolerance, cough†

Clinical signs → Pulmonary crackles, tachypnea, gallop rhythm, functional mitral regurgitation, cyanosis caused by ventilation-perfusion inequality

Right side (systemic venous congestion)

Complaints → Abdominal enlargement (ascites), subcutaneous edema

Clinical signs → Jugular distention and pulsation, ascites, hepatomegaly, splenomegaly, hepatojugular reflux, gallop rhythm

Bilateral

Complaints → Left side plus right side complaints, dyspnea caused by pleural effusion

Clinical signs → Left side plus right side clinical signs, muffled heart and lung sounds with fluid line in the chest (pleural effusion)

197.5.1.4 Other Signs

Arrhythmias

Weight loss

Cough

* Activation of metaboreceptors and peripheral chemoreceptors may contribute to dyspnea in patients without congestion.

† Cough may also occur in dogs without congestive heart failure because of left main stem bronchus compression.

A decrease in cardiac output may lead to exercise intolerance, tiring, and fatigue. Because exercise intolerance can occur only in animals that exercise, it is not a prominent complaint of cat owners or of the owners of dogs that spend most of their life on the lap. Syncope may be due to low cardiac output of the failing heart or to concurrent arrhythmia. Low-output signs are nonspecific but, when due to CHF, tend to worsen with exercise.

Dyspnea is usually caused by pulmonary edema or pleural effusion, but it may also occur before the patient develops severe fluid retention. Dyspnea and exercise intolerance may be related to skeletal muscle changes that occur during CHF. Abnormal muscle function and increased fatigability during CHF have been linked to the decrease in muscle bulk, an increased reliance on anaerobic metabolism, decreased muscle blood flow, and metaboreceptor activation.[28] Normal animals become dyspneic during exercise in a manner similar to that which occurs in CHF. The main difference among a normal, fit animal, an untrained animal, and a patient with CHF is the amount of exercise that leads to dyspnea and fatigue. Muscle fatigue is an important determinant of exercise intolerance and dyspnea (fatigue of respiratory muscle) during CHF. In human beings, the same patient may complain of fatigue or dyspnea, depending on the type of exercise performed. It has been proposed that the sensation of fatigue during CHF is generated as a central mechanism to protect against hypoxic damage to essential organs. Ergoreceptors may be responsible for mediating both dyspnea and sensation of fatigue.[105] The muscle hypothesis for CHF states that abnormalities in skeletal muscle blood flow, bulk, and function are major determinants of clinical signs, leading to fatigue and increased ventilatory stimulus. Activation of ergoreceptors leads to persistent sympathetic activation, increasing afterload and reducing blood flow. As cardiac function deteriorates, a catabolic state exacerbates muscle wasting (cardiac cachexia), and patient inactivity leads to further deterioration of muscle function. Such a progression leads to a vicious cycle, in which muscle abnormalities cause clinical signs and favor progression of left ventricular dysfunction, worsening muscle abnormalities and increasing clinical signs.[28]

Cardiac cachexia is a common finding in CHF. It is usually more prominent in right-sided CHF and in giant breeds with dilated cardiomyopathy. In one study, more than half of the dogs with CHF secondary to dilated cardiomyopathy were cachectic.[106] It is very uncommon for an animal with overt CHF to be obese. Obesity is usually associated with respiratory problems. When CHF develops rapidly (e.g., with rupture of a chorda tendineae or the development of atrial fibrillation, or in a few Dobermans with dilated cardiomyopathy), time may not be sufficient for cardiac cachexia to develop, and the animal may show a reasonably normal body condition. The cachectic state is a strong independent risk factor for mortality in patients with CHF.[107] Cachexia is more closely associated with hormonal changes in CHF than are conventional hemodynamic measures of the severity of CHF.[108] Neuroendocrine activation leads to increases in TNF-alpha, IL-1β, norepinephrine, and cortisol and to insulin resistance. All these factors appear to play a major role in the development of cardiac cachexia. An increase in TNF-alpha and its soluble receptors is seen in chronic heart failure. This increase is associated with a rise in the cortisol/dehydroepiandrosterone (catabolic/anabolic) ratio, suggesting that an increase in TNF-alpha is at least partly responsible for the cachexia.[109] In right-sided heart failure, interference with normal absorption of nutrients in the gastrointestinal tract, caused by intestinal and hepatic congestion, may also contribute to cachexia.

933

934

Cough is a common sign of heart disease in dogs but not in cats. Dogs with heart disease may cough because of left-sided CHF, compression of the left main stem bronchus without CHF, or a concurrent respiratory disease (e.g., collapsing trachea, chronic bronchitis). Dogs that cough from pulmonary edema are frequently thin, show severe weight loss, and have a more subtle cough that tends to worsen at night and may be accompanied by a pink nasal discharge or sputum. Dogs that cough because of left main stem bronchus compression or respiratory disease are more likely to be obese or of normal weight and tend to have dry, hacking coughs that are usually worse during the day. Dogs with left-sided CHF usually have fast heart rates caused by sympathetic activation, whereas dogs with left main stem bronchus compression or respiratory disease have normal heart rates with pronounced sinus arrhythmia due to high vagal tone.

Arrhythmias in patients with heart failure may be caused by the underlying disease or by the CHF itself. In addition, chronic, persistent tachycardia may cause left ventricular dysfunction and CHF. The enlargement,

fibrosis, and hypertrophy that occur during left ventricular dysfunction lead to conduction abnormalities that predispose the animal to arrhythmias. A rise in cytosolic calcium, caused by sympathetic activation, may also cause arrhythmias. The presence of arrhythmias is an important negative prognostic factor in patients with CHF.

Clinical signs suggestive of heart disease (although not necessarily CHF) include a diastolic, continuous, or loud systolic murmur; arrhythmias with pulse deficit and gallop rhythms; and ascites with jugular distention and hepatojugular reflux. An aortic thromboembolism (saddle thrombus) in cats also suggests the presence of heart disease. Right-sided CHF is a clinical diagnosis in dogs. It is likely to be present in patients with ascites and jugular vein distention, hepatomegaly, and abnormal cardiac auscultation. Diagnosis of left-sided heart failure, however, requires a chest radiograph. Auscultative pulmonary abnormalities in pulmonary edema are neither sensitive nor specific. A patient with dyspnea, cough, or pulmonary crackles, even with abnormal heart ausculation, may have respiratory signs caused by a primary respiratory disease. In cats, chest radiographs are very useful for diagnosing both right-and left-sided CHF.

197.6 WHY DOES A PATIENT DEVELOP CLINICAL SIGNS OF CONGESTIVE HEART FAILURE?

CHF is a progressive disease, and systolic or diastolic function is eventually compromised to a degree that clinical signs are inevitable. One should not conclude, however, that recent development or worsening of clinical signs is due to disease progression. In many patients a precipitating factor for the CHF can be found, and it may not necessarily be related to the heart itself. Lack of client compliance is a common cause of treatment failure. Clients should be carefully questioned about medications used. Treatment of heart failure usually requires multiple drugs, and confusion about the proper use of the medications is not uncommon. The doses given, the frequency and route of administration, and use of the proper formulation should be verified. Furthermore, the possibility that a person other than the owner (e.g., a pet sitter) may have been temporarily responsible for the dog or cat should be investigated. Inappropriate reduction of therapy is the most common reason for sudden worsening of the clinical condition in human patients with CHF. In small animal practice, inappropriate therapy is more likely when a person who is not completely familiar with the patient's clinical condition is caring for the dog or cat or when the patient goes for a long period without clinical signs and is assumed to be “cured.”

The development of complications is an important precipitating factor for CHF in small animal medicine. Extracardiac complications that impose an extra load on the cardiovascular system may induce CHF in patients with heart disease. Conditions that lead to a hyperdynamic circulation (e.g., anemia, hyperthyroidism, infection, fever) increase MVO_2 and sympathetic tone. Systemic arterial hypertension causes an increase in afterload, which has a devastating effect on a failing myocardium. Systemic hypertension also increases the regurgitant fraction in patients with aortic and mitral regurgitation. In addition, physical, environmental, and emotional stress may lead to CHF, and a second, unrelated disease may affect cardiac function indirectly. Renal failure can potentially cause hypertension and may interfere with sodium excretion, exacerbating the CHF.

A common cause of sudden decompensation of CHF is a cardiac complication. The two most common cardiac complications leading to CHF are the development of mitral regurgitation and arrhythmias. Mitral regurgitation may develop suddenly as a result of dilatation of the annulus valvulus in patients with dilated cardiomyopathy or as a result of the Venturi effect in cats with hypertrophic cardiomyopathy. However, the most devastating cause of acute worsening of mitral regurgitation that leads to CHF is the rupture of chordae tendineae, which occurs in dogs with mitral endocardiosis. The sudden appearance of atrial fibrillation is a common cause of the precipitation of CHF in dogs with dilated cardiomyopathy or mitral endocardiosis. Progression of the cardiacdisease, usually with development of myocardial failure, eventually leads to the appearance of signs of CHF in patients with heart disease.

197.7 HOW CAN WE CLINICALLY EVALUATE HEART FUNCTION?

197.7.1 Is Heart Failure Present?

Heart disease is not synonymous with heart failure. A patient may be presented with a heart murmur or gallop and may even have myocardial failure, yet may not necessarily be in CHF. To facilitate characterization of the severity of heart failure, functional classifications based on clinical signs at rest are used (Box 197-6). The presence of heart failure may be suspected during the physical examination. Right-sided CHF is a clinical diagnosis based on jugular distention and pulsation, the presence of ascites (dogs) and pleural effusion (cats, usually indicating bilateral failure), and peripheral edema. The diagnosis is confirmed by showing elevation of the central venous pressure or, more loosely, by observing a large right heart on radiographs or echocardiography. Left-sided heart failure is a radiographic diagnosis that can be suspected in patients with dyspnea and abnormal respiratory sounds. It can be confirmed by showing elevation of the pulmonary capillary wedge pressure, but identification of pulmonary edema in association with left-heart enlargement would suffice from a clinical standpoint.

935

197.7.1.1 Box • 197-6 Functional Classification of Heart Failure

197.7.1.1.1 Modified from the New York Heart Association Classification*

I. Normal activity does not produce undue fatigue, dyspnea, or coughing.

II. The dog or cat is comfortable at rest, but ordinary physical activity causes fatigue, dyspnea, or coughing.

III. The dog or cat is comfortable at rest, but minimal exercise may produce fatigue, dyspnea, or coughing. Signs may also develop while the patient is in a recumbent position (orthopnea).

IV. Congestive heart failure, dyspnea, and coughing are present even when the dog or cat is at rest. Signs are exaggerated by any physical activity.

197.7.1.1.2 International Small Animal Cardiac Health Council†

I. Asymptomatic patient

Ia. Signs of heart disease but no cardiomegaly

Ib. Signs of heart disease and evidence of compensation (cardiomegaly)

II. Mild to moderate heart failure

Clinical signs of heart failure are evident at rest or with mild exercise and adversely affect the quality of life.

III. Advanced heart failure

Clinical signs of congestive heart failure are immediately obvious.

IIIa. Home care is possible.

IIIb. Hospitalization is recommended (cardiogenic shock, life-threatening edema, large pleural effusion, refractory ascites).

Some clinical findings may be helpful, providing indications of cardiovascular function. Gallop rhythms suggest the presence of ventricular dysfunction. The fourth heart sound (S_4 gallop) occurs during late diastole and represents atrial contraction. An S_4 gallop is associated with elevated ventricular end-diastolic pressure related to a decrease in ventricular compliance. An early diastolic filling sound (S_3 gallop) may occur during ventricular dysfunction of any cause and is a very sensitive indicator of ventricular dysfunction. Increased loudness and splitting of the second heart sound suggest the presence of pulmonary hypertension. A distended and sometimes pulsating jugular vein suggests that the right atrial pressure is elevated and the patient is in right-sided heart failure.

197.7.2 What Tests Should Be Performed?

Laboratory tests are used to confirm the presence and cause of the heart disease, the presence and severity of the CHF and ventricular dysfunction, and the presence of complications. Some tests are useful for diagnosing specific conditions and may offer no information about cardiovascular function, whereas others may assess only function or may offer a combination of functional and diagnostic information. In addition to the physical examination, confirmation of the exact cause of CHF usually requires a combination of radiographic, electrocardiographic, echocardiographic, and laboratory assessment techniques. Echocardiography is very helpful in determining the disease leading to the CHF.

Electrocardiography can be used to evaluate the heart rhythm, but it provides only indirect information about cardiovascular function. Arrhythmias may be due to heart disease, but they also can arise from noncardiac causes. The electrocardiogram provides no definitive criteria for diagnosing heart failure. However, it may contribute to the diagnosis (e.g., showing a decrease in QRS voltage and electrical alternans with pericardial effusion). One should bear in mind that a normal electrocardiogram does not rule out CHF or heart disease.

Chest radiographs are very important for patients suspected of having heart disease. Changes in cardiac size and shape may show the compensation effects in the heart (cardiomegaly) and can be very helpful in determining the cause of CHF in dogs. Unfortunately, in cats, chest radiographs do not discriminate among the different

myocardial diseases that may lead to heart failure, and echocardiography is usually necessary. Chest radiographs are of paramount importance in the detection of left-sided CHF (pulmonary venous congestion, pulmonary interstitial or alveolar edema). They are also useful for visualization of pleural effusion in patients with CHF.

Echocardiographic examination is extremely helpful for determining the cause of CHF. There are no echocardiographic criteria for diagnosing CHF, but it is uncommon to see left-sided CHF without echocardiographic abnormalities, such as left atrial enlargement; and right atrial enlargement or pericardial effusion, in right-sided CHF.

Echocardiography, measurement of the arterial blood pressure, and cardiac catheterization may all provide useful information about cardiovascular function. Cardiac catheterization has been used less and less, because most of the information provided by cardiac catheterization can now be obtained noninvasively and without the need to anesthetize the patient. Pressures behind the pumping chambers are useful for estimating ventricular filling pressures. The central venous pressure can be measured with a water-or saline-filled catheter placed in the cranial vena cava or right atrium. The central venous pressure provides an estimation of the right ventricular end-diastolic pressure. The pulmonary capillary wedge pressure is obtained by placing a balloon-tipped (Swan-Ganz) catheter in the pulmonary artery, inflating the balloon to wedge the catheter tip, and then recording the pressure. The pulmonary capillary wedge pressure provides an estimate of the left ventricular end-diastolic pressure. Clinically speaking, congestive heart failure is evidenced by increased ventricular filling (end-diastolic) pressures.[110]

The arterial blood pressure should be measured in all patients with heart disease or CHF. Arterial hypertension can lead to left ventricular hypertrophy and dysfunction and eventually to CHF. CHF secondary to systemic hypertension appears not to be as common in dogs and cats as it is human beings. However, hypertension is a potentially controllable reason for heart disease. In addition, systemic hypertension in a patient with any left ventricular dysfunction increases left ventricular afterload and decreases cardiac output. It also favors progression of left ventricular dysfunction. Hypertension increases valvular regurgitation in patients with mitral or aortic insufficiency and the shunt fraction in dogs and cats with left-to-right shunts.

935
936

Measurement of biochemical markers that are increased during heart disease or CHF can provide information about the disease and in some cases may have prognostic value. The most commonly used markers in small animals are cardiac troponin I, cardiac troponin T, ANP, and BNP. Cardiac troponins are leakage markers that are released into the circulation when cardiac cell membrane integrity has been compromised; they therefore indicate myocardial damage. Any myocardial injury, including CHF, can increase cardiac troponins; a correlation exists between the magnitude of myocardial damage and the degree of elevation of cardiac troponins only in acute states.[111] ANP and BNP are functional markers that increase with an increase in circulating volume (e.g., CHF) or during left ventricular hypertrophy. ANP and BNP tend to increase regardless of the underlying heart disease, but their levels correlate well with the degree of left ventricular dysfunction. They can potentially be used to assess cardiac function, to monitor therapy, and to help determine the prognosis.[49,112] Unfortunately, few clinical studies have highlighted the indications, usefulness, and limitations of different biochemical markers in heart disease in dogs and cats, which limits the use of these markers. As more information becomes available, clinical use of biochemical markers likely will increase.

Several indices are available to aid the evaluation of systolic and diastolic function in intact animals. The large number of indices (Box 197-7 presents a partial list) probably reflects the fact that no single index meets all needs. Only indices that are clinically useful are discussed here.

197.7.2.1

Systolic function

Systolic function is assessed by evaluation of the determinants of stroke volume (preload, afterload, and contractility) and by use of indices of global ventricular systolic performance. For evaluation of cardiac function, many indices require a knowledge of the left ventricular volume or stroke volume. The left ventricular volume can be estimated echocardiographically or by angiography. An echocardiogram provides a good estimation of left ventricular volume non-invasively in dogs and is economically feasible. Two-dimensional echocardiography is superior to M-mode echocardiography in the estimation of left ventricular volume in dogs. The stroke volume can also be obtained by two-dimensional echocardiography (end-diastolic volume/end-systolic volume) or preferentially by Doppler echocardiography. Using Doppler echocardiography, the stroke volume can be determined from the integrated velocity of blood flow across the aorta or pulmonary artery, multiplied by the cross-sectional area of the respective valve orifice.

197.7.2.2

Preload

Left ventricular end-diastolic volume is the best clinical approximation of preload. M-mode–based models for evaluation of the left ventricular volume are associated with unacceptably high variation, especially for the end-diastolic volume. Whenever possible, left ventricular volume should be estimated with two-dimensional echocardiography, using the Simpson's rule or the cylinder-truncated-cone-cone method.[113] Alternatively, preload can be estimated as being equal to the left ventricular end-diastolic pressure based on the relationship between left ventricular pressure and volume. Pressure, rather than volume, cannot be used to estimate preload in stiff or noncompliant ventricles.

197.7.2.3

Afterload

Ideally, afterload should be measured as the aortic input impedance, but this is not clinically feasible. An alternative is to use the effective arterial elastance (Ea). The Ea is a steady-state arterial parameter that incorporates the principal elements of vascular load and is obtained from the ratio of end-systolic pressure to stroke volume.[10] To avoid the need for cardiac catheterization, the mean femoral artery pressure can be used as an estimation of the left ventricular end-systolic pressure.[114] Changes in the Ea show a high correlation with changes in input impedance. Peripheral resistance is another option for estimating left ventricular afterload, but it accounts only for the opposition to steady flow and not for the opposition to pulsatile flow. Peripheral (systemic) vascular resistance (SVR) can be calculated using cardiac output (CO), mean aortic pressure (MAP), and venous pressure (VP) as follows:

936 937

$$SVR = 80 \times (MAP - VP)/CO$$

The arterial blood pressure can be used as a simple, non-invasive means of assessing the opposition to left ventricular ejection. CHF, however, involves a combination of decreased cardiac output and increased afterload. Because the arterial blood pressure depends on both these factors, it does not provide an adequate evaluation of left ventricular afterload.[115] Nevertheless, it is important to know whether a patient with CHF also has systemic hypertension. The arterial blood pressure may also be important for monitoring vasodilator therapy during CHF.

197.7.2.4 Contractility

Contractility is difficult to define and even more difficult to measure without interference from preload and afterload. Ventricular contraction has an isovolumic phase and an ejection phase. Isovolumic indices evaluate only the isovolumic contraction phase but are less affected by load changes. Ejection phase indices are so affected by changes in afterload and preload that they reflect not the contractility but the integrated systolic function. Indices based on the pressure-volume relationship are relatively load independent and are probably the best indices for evaluating contractility in intact animals. However, they are not routinely used clinically and are beyond the scope of this chapter.

The isovolumic index most commonly used in the evaluation of cardiac contractility is the maximum rate of pressure rise (dP/dt_{max}). dP/dt_{max} is the tangent to the maximum slope of the ascending portion of the left ventricular pressure curve, therefore it can be obtained only with left ventricular catheterization. dP/dt_{max} is influenced by preload (and to a lesser extent by afterload) and cannot be used in presence of valvular regurgitation. It is a sensitive index of contractility but is not specific because of its load dependence. Many other indices based on dP/dt have been developed, but they have roughly the same limitations as the dP/dt_{max}.

197.7.2.5 Integrated left ventricular systolic function

Indices of left ventricular function that evaluate global systolic function can be based on systolic time intervals or on left ventricular volume, diameter, or flow characteristics. The most commonly used systolic time intervals are the left ventricular ejection time (LVET) and the pre-ejection period (PEP). The PEP corresponds to the electric-mechanic interval plus the pressure rise time (onset of QRS to the opening of the aortic valve); it is influenced by changes in afterload, preload, and contractility. The LVET (opening to closing of the aortic valve) is affected by the heart rate and contractility and only mildly by preload and afterload. The information necessary to determine the PEP and LVET can be obtained with an electrocardiogram, a phonocardiogram, and an arterial pressure curve or M-mode echocardiogram of the aortic valve. The PEP/LVET ratio is independent of the heart rate and inversely related to systolic function.[116]

The ejection fraction (stroke volume/end-diastolic volume) and fractional shortening ([end-diastolic dimension – end-systolic dimension]/end-diastolic dimension) are two indices of systolic function expressed as a percentage. They are very sensitive and easy to measure using echocardiography, but they are influenced by changes in load. In addition, the low correlation between M-mode–derived volumes and the true left ventricular end-diastolic volume[113] probably renders an ejection fraction obtained with M-mode echocardiography inaccurate. The left ventricle also must be contracting uniformly, and the ultrasound beam must be parallel to the short axis of the ventricle for an M-mode–derived volume to be representative of global ventricular function.

M-mode imaging of the left ventricle may be performed using short or long axis views of the heart. Left ventricular dimensions obtained from short axis views tend to be higher than those obtained from long axis views, and there may be a lack of agreement between short and long axis views in dogs with heart disease.[117] Fortunately, fractional shortening values obtained from short axis views have shown good agreement with those obtained from long axis images in normal dogs and in dogs with heart disease.[117] When an M-mode of the left ventricle is recorded, it is important to be in the center of the left ventricle, perpendicular to the left ventricular wall, and with the ultrasound beam just below the mitral valve. The short

axis view allows better centering of the beam in the heart, whereas the long axis view is preferred for assuring that the beam is perpendicular to the wall. Either plan can be used to place the beam below the mitral valve. The choice of view (short axis, long axis, or both) for obtaining M-mode measurement of fractional shortening in dogs and cats remains a matter of the examiner's personal preference. Fractional shortening in dogs is also affected by body size, being smaller in giant breed dogs. The end-systolic volume index, left ventricular end-systolic volume obtained by M-mode indexed to body surface. It has been used in dogs,[118] but it is also dependent on afterload and in M-mode estimation of left ventricular volume. The end-systolic volume index may be more accurate than other volume-based indices because only one volume must be estimated, which avoids compounding error from multiple measurements. In addition, measurement of the end-systolic volume improves precision because of the better correlation between M-mode–derived volumes and true ventricular volume at smaller volumes.[113] The time to aortic peak velocity, which can be obtained by Doppler echocardiography, correlates well with global systolic function. Like all ejection indices, it is affected by changes in afterload.

197.7.2.6 Diastolic Function

Diastolic function is harder to evaluate noninvasively than systolic function. Doppler echocardiography remains the primary technique for assessing diastolic function noninvasively. Some indices of diastolic function assess ventricular function during a specific phase, whereas others evaluate global performance during diastole.

Diastolic time intervals can be used to evaluate diastolic properties. The most commonly used diastolic time interval is the isovolumic relaxation time, which is the time from aortic valve closure to mitral valve opening, when the left ventricular volume is constant. It is a relaxation index and can be obtained from phonocardiography (for aortic closure) and M-mode echocardiography (to mitral opening) or from Doppler echocardiography (the time from cessation of aortic flow to commencement of transmitral flow). An isovolumic relaxation time obtained echocardiographically correlated well with the time constant of isovolumic relaxation (τ) in anesthetized cats.[119] Unfortunately, the rate of decline in left ventricular pressure is only one of several factors that determine the isovolumic relaxation period. The aortic diastolic pressure and left atrial pressure affect the length of this period. The isovolumic relaxation time cannot be used in patients with aortic or mitral regurgitation because there is no true isovolumic period.

Doppler echocardiogram–derived changes in blood flow can be used to evaluate diastolic function. Many indices have been proposed, but the ones based on the transmitral valve flow profile (E and A waves) are more commonly used. The E wave represents early ventricular filling and precedes the A wave (atrial filling wave). The E wave is normally larger than the A wave (E/A ratio usually greater than 1). During fast heart rates, especially in cats, E and A waves are often fused, and the E/A ratio cannot be evaluated. An increase in the size of the A wave and a decrease in the E wave occur in patients with relaxation abnormalities. Unfortunately, with progression of the disease and an increase in the left ventricular end-diastolic pressure, the presence of mitral regurgitation, and an increase in the left atrial pressure, pseudonormalization of the E and A waves occurs. Patients with restrictive diseases tend to have smaller A waves and larger E waves.

937 938

M-mode echocardiography can also be used to evaluate diastolic function. The rate of change in wall thickness, the rate of wall relaxation, and the relaxation half time can be obtained with an M-mode echocardiogram (ideally a digitized echocardiogram). The peak rate of posterior wall motion has also been used, but this measurement is susceptible to distortion because of translational motion.

Hemodynamic indices that use pressure rather than volume have been used to evaluate diastolic function. These all require cardiac catheterization. The peak negative dP/dt measures the maximal rate of decline of left ventricular pressure during relaxation and is usually taken as the lowest value of the first derivative of this pressure. It usually occurs around the time of aortic closure. It should be remembered that the peak negative dP/dt occurs at one point in time and does not represent the totality of events, even during relaxation only. In addition, the peak minimum dP/dt is highly dependent on the left ventricular and the aortic systolic pressures.

197.7.2.7 Integrated Function

Cardiac output is considered a measure of integrated cardiovascular performance. Cardiac output is usually measured by thermodilution, a technique based on the indicator-dilution method. Thermodilution offers advantages because it does not require arterial puncture or the withdrawal of blood, and an inert and inexpensive indicator (e.g., cold saline or 5% dextrose in water) is used with virtually no recirculation. However, all indicator techniques require placement of a catheter in the pulmonary artery, which makes these techniques impractical for routine use in clinical veterinary medicine outside critical care units. Doppler echocardiography can also be used to estimate cardiac output. The stroke volume can be determined from the integrated velocity of blood flow across the aorta or pulmonary artery multiplied by the cross-sectional area of the respective valve orifice.[120] Doppler determination of blood flow velocity is a noninvasive method that can be performed in awake, untrained, dogs.[121] It is useful for documenting beat-to-beat variation in the stroke volume in dogs[122] and can be used to determine the cardiac output when the stroke volume is multiplied by the heart rate. As with thermodilution determination of cardiac output, Doppler-derived values for cardiac outputs are variable.[123] Cardiac outputs obtained by Doppler echocardiography and thermodilution show an excellent correlation[124]; however, the technique for obtaining cardiac output by echocardiography appears to be quite operator dependent. It should be remembered that cardiac output at rest is not a sensitive indicator of heart function during CHF because all compensatory mechanisms act to increase cardiac output.

197.7.3 What Tests Should I Use in a Clinical Patient?

Of all the tests available for the evaluation of cardiovascular function, a few are routinely used. Chest radiographs and echocardiography are performed in virtually all patients with CHF. Measurement of the arterial blood pressure and central venous pressure can be easily performed and provides important information about cardiovascular status. Not surprisingly, the most commonly used tests of cardiovascular function are based on echocardiography, whereas chest radiographs are used to confirm left-sided CHF. In the majority of patients, systolic performance is assessed by fractional shortening, the ejection fraction, or the end-systolic volume index. No clinical comparison of these indices has been performed in small animals, therefore the choice of index is a matter of personal preference. In selected patients the aortic velocity, time to peak aortic velocity, and cardiac output can be measured using Doppler echocardiography. Diastolic performance is usually assessed by Doppler evaluation of transmitral flow. In patients undergoing cardiac catheterization, pressure traces, dP/dt_{max}, cardiac output, and estimated systemic vascular resistance, among other measurements, can be obtained.

197.8 HOW DOES HEART FAILURE BECOME A PROGRESSIVE DISEASE?

197.8.1 Vicious Cycles in Congestive Heart Failure

Compensatory mechanisms activated during heart failure paradoxically serve simultaneously as adaptive, compensatory changes and, by causing myocardial cell death, as major contributing elements in the progression of CHF. Cell death in an already overloaded heart adds to the overload on survival myocytes in a vicious cycle. Three primary, interlocked vicious cycles ultimately result in myocardial cell death (Figure 197-18).

197.8.1.1 Increased Left Ventricular Afterload and Myocardial Oxygen Consumption (Cycle 1)

Vasoconstriction and increases in cardiac contractility and the heart rate help maintain blood pressure but also increase MVO_2. Increasing cardiac MVO_2 accelerates myocardial cell death. Wall stress (a function of afterload), contractility, and the heart rate are the main determinants of MVO_2. Myocardial hypertrophy reduces oxygen consumption by decreasing wall stress during ejection. Hypertrophy caused by increases in load, however, does not yield a normal heart. Load-induced hypertrophy sets the stage for myocardial death. An increase in afterload leads to further left ventricular dysfunction, and the patient spirals down until a new, decreased steady-state level is reached, where cardiac output is lower and vasoconstriction is higher than is optimal for the patient.

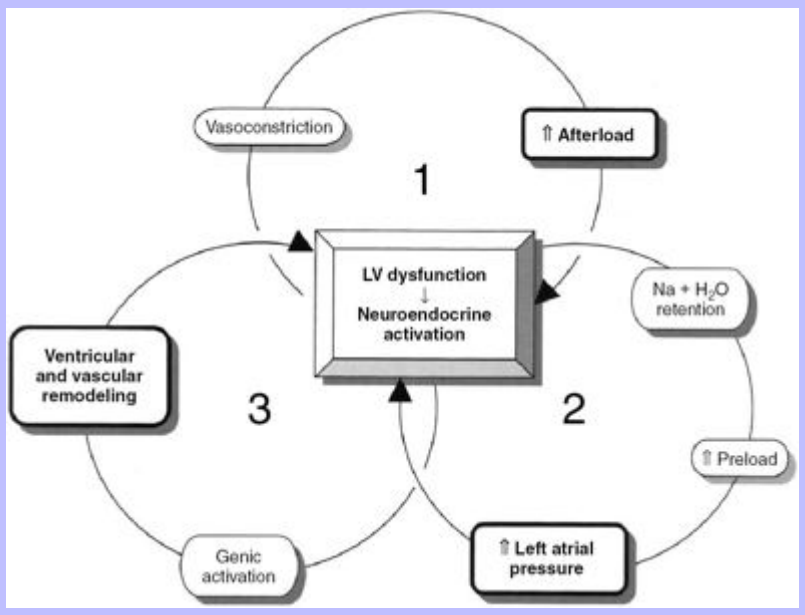
197.8.1.2 Sodium and Water Retention and Increased Left Atrial Pressure (Cycle 2)

Sodium and water retention increase the circulating volume, resulting in increases in preload and the left atrial pressure. An increase in preload increases cardiac output and helps maintain filling pressures but also leads to signs of congestion and edema. An excessive preload increases ventricular pressures, volume, and wall stress, further adding to the deterioration of left ventricular function.

197.8.1.3 Left Ventricular and Vascular Remodeling (Cycle 3)

Stretching of myocardium as a result of overload seems to be the initiating signal for adaptive processes to begin in the myocardium. This leads to hypertrophy as a result of growth factor and proto-oncogene stimulation.[66] Hypertrophy unloads the cells of the failing heart by adding new sarcomeres and also increases contractility and cardiac output. Unfortunately, hypertrophy ultimately leads to cellular abnormalities that result in mitochondrial deoxyribonucleic acid (DNA) abnormalities and apoptosis (programmed cell death), which hasten myocardial cell death.[66] Chronic neuro-endocrine activation, especially increases in angiotensin II and norepinephrine, and increases in afterload lead to left ventricular and vascular remodeling. Globally, the remodeling process in the ventricle is characterized by progressive left ventricular enlargement and increased chamber sphericity. At the cellular level, the remodeling process is associated with myocyte slippage, hypertrophy, and accumulation of collagen in the interstitial compartment. The final result of this process is the so-called cardiomyopathy of overload. Angiotensin II also causes vascular remodeling, which leads to hypertrophy of smooth muscle cells of the vessel walls.[125] Vascular remodeling decreases vessel compliance, thereby increasing ventricular afterload.

Figure 197-18 Interlocked vicious cycles that lead to progression of congestive heart failure: increased afterload (cycle 1), increased left atrial pressure (cycle 2), and ventricular and vascular remodeling (cycle 3). *LV,* Left ventricle.



197.8.1.4 Cardiomyopathy of Overload

Long-term overload-induce hypertrophy in the heart is accompanied by myocardial cell death and cardiac fibrosis. This progressive and eventually lethal growth abnormality has been called cardiomyopathy of overload.[23,66] In embryonic hearts, growth factors induce protein synthesis, leading to normal cell division. Soon after an animal is born, cardiac myocytes withdraw from the cell cycle and are no longer able to divide, and protein synthesis slows to rates appropriate for maintaining and repairing the cells. Stimulation of growth factors by chronic overload leads to an increase in protein synthesis. The cell cycle, however, remains blocked, and the end result is not normal cell division but abnormal hypertrophy. Increases in angiotensin II, a peptide that is not only a vasoconstrictor but also a mitogen, appear to be an important mediator of the reversal of protein synthesis inhibition in the adult heart.

Overload-induced hypertrophy leads to a state of chronic energy starvation in the heart. Because the increase in cardiac mass is not accompanied by an increase in capillary vessels, the hypertrophied ventricle outstrips its blood supply. The cell volume occupied by sarcomeres increases, leading to an increased ratio of mitochondria to myofibrils, which can exacerbate the energy deficit. The net result is a decrease in capillary density and coronary reserve, with the myocardium becoming prone to ischemia, especially in the subendocardium. The relative decrease in oxygen delivery complicates the failing heart's increased need for oxygen, which is already increased by vasoconstriction and sympathetic activation. Hypertrophy and increasing systolic dysfunction are closely linked. The ischemia resulting from hypertrophy leads to the development of focal fibrosis, which increases the myocardial collagen content. The early increase in

collagen helps maintain systolic function, but it also interferes with diastolic function. With progression of the myocardial hypertrophy, the early interstitial fibrosis progresses to perimuscular fibrosis, impairing both systolic and diastolic function. Myocardial cell necrosis occurs in overloaded hearts in the transition to heart failure. Myocyte cell death results not only from necrosis (accidental cell death) but also from apoptosis (programmed cell death). The activation of proto-oncogenes and the increased concentrations of TGF-1α that occur in CHF may induce apoptosis. Regardless of the cause, myocardial cell death occurs in overload-induced hypertrophy, increasing the overload in the surviving myocytes in a vicious cycle. Cardiomyopathy of overload, therefore, represents an unnatural growth of the adult heart that leads to myocardial cell death, progression of myocardial failure, and death.

197.9 SUMMARY

Heart failure is a state in which cardiac output is inadequate to meet the perfusion needs of the metabolizing tissues and exercise capacity is limited. It may be the result of inability of the heart to eject blood properly (systolic failure) or of inadequate ventricular filling (diastolic failure). Correct identification of the cause of heart disease and of the mechanism leading to heart failure allows the clinician to choose the appropriate therapy, thereby improving the prognosis.

Regardless of the mechanism, CHF is associated with a fall in blood pressure and activation of compensatory mechanisms aimed at restoring normal arterial blood pressure. These mechanisms include neuroendocrine activation and renal retention of sodium and water. Vasoconstriction, tachycardia, and volume retention are the initial responses of the circulation to the fall in blood pressure. Excessive compensatory response may lead to overcompensation, and compensatory mechanisms that are beneficial in the beginning become responsible for the development of clinical signs.

939

940

Therapy is aimed at modulating the excessively activated compensatory mechanisms. The inciting cause of the cardiac dysfunction and neuroendocrine activation also stimulates myocardial compensation, leading to increased contractility and relaxation, sympathetic desensitization, and unnatural growth (hypertrophy). Modulation of the unnatural growth response with drugs that have growth-inhibitory as well as vasodilative properties (e.g., ACE inhibitors and nitrates) may delay the appearance of cardiomyopathy of overload and improve the prognosis for patients with CHF. Myocyte changes determined by overload-induced hypertrophy ultimately lead to myocardial cell death, which further compromises myocardial function. Thus once a certain point of myocardial dysfunction is reached, CHF becomes a progressive, irreversible disease.

198 CHAPTER • 198 Biochemical Markers of Cardiovascular Disease

Karsten E. Schober

During the past decade, considerable research has been conducted into the use of circulating markers of myocardial cell integrity *(leakage markers)* and of specific proteins of cardiac function *(functional markers)*, their diagnostic capability, and their potential to aid therapeutic decisions and allow prognostic risk assessment in patients with cardiovascular abnormalities (Box 198-1). Biochemical screening for heart disease or for definition of the functional status of the heart in certain pet populations based on readily available circulating marker proteins such as cardiac troponins, natriuretic peptides, or endothelin is an attractive hypothesis. Moreover, the prospect of identifying dogs and cats with early asymptomatic or minimally symptomatic congestive heart failure (CHF) or patients at risk for sudden deterioration of ongoing disease processes via biochemical testing is exciting from several perspectives. For example, it would allow individuals without extensive training in cardiology to detect animals with cardiac abnormalities more accurately and at an earlier point in time. This would permit early therapeutic intervention and potentially reduce the morbidity and mortality associated with advanced stages of heart disease, while avoiding unnecessary treatment of unaffected or mildly affected animals. In addition, conditions that currently are still difficult to identify clearly with conventional diagnostic methods (e.g., myocarditis, ischemic heart disease, and pulmonary hypertension) could be detected more specifically.

Biochemical testing might also help clarify the status of animals with equivocal results from other diagnostic modalities, such as for dogs with borderline systolic function on echocardiography, animals with arrhythmias of unknown origin, or dogs with questionable cardiomegaly on thoracic radiographs. Other applications might include monitoring of the effects of potentially cardiotoxic drugs or of extracardiac disease on myocardial integrity and function.

The advent of biochemical markers also opens a category of the pathophysiologic aspect of nonischemic cardiac damage that is not yet fully understood or verified. It likely will provide important prognostic information and may prove useful for monitoring the success of treatment or for determining the need to change treatment protocols. Screening of certain breeding populations for asymptomatic myocardial diseases, such as hypertrophic cardiomyopathy (HCM) and dilated cardiomyopathy (DCM), may be another possibility.

198.1 LEAKAGE MARKERS

Circulating markers of myocardial integrity provide evidence of cell degradation, supplying the rationale for diagnosis of a disease process using such markers. That is, detection of intracellular constituents released into the blood when a cell either ruptures or loses membrane integrity allows identification of the damaged target tissue. Measurable changes in the serum concentration of these markers are determined primarily by the markers' molecular mass, intracellular compartmentalization, solubility, release kinetics, post-translational modifications, and assay characteristics; by local blood and lymphatic flow; and by the route by which the markers are cleared from the circulation.

Myocardial cell injury is a common event in the pathogenesis of heart failure in dogs and cats.[1,2] Pressure and volume overload, hypoxia and ischemia, abnormal neurohormonal stimulation, toxins, and cytokines all may cause myocardial remodeling, characterized by hypertrophy and dilatation or, at the cellular level, by oxidative and mechanical stress, degeneration, inflammation, fiber slippage, apoptosis, necrosis, and fibrosis of myocardial tissue that finally results in cardiac functional abnormalities.

Analysis of cardiac leakage markers has progressed from measurement of enzymes (e.g., plasma aspartate transaminase) to measurement of structural proteins, including cardiac troponins (see Box 198-1; Table 198-1). Although commonly used diagnostic procedures can serve as the current gold standard for the assessment of cardiac anatomy and function in clinical practice, they most often are inadequate for detecting and quantifying minor myocardial cell injury or active myocardial damage.

198.2 ALPHA-HYDROXYBUTYRATE DEHYDROGENASE (ALPHA-HBDH)

Lactate dehydrogenase (LD) is a tetrameric enzyme with *M* (muscle) and *H* (heart) subunits that is responsible for the interconversion of pyruvate and lactate as the final step in glycolysis. The two subunits are encoded by different genes and give rise to five distinct isoenzymes that provide LD with an element of tissue specificity. LD-1 has four H subunits, and LD-2 has three H subunits and one M subunit. LD-1 and LD-2 form alpha-HBDH, which has some cardiac specificity. However, because other sources of LD-1 and LD-2 exist (i.e., erythrocytes, as well as the brain, kidneys, pancreas, and stomach), tissue specificity for the detection of myocardial injury is rather poor. Reference values for alpha-HBDH in dogs and cats have been published (see Table 198-1),[3,4] but because more specific serum markers of myocardial cell damage are available, analysis of alpha-HBDH is no longer recommended for the diagnosis of myocardial injury in dogs and cats.

† After acute ischemic myocardial damage. “0” refers to the lower limit of detection of the assay used (1.0 ng/mL for Mb, 0.5 ng/mL for CK-MB, 0.1 ng/mL for cTnI [OPUS Troponin I; Dade-Behring Diagnostics, Westwood, Massachusetts], and 0.01 ng/mL for cTnT [ELECSYS 1010 Troponin T STAT; Boehringer, Mannheim, Germany]).

198.3 MYOGLOBIN (Mb)

Myoglobin is a low-molecular-weight heme protein that is abundant in cardiac and skeletal muscle but not smooth muscle. It is found predominantly in the cytosol of the cell.[5] Because of its high sensitivity and rapid release after myocardial injury, it has drawn considerable attention in the early diagnosis of acute myocardial infarction (AMI) in humans. It may be less clinically useful in animals, however, because of its low cardiac specificity and rapid clearance after injury, and because, compared with humans, dogs and cats have a low incidence of ischemic heart disease.

198.4 CREATINE KINASE ISOENZYME MB (CK-MB)

Creatine kinase (CK) is a dimeric enzyme with *M* (muscle) and *B* (brain) subunits, each having 381 amino acids.[5] CK catalyzes the transfer of a high-energy phosphate from adenosine triphosphate (ATP) to creatine, producing creatine phosphate. CK isoenzymes consist of CK-MM, CK-MB, or CK-BB. A unique dimeric mitochondrial form not composed of either M or B subunits also exists. Each subunit of CK is regulated by a distinct gene and is expressed in a tissue-specific manner. CK-MB is functionally unbound and cytosolically dissolved and is found predominantly in the myocardium[6] in concentration ranges of 1% to 42% of total CK activity of the heart. There is a significant difference in the concentration of CK-MB between normal and diseased myocardium,[6] depending on the disease state, the patient's age, the chronicity of myocardial stress, and the severity and duration of ischemia. Marked upregulation of CK-MB synthesis in cardiomyocytes may be seen after myocardial injury despite a decrease in absolute CK concentrations. Such dynamic CK-MB alterations may cause a significant elevation of the relative amount of CK-MB in ventricular myocardium within several weeks of the onset of disease. Circulating CK-MB is not 100% specific for cardiac muscle tissue, because a significant portion of CK-MB may be expressed in skeletal muscle, the lungs, intestines, and spleen. Moreover, CK-MB immunoreactivity is not well conserved across species,[7] and species-specific immunoassays for CK-MB are not commercially available for use in dogs and cats. CK-MB is released early after acute myocardial cell damage (see Table 198-1), is inactivated by proteolysis in lymph, and is rapidly cleared by the reticulo-endothelial system. In normal dogs and cats, CK-MB in serum is not detectable.[3,4]

941 942

198.5 CARDIAC TROPONIN (cTn)

Since the descriptions of the measurement of cardiac troponin T (cTnT) in 1989 and cardiac troponin I (cTnI) in 1992, analysis of circulating cTn has revolutionized the noninvasive diagnosis of acute coronary syndromes in human beings. Cardiac troponin levels allow more specific detection of myocardial damage than do traditional “cardiac enzymes” such as LD and CK-MB. A series of landmark clinical studies has defined cTn measurement as the gold standard test for AMI in humans. The advantage of cTn lies in its ability to provide an early, highly cardiac specific diagnosis of even micronecrotic pathology and prognostic risk assessment and to guide therapy. Despite the obvious lack of importance of ischemic heart disease in small animals compared with humans, studies performed in dogs and cats have suggested similar findings indicating superior efficacy of cTnI and cTnT in the diagnosis of myocardial injury in a variety of clinical conditions.[1–17]

198.5.1 Structure and Function

The troponin complex is made up of three structurally and functionally different proteins (TnI, TnT, and TnC), which exist in different isoforms in both skeletal and cardiac muscle but not in smooth muscle. It is located on the thin filament of the contractile apparatus that regulates the calcium-mediated interaction of myosin and actin. Although both TnI and TnT are present in skeletal muscle (in slow-and fast-twitch fibers) and cardiac muscle, they are encoded by individual genes, yielding proteins that are immunologically distinct. Cardiac troponin T has 276 amino acids and is a structural protein that binds the troponin-tropomyosin complex to the actin filament. Cardiac troponin I is a linear protein with five alpha-helices; it has 211 amino acids[18] and is an inhibitory protein that regulates muscle contraction. Its phosphorylation causes a decrease in the affinity of Ca^{2+} for the calcium-binding TnC, leading to inhibition of actomyosin ATPase activity. Cardiac TnI is uniquely specific to the heart, containing an additional 31-amino-acid sequence on its N-terminal region. The remaining amino acid sequence shows approximately 40% dissimilarity from skeletal muscle forms. In the cardiomyocyte, the troponins are compartmentalized into a major, structurally bound pool and a minor, free cytosolic pool, estimated at 6% to 8% for cTnT and 2% to 6% for cTnI. This cellular distribution determines release kinetics, with free cytosolic proteins released earlier. The third protein of the troponin-tropomyosin complex, TnC, has only two isoforms (160 and 161 amino acids) and is an 18 kDa protein with calcium-binding properties. The complete homology between the cardiac and the skeletal muscle isoforms of TnC has limited its diagnostic value.

198.5.2 Release, Degradation, and Clearance

Both loss of membrane integrity and cell necrosis cause the release of cTn from damaged cardiomyocytes. Two basic cTn release patterns have been postulated, depending on the type of underlying disease, the time to peak damage, and the severity of cell injury. In cases of slow disintegration of myofibrils, the release pattern may be biphasic, with the cytosolic pool released first. If the insult is more severe, a more protracted, persistent release from structurally bound stores may occur, representing irreversible cell damage. An important question is whether cTnI and cTnT leaks across the myocardial cell membrane in reversible injury, such as transient ischemia (*reversible injury* concept), as postulated by some investigators. In such cases, only mild cTn elevations and a temporary, monophasic release pattern would be expected.

Early work revealed that cTn first is released as a ternary complex of cTnT-I-C, which subsequently degrades into binary complexes of cTnI-C, free cTnT (with little or no free cTnI), and smaller immunologic fragments. However, more recent data suggest that troponin may already be degraded into small fragments within the myocyte. Once released into circulation, N-and C-terminal regions of cTn are particularly vulnerable to additional, progressive, and highly variable biochemical modifications, including phosphorylation, complex formation, and proteolytic cleavage. The newly formed degradation products may alter their recognition by monoclonal antibodies, affecting assay performance. Furthermore, different pathologic states (e.g., ischemia, inflammation, toxic injury) result in different post-translational profiles of cTn, with cTnI being more susceptible to postrelease modifications and less stable than cTnT.

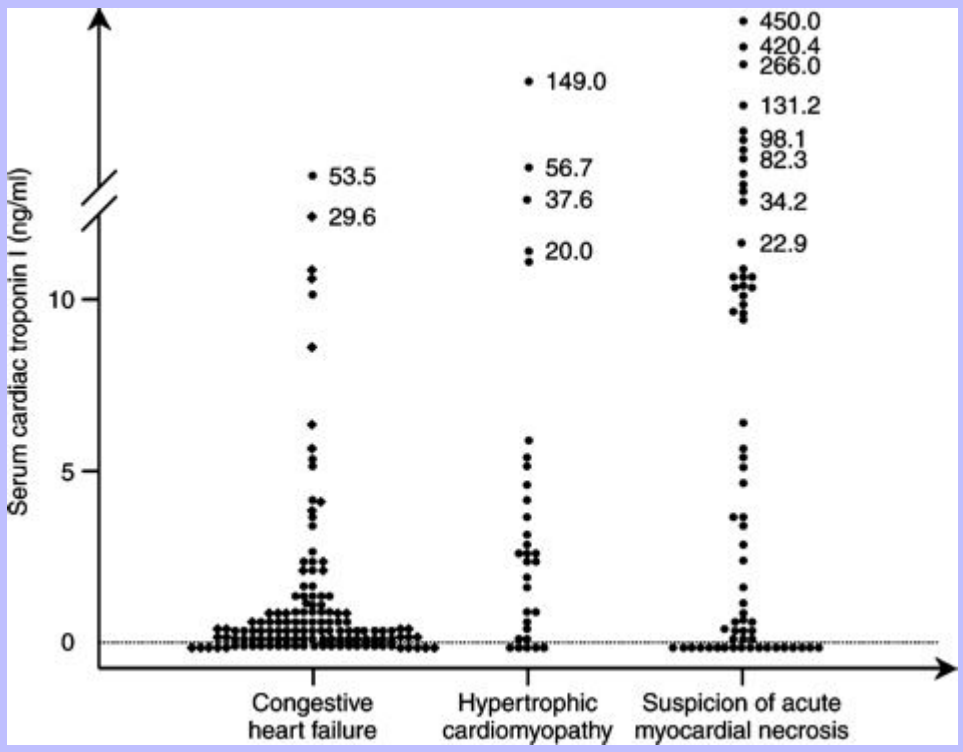
Clearance of cTn is not well documented. As with most marker proteins with molecular weights above 20 kDa, cTn appears to be catabolized in organs with a high metabolic rate, such as the liver and pancreas, and the reticuloendo-thelial system. The serum half-life of cTnT is approximately 120 minutes, with a prolonged window of detection due to continuous release of cTnT from the myofibrillar pool during the myocyte degradation processes.

198.5.3 Analysis

Clinicians must be aware of several analytic issues. Investigations in animals have demonstrated that both cTnI and cTnT immunoassays designed for use in humans can be used reliably and specifically to detect myocardial injury in dogs and cats, because cTn immunoreactivity has been highly conserved across species.[19] The monoclonal antibodies used in second-and third-generation assays for cTn analysis have no known species specificity and no detectable cross-reactivity with skeletal muscle isoforms.

Due to patent restrictions, assays for cTnT are available from only one manufacturer; they therefore are relatively uniform with regard to cutoff concentrations and precision. In contrast, at least 16 different assays for cTnI have been approved by the U.S. Food and Drug Administration (FDA). Because of the lack of standardization in cTnI assays, significant variability exists in the assay methods and cutoff values used. Up to 100-fold differences in absolute concentrations of cTnI for a given patient sample have been observed. With so much variation, attention must be paid to the assay used when the data and results of troponin I measurements are interpreted. Sample requirements for the different assays also may vary. The optimal sample material for most systems seems to be serum clotted adequately. The cTnT molecule is stable at a room temperature of 4° C and when frozen. Cardiac TnI is more susceptible to early epitope degradation; however, serum samples may be stored at room temperature for 4 days without clinically relevant reduction of detectable cTnI concentrations.[2,8,20] In terms of substate stability for analyns, differences between different CTnI assays may, however, exist.

Figure 198-1 Serum cardiac troponin I concentrations in 129 dogs with congestive heart failure (•, dilated cardiomyopathy; ♦, congestive heart failure of other cause), 31 cats with hypertrophic cardiomyopathy, and 67 dogs with the clinical suspicion of acute myocardial necrosis of non-cardiomyopathic origin based on the occurence of venticular arrhythmia. Zero CTnI refers to the lower limit of detection of the immunoassay used (0.1 ng/ml; opus® Troponin I, Dade-Behring Diagnostics Inc., Westwood, MA). From the veterinary medical database of the Department of Small Animal Medicine, University of Leip zig and reference 2 with permission.



198.5.4 Reference Intervals and Clinical Cutoff Values

In healthy dogs and cats, the background level of cTn in the circulation appears to be undetectable (see Table 198-1). Several clinical studies, involving more than 331 dogs[4,9,15–17,21] and 150 cats,[3,10,17,21–23] have shown that both cTnI and cTnT are below the detection limit of the assay used or occur only in trace amounts in the peripheral circulation. However, because of the very high sensitivity of second-and third-generation immunoassays, minimal elevations of cTn may occur in obviously healthy animals as a result of strenuous

exercise or noncardiac disease. This is particularly true for cTnI. To distinguish between minor myocardial cell damage (so-called micronecrosis) and major myocardial injury, two cutoff points were suggested for clinical use in humans: the upper reference limit, defined as the 97.5th percentile of the values measured in the normal control population, and a higher limit, indicating clinically relevant myocardial damage. Given the difficulties in objectively defining the latter value and the currently used, rather liberal thresholds, it is not clear whether the exact magnitude of troponin elevation is indeed essential for clinical decision making. From the clinician's point of view, it appears that characterizing patients as “troponin negative/mildly elevated” or “troponin positive/moderately to severely elevated” and dynamic monitoring of cTn concentrations are most useful for diagnosing and semiquantifying myocardial necrosis and for making a subsequent risk assessment.

198.5.5 Sensitivity and Specificity

When the most current assays are used, cTnI is elevated earlier and more frequently than cTnT in a variety of clinical conditions in dogs and cats, as confirmed by meta-analysis using 500 simultaneously measured serum samples.[2] Circulating cTn is highly specific for myocardial cell injury. Correlation of histopathologic findings with biochemistry results showed that elevated cTn values can be directly related to evidence of cardiac myonecrosis in dogs.[*]

Comparative values for differences in the level of cardiac specificity between cTnI and cTnT have not yet been defined in animals. In humans, however, both markers demonstrated equivalent specificity for myocardial damage. The author believes that cTnI has some advantage in terms of sensitivity, whereas cTnT appears to have a stronger association with the patient's outcome.

* References 2, 5, 7, 8, 12-14, and 16.

198.5.6 Circulating Cardiac Troponin in Disease

The diagnostic benefit of assessing myocardial injury in dogs and cats through cTn analysis has been shown in numerous studies (Figure 198-1).[2–5,7–12,15,16,23] Circulating cTn levels are frequently above normal in different clinical settings (Box 198-2), even in disease states in which acute myocardial necrosis is not a prominent aspect, such as dilated cardiomyopathy, chronic CHF, cardiac contusion, pericardial disease, or cardiac injury in critically ill patients. In general, increased concentrations of cTnI or cTnT in circulation reflect myocardial damage; thus cTn serves as a means to detect both major and minor injury. An association exists between the magnitude of myocardial damage and serum concentrations of cTn in acute situations; this has been verified by histopathologic testing in canine myocardial infarction,[5,7,11,12,16] gastric dilatation-volvulus syndrome (GDV),[8] canine myocarditis,[2,15,16] and dogs with sepsis.[2] In chronic myocardial disease, however, this relationship is not as obvious, for several reasons. Only minor myocardial injury may be present at the time of cTn determination; also, permanent leakage of cTn leads to a significant reduction in the tissue concentration of cTn over time.[13] Therefore absolute levels of circulating cTn do not necessarily represent the amount of irreversibly damaged myocardium in chronic situations.

In symptomatic canine DCM,[2,9,16] circulating cTn is increased in a significant number of patients (see Figure 198-1), with rather minor elevations being the most common finding.[2,9,16,21] Serial monitoring of cTn has revealed different release patterns (Figure 198-2) that not only define the status of the failing heart with regard to acute myocyte damage, but also provide prognostic information. Progressive left ventricular (LV) remodeling, a hallmark of DCM, leads to intermittent or permanent leakage of cTn into the circulation. In addition, the presence of coronary artery disease with small myocardial infarctions, focal myocarditis, and

increased wall strain may contribute to cTn release in heart failure. Elevated concentrations of circulating cTn in such patients reflect ongoing degradation of the contractile apparatus. Presumably, continuous loss of cTn facilitates the process of myocyte dysfunction that accompanies the spontaneous progression of heart failure. In humans, an inverse relationship between peak cTn values and LV function, as assessed by echocardiography, has been reported, and detectable cTn was associated with an adverse prognosis. A similar situation may be expected in animals. Clinical improvement in signs of CHF is associated with normalization of cTn levels, which may serve as a biochemical target in the management of DCM. Therefore dynamic monitoring of serum cTn is recommended in animals with heart failure.

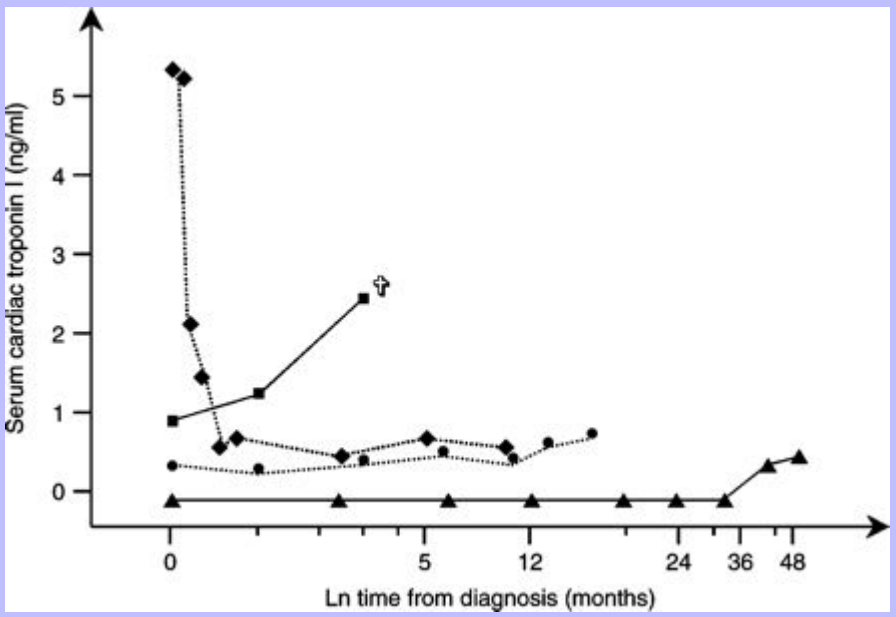
Detectable cTn concentrations in blood with asymptomatic DCM is a rare event that recently was described in only one of 28 affected dogs.[2,9,16] For this reason, screening of selected populations of dogs for DCM based on cTn analysis does not seem to provide any advantage over commonly used diagnostic methods. However, with further improvement of test sensitivities and with large-scale clinical trials in affected breeds, more promising findings may be anticipated.

Figure 198-2 Different patterns of cardiac troponin I release in 4 dogs with dilated cardiomyopathy (DCM). ♦ Pattern 1: High initial CTnI with fast decrease to mildly, but persistently elevated CTnI (German shephard dog, male, 10 years of age with acute congestive heart failure, prolonged episodes of ventricular tachycardia, and finally complete AV-block); ▪ Pattern 2: Mildly elevated baseline value of CTnI with fast increase despite medical management (German shepherd dog, male, 9 years of age with atrial fibrillation and slow onset of heart failure but fast progression and early death); • Pattern 3: Persistently low serum levels of cTnI (Great Dane, female, 8 years of age with atrial fibrillation); ▲ Pattern 4: Undetectable circulating CTnI for an advanced period of time with fully compensated DCM (Great Dane, male, 6 years of age with persistent atrial fibrillation and late onset of congestive heart failure). Zero CTnI refers to the lower limit of detection of the immunoassay used (0.1 ng/ml; OPUS® Troponin I, Dade-Behring Diagnostics Inc., Westwood, MA). †, died. (Recently unpublished observations).



Analysis of cTn may also be useful in cats with HCM, primarily to identify animals suspected of having inflammatory myocardial lesions or ischemic heart disease as a result of microvessel pathology or intramural coronary artery embolism. Circulating cTn is detectable in almost all cats with HCM, regardless of whether

heart failure is present.[2,10,19,21,23] Cats with CHF have higher cTn levels than cats with no clinical signs or those with a history of heart failure.[10] Further studies are needed to determine whether serum cTn levels may be used to differentiate HCM from other types of cardiomyopathy in cats and to obtain reliable prognostic information.

Monitoring of animals undergoing chemotherapy for signs of cardiotoxicity of antineoplastic drugs may be another promising application of cTn analysis. A small-scale clinical trial in dogs with lymphosarcoma has provided evidence of detectable myocardial injury at cumulative doses of doxorubicin of at least 150 mg/m^2.[6] It has been recommended that serum cTnT levels be analyzed 2 to 3 weeks after each dose of doxorubicin beyond a 90 mg/m^2 cumulative dose. Elevations of cTn may accurately predict the future development of LV systolic dysfunction and ventricular arrhythmias in dogs with anthracycline chemotherapy.

944

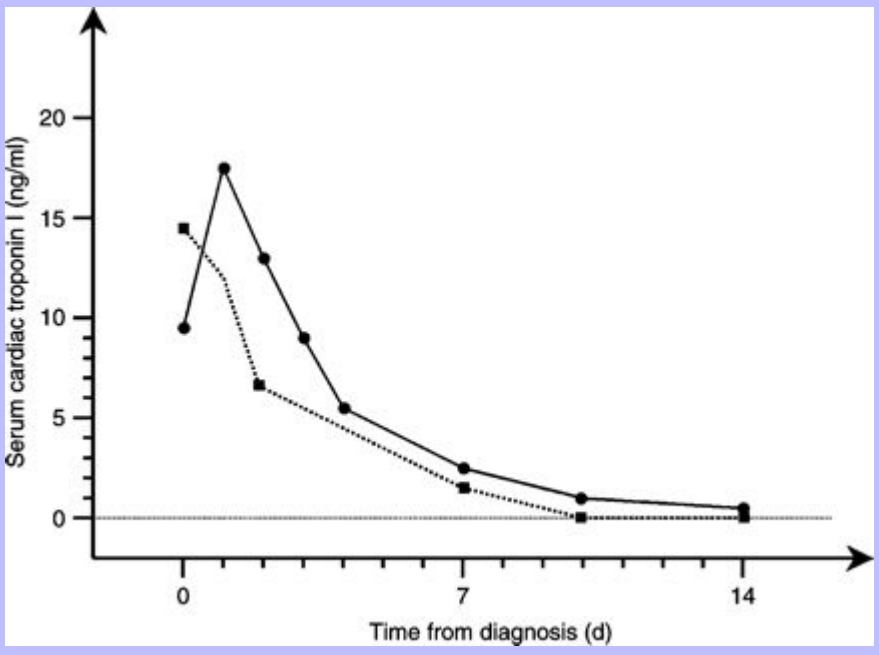
Figure 198-3 Cardiac troponin I release in 2 dogs with suspected acute myocardial necrosis. •, Old English sheepdog, male, 9 years of age with a splenic mass and polymorphic ventricular arrhythmia on days 0, 1, and 2. Splenectomy was done on day 1. ▪, Doberman pinscher, female, 2 years old with acute spinal cord trauma on the day before admission and ventricular arrhythmia prior to and after surgery done on day 0. Zero CTnI refers to the lower limit of detection of the immunoassay used (0.1 ng/ml; OPUS® Troponin I, Dade-Behring Diagnostics Inc., Westwood, MA). (Recently unpublished observations).



Subendocardial injury caused by increased myocardial stress can induce a rise in cTn in patients with arterial hypertension, tachycardia, aortic and pulmonic stenosis,[2] volume overload, or pulmonary embolism. Alternatively, increased serum concentrations of cTn may occur after severe blunt trauma to the thorax that causes myocardial contusion[3,4,9] or in response to severe hypotension or the release of endogenous substances in critically ill patients (e.g., in animals with multiple organ dysfunction syndrome in GDV or after septic shock).[2,8] The clinical usefulness of serial cTn analyses in detecting myocardial cell injury, predicting electrocardiographic abnormalities, and identifying patients at high risk for a fatal outcome has previously been reported in dogs with GDV.[8] In those studies, the predictive abilities of cTnI and cTnT for an adverse outcome were comparable. Furthermore, increased levels of cTn were observed in dogs with pericardial disease,[2,16,24] suggesting involvement of the myocardium in ischemic, degenerative, or inflammatory processes, and in animals with cerebrovascular events and splenic masses (Figure 198-3), most likely due to myocardial necrosis secondary to abnormal catecholamine release.

Monitoring of circulating cTn may also be useful for assessing myocardial cell damage caused by DC cardioversion or interventional cardiac procedures. In addition, cTn analysis has been used to detect myocyte injury in clinically suspected myocarditis and endomyocarditis in dogs[2] and in experimental myocarditis in laboratory animals. However, the diagnosis of myocarditis can be confirmed only by immune histochemical techniques using tissue samples, which makes unambiguous clinical diagnosis based on elevated cTn concentrations difficult. The extent to which knowledge of the troponin status could affect medical care under these conditions deserves further investigation.

198.6 FUNCTIONAL MARKERS

Since the discovery of atrial natriuretic peptide more than 20 years ago, it has been apparent that the heart is not only a simple pump, but also a true endocrine organ that releases specific hormones in response to defined stimuli. Recent studies in humans and preliminary findings in dogs[25–34] and cats[35–37] with heart disease indicate that biochemical markers of cardiovascular function, such as natriuretic peptides (NPs) and endothelin (ET), as well as circulating catecholamines, vasopressin, aldosterone, and cytokines, including tumor necrosis factor-alpha (TNF-alpha), can be used to identify patients with heart disease, to predict disease severity, to monitor therapy, and to obtain prognostic information. In the near future, routine immunoassays for functional marker proteins may provide a preliminary test of cardiac performance and may permit clinicians to more carefully select patients for further investigation and treatment.

198.6.1 Natriuretic Peptides

Natriuretic peptides belong to a unique family of naturally occurring, structurally similar, but genetically distinct hormones that share a central loop containing 17 amino acids closed by a disulfide bond between 2 cysteine residues, with variable carboxy-terminal and amino-terminal tails. The NPs include atrial natriuretic peptides (ANP), brain natriuretic peptides (BNP), C-type natriuretic peptides (CNP), dendroaspis natriuretic peptides (DNP), and urodilatin. The NPs act as key regulators of salt and water homeostasis and blood pressure control. They have potential value as diagnostic and prognostic markers and as therapeutic tools for several clinical conditions associated with expanded fluid volume, such as CHF.

198.6.1.1 Atrial Natriuretic Peptides and Brain Natriuretic Peptides

198.6.1.1.1 Structure

ANP is typically produced by the left and right atrium but may also be expressed in the ventricular myocardium, particularly with ventricular hypertrophy or myocardial ischemia. ANP transcripts also may be present in noncardiac tissues. ANP is synthesized as pre-proANP, which contains 153 amino acids in cats.[38] After cleavage of a 25-amino-acid signal peptide, the precursor proANP, consisting of 128 amino acids, is stored in atrial myocyte granules. In response to an adequate stimulus, proANP is split by a membrane-bound protease into inactive 98-amino-acid N-terminal (NT)-proANP and biologically active 30-amino-acid C-terminal ANP on an equimolar basis and released into the blood. NT-proANP may be further cleaved into smaller, endocrinologically active fragments.[38] The amino acid sequences of ANP and CNP have been highly conserved across species. Canine and human mature ANP are structurally very similar.

Under normal conditions, BNP is produced primarily in the cardiac atria, with very little synthesis in the ventricles. In cardiac pathologies with chronic pressure or volume overload or ventricular hypertrophy, ventricular myocytes become the major source of BNP. Minor extracardiac BNP production has also been reported. Unlike with ANP, regulation of BNP synthesis and excretion occurs mainly at the level of gene expression. Cardiac BNP is stored to a much smaller extent than ANP (coexisting with ANP in granules of atrial and ventricular myocardium), therefore increased BNP release requires increased synthesis. BNP arises from a single precursor pre-proBNP molecule containing 132 amino acids in cats.[39] The signal peptide has 26 amino acid residues, followed by 106 amino acids of proBNP. This peptide is further processed into mature, active BNP that has 35 amino acid residues at the C-terminus, with likely 26 and 29 amino acid isomers. The biologically inactive peptide, NT-proBNP, has 71 amino acids in cats.[39] BNP and NT-proBNP are secreted into the circulation in equimolar quantities. Mature BNP in dogs and humans has only 32 amino acid residues. In contrast to ANP, there is much variability in the length and structure of BNP across species, and the predominant forms differ considerably, resulting in variations in cross-species actions.

945

946

198.6.1.1.2 Physiologic actions

The principal function of NPs is to protect the cardiovascular system from volume overload. The major biologic effects of ANP and BNP are qualitatively similar and include potent natriuresis, diuresis, and balanced vasodilatation. Both NPs antagonize the renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system (SNS), inhibit the release and action of vasopressin, prevent myocardial fibrosis, and modulate cell growth and myocardial hypertrophy. In addition to the many other important actions of natriuretic peptides, ANP, in particular, enhances vascular permeability, causing redistribution of plasma volume to the extravascular space. The biologic actions of NPs are mediated by two specific receptors, natriuretic peptide receptor type A (NPR-A) and natriuretic peptide receptor type B (NPR-B). A third natriuretic peptide receptor, NPR-C, mainly acts as a clearance receptor. NPRs are widely distributed throughout the body and can be found in the heart, kidneys, vascular endothelium and smooth muscle, adrenals, and central nervous system.

198.6.1.1.3

Release, metabolism, and clearance

ANP secretion is controlled by immediate release from previously synthesized atrial storage granules in direct proportion to atrial stretch,[25,26,29,31,35] which occurs during intravascular volume expansion. Only a minor part is derived from newly synthesized hormone. A second stimulus for ANP secretion is an increase in the heart rate.[26,31,35] The plasma concentration of ANP therefore can change rapidly in response to acute alterations in posture, volume loading, or tachycardia. Thus ANP is a good marker of acute volume overload or of rapid hemodynamic changes. Release of BNP is chiefly controlled at the transcription level, with increased secretion preceded by an increase in messenger ribonucleic acid (mRNA) production. Therefore, in contrast to ANP, a longer term stimulus is required to increase plasma BNP concentrations; this makes BNP blood levels less susceptible to wide fluctuation in response to short-term external stimuli. The production and secretion of BNP are regulated by myocardial stretch and wall tension, primarily that induced by volume load. Circulating BNP is also increased in ventricular dysfunction and in states of ventricular hypertrophy (even in the absence of elevated intraventricular pressure). Atrial production of BNP occurs within 60 minutes of stretch, whereas ventricular production of BNP is stimulated within a few hours. In humans, the plasma half-life of ANP and BNP is approximately 1 to 3 minutes and 20 to 22 minutes, respectively, and that of both N-terminal peptides is 60 to 120 minutes.

Clearance of NPs occurs through two major mechanisms: first, binding to NPR-C, which is followed by endocytosis and subsequent lysosomal degradation, and second, degradation by the nonspecific membrane-bound enzyme neutral endopeptidase 24.11 (NEP), in a competitive fashion. However, enzymatic degradation via NEP does not seem to be as important for N-terminal fragments, resulting in longer half-lives. A small amount of the NPs is accounted for by renal elimination (less than 15%) and other nonspecific degradative enzymes. The liver, lungs, and especially the kidneys are major sites of extraction of the NPs.

198.6.1.1.4

Analysis, storage, and reference intervals

Currently, no consensus exists on the best procedure for measuring NPs in humans and animals, because determination by different immunoassay methods is affected by several analytic problems concerning a lack of sensitivity, specificity, and precision. Commercial assays are not yet standardized, and the results obtained with assays from different manufacturers may differ markedly, affecting reference intervals and decision limits. Commonly used assays for measuring NPs are either competitive immunoassays (radioimmunoassay [RIA] and electroimmuno-assay [EIA]) or noncompetitive sandwich immunoassays (IRMA and EIMA). RIA methods use radiolabeled tracers and usually require a time-consuming extraction step before NPs can be measured. In addition, the detection limit of RIA tends to be higher than that of IRMA. IRMA methods are generally highly sensitive and more specific, and extraction and purification of plasma samples are not required. NT-proANP and NT-proBNP are larger molecules than the C-terminal biologically active peptides, which makes it easier to use immunometric assay design to measure them. In addition, much higher plasma concentrations of the N-terminal fragments (20 to 50 times) and longer plasma half-lives lead to high analytic precision. Unlike the universal nature of ANP antibodies, antibodies for BNP are species specific. Therefore, in contrast to assays for ANP and NT-proANP, C-or N-terminal human BNP assays cannot be used in dogs and cats.

The *in vitro* stability of BNP, NT-proBNP, and proANP in ethylenediamine tetra-acetic acid (EDTA) in whole blood at room temperature is sufficient for routine use. BNP is stable for up to 72 hours, even in the

absence of aprotinin. NT-proBNP and proANP appear to be stable for up to 48 hours, and NT-proANP for 6 hours, in whole blood. ANP is stable only for 2 to 3 hours in blood at room temperature, it is stable for up to several months in plasma frozen at −80° C.

Because of the lack of assay standardization and the differences in methodology, no generally applicable reference intervals for NPs and their N-terminal prohormone fragments can be defined. In addition, normal plasma concentrations of NPs have been shown to increase with age[27] and to be dependent on gender and body weight.[27] Thus reference limits vary, depending on the nature of the control population and the assay used. In general, circulating ANP and BNP concentrations in normal subjects are very low, ranging from 3 to 15 pmol/L* for different assays, with plasma BNP being lower than ANP. Unlike ANP, circulating BNP does not generally show rapid and wide fluctuations in healthy subjects. A cutoff point for BNP (23 pmol/L) for the detection of heart failure in humans more than 55 years of age was recently suggested (BNP-Triage; Biosite Diagnostics, San Diego, California). Small-scale clinical trials in healthy dogs reported similar values for plasma ANP[25,29,31] using a human RIA (means between 10 and 22 pmol/L) and for plasma BNP using a porcine RIA[25,27] (means of 7.0 and 13.6 pmol/L). Preliminary RIA studies in healthy cats revealed a normal BNP range of 1.6 to 8.3 pmol/L (mean, 3.3 pmol/L).[35] As mentioned earlier, the plasma concentrations of N-terminal NPs are much higher than those of ANP[25] and BNP. The NT-proANP concentration has been reported in normal pets (mean, less than 500 pmol/L in dogs[25–27]; and 540 pmol/L in cats),[35] and an optimal cutoff point for cardiac decompensation in Cavalier King Charles spaniels with chronic mitral valve disease (MVD) has been suggested (700 pmol/L).[25]

946 947

* Equivalent units of measurement can be determined as follows: 1 pmol/L of ANP = 3.1 pg/mL; 1 pmol/L of BNP = 3.5 pg/mL; 1 pmol/L of NT-proANP = 10.5 pg/mL; and 1 pmol/L of NT-proBNP = 8.6 pg/mL.

198.6.1.2 Circulating Natriuretic Peptides in Disease

In general, the plasma concentrations of the NPs are increased in disease states characterized by an expanded fluid volume, reduced renal clearance of the peptides, and stimulation of peptide production (e.g., disease states caused by ventricular hypertrophy or myocardial strain, tachycardia, hypoxia, ectopic production from tumor, or excessive circulating glucocorticoid or thyroid hormones). However, the most promising use of NPs may be in their diagnostic potential as functional markers of cardiac disease. As with increased levels of circulating cTn, ANP and BNP are not specific for a particular cardiac pathology. Plasma levels of NPs are increased in many disease states, including chronic MVD, DCM, pacing-induced heart failure, aortic stenosis, congenital heart disease, and dirofilariasis in dogs[25,26,29,31–34] and in different types of cardiomyopathy in cats.[35] In addition, elevated concentrations of NPs have been demonstrated in humans with AMI, hypertension, supraventricular tachycardia, cardiac amyloidosis, myocarditis, right ventricular dysfunction and hypertrophy due to chronic respiratory disease, renal failure, and severe LV diastolic dysfunction.

Considering that ANP originates primarily from the atria and BNP from the ventricles, increased circulating levels of these peptides may reflect different abnormalities. Thus, depending on the underlying disease process in heart failure patients, the secretion pattern of ANP and BNP may vary. ANP and NT-proANP have been shown to be more useful than BNP in the overall assessment of disease severity in chronic MVD[25] and cardiac abnormalities characterized by acute volume overload. In addition, particularly high concentrations of NT-proANP have been reported in patients with DCM and atrial fibrillation compared with

DCM and sinus rhythm.[26] However, BNP is more sensitive than ANP in detecting chronic LV systolic and diastolic dysfunction and ventricular hypertrophy of any cause. BNP secretion increases in proportion to the severity of LV dysfunction.[32] The negative predictive value is the strongest feature of this peptide in humans (more than 90%); however, the reverse is not true, because the positive predictive value is only 30% to 40% in people. BNP analysis may be used as a screening tool, with a value in the normal range virtually excluding LV systolic dysfunction. However, analysis of BNP is not a stand-alone test. An increase in BNP would always warrant follow-up examinations, such as echocardiography, to identify the underlying cardiac pathology. NT-proBNP and BNP appear to be equivalent markers for the detection of LV dysfunction, but the N-terminus has some clinical advantage with respect to plasma concentration, half-life, and stability.

In contrast to humans, there is limited evidence in dogs and cats suggesting that plasma NPs are useful markers for the detection of LV dysfunction in asymptomatic patients.[32] NT-proANP has been found elevated in only a subset of dogs with asymptomatic chronic MVD[25] or DCM[26] despite significant cardiac enlargement. However, in cats with hypertrophic, restrictive, or unclassified cardiomyopathy and no clinical signs, proANP, NT-proANP and, in particular, BNP were raised. If BNP or its N-terminal fragment emerge as a superior diagnostic marker of LV dysfunction in companion animals with asymptomatic heart disease, it may also be used for routine screening for DCM and HCM in selected, high-risk populations; however, this requires further confirmation. In humans, for the time being, analysis of circulating BNP is the most promising biochemical marker for the diagnosis of CHF and has shown the best characteristics for a screening test.

Circulating NP levels have been shown to correlate with the class of heart failure in dogs,[25,26,29,31–33] and their measurement may allow veterinarians to offer pet owners a more accurate long-term prognosis. Elevated concentrations of BNP and NT-proBNP were found to be independent predictors of increased mortality in humans with CHF and both systolic and diastolic dysfunction. In addition, BNP correlates with right and left ventricular mass and may potentially be used as a marker for ventricular remodeling in hypertension and HCM. ANP as well as BNP may also be clinically useful as a biochemical discriminators of cardiogenic and noncardiogenic cough and dyspnea.

As congestion in heart failure is relieved, the levels of ANP and BNP rapidly regress,[29] thus serial analyses of plasma NPs might also prove useful as a guide to therapy in chronic CHF. Moreover, determination of circulating NPs may be used to identify patients that would likely benefit from therapeutic angiotensin-converting enzyme (ACE) inhibition or beta-receptor blockade. In the future, the treatment of patients with CHF may be tailored by neurohormonal profiling.

198.6.1.3 Other Natriuretic Peptides

C-type natriuretic peptide is primarily secreted by vascular endothelial cells and has local vasodilatatory and antiproliferative effects. It is usually undetectable in cardiac tissue. DNP was first isolated from the venom of the green mamba snake but has also been found in human plasma. Its importance in small animal cardiology has not yet been determined. Urodilatin (ANP 95-126) is localized in the kidney and secreted into the urine. It is a paracrine factor involved in the local regulation of body fluid volume and water and electrolyte excretion.

198.7 ENDOTHELIN

Endothelin (ET) belongs to a family of vasoactive peptides, including ET-1, ET-2, ET-3, and ET-4, that are genetically distinct. ET is composed of 21 amino acids in humans, dogs, and cats and is derived from precursors known as pre-proET, which has 212 amino acid residues. The large precursors undergo intermediate cleavage by endopeptidases to form the biologically inactive proET, also called big ET. Big ET is converted to active ET by endothelin-converting enzyme (ECE), which exerts its effects either locally or after release into the circulation. The predominant form of ET produced by endothelial cells and cardiac myocytes is ET-1. It has a wide spectrum of biologic actions, which are mediated by three receptor subtypes: ET_A, ET_B, and ET_C. ET_A is selective for ET-1, but the other receptor types are considered nonselective. ET-1 is a strong, long-lasting, balanced vasoconstrictive agent with inotropic and mitogenic actions; it is a potent stimulus for activation of the RAAS and SNS and plays an important role in the regulation of vascular tone and blood pressure.

Release of ET is regulated at the level of gene expression and peptide synthesis because cells do not store ET. The ET system is activated and synthesis of ET-1 is induced within minutes in response to a variety of factors, including pulsatile stretch, low shear stress, hypoxia, angiotensin II, epinephrine, cytokines, and growth factors. Most ET-1 (about 90%) is released from endothelial cells abluminally, where it acts on endothelial and smooth muscle cells as an autocrine and paracrine mediator. The concentration of ET in vascular tissue is approximately 100 times higher than in plasma. The plasma half-life of ET-1 in healthy humans is only 1 to 4 minutes because it is rapidly cleared from the circulation by ET_B receptors, the kidneys, and NEP. The plasma ET-1 level therefore may not accurately reflect the synthesis of ET-1. The plasma big ET-1 level has been proposed as a more reliable measure of ET-1 synthesis because its removal from the circulation is slower and less variable.

947

948

Plasma ET currently is analyzed either by RIA or by enzyme-linked immunosorbent assay (ELISA). In healthy humans, the plasma ET-1 concentration ranges from 1 to 5 pg/mL. Preliminary results from small scale clinical studies in healthy dogs[40] and cats[37] reported mean (±SD) plasma ET-1 concentrations of 2.07±0.15 pg/mL and 0.805±0.230 fmol/mL, respectively. However, many problems are still associated with the measurement and interpretation of plasma ET-1 concentrations, because the assays available are not yet standardized. In dogs, plasma ET immunoreactivity can be broken down as about 60% big ET-1, 30% ET-1, and 10% ET-3.[30] Because of marked cross-reactivity of the ET antibodies used in current assays, the more realistic term *ET-like immunoreactivity* should be used, rather than “ET-1 concentration.”

There is compelling evidence that the ET system is activated in CHF in people, dogs[33–40], and cats[37] and therefore may be diagnostically useful. Plasma ET–like immunoreactivity is increased twofold to tenfold in CHF compared with controls, regardless of disease etiology, and the magnitude of elevation correlates with hemodynamic compromise and functional class in people and small animals.[37,40] The plasma level of ET appears to be a less powerful discriminator between patients with asymptomatic or mild CHF and control subjects with normal function compared with BNP, NT-proBNP, and NT-proANP but is equally sensitive for predicting short-term mortality. An alternative approach may be measurement of the salivary ET concentration. In addition, ET seems to be important in the pathogenesis of primary and secondary pulmonary hypertension, and a close correlation between plasma ET-1 levels and the extent of pulmonary circulatory abnormalities has been identified in dogs[40] and people. This relationship is unique and deserves further attention with regard to the diagnostic and therapeutic potential of ET-1 and ET-1 antagonists in pulmonary hypertension.

198.8 OTHER MARKERS OF CARDIOVASCULAR FUNCTION

TNF-alpha is a proinflammatory cytokine that seems to be involved in the pathophysiology of CHF. It is produced mainly by activated macrophages but is also expressed in failing cardiac tissue. TNF-alpha has a variety of biologic effects, including induction of cachexia, ventricular systolic dysfunction, pulmonary edema, and direct myocardial cytotoxicity. Moreover, it may play a role in apoptosis, cell dropout, and myocardial fibrosis associated with ventricular remodeling, leading to progression of heart failure. The bioactivity of TNF-alpha and its soluble receptors in serum is likely to be increased in patients with chronic CHF,[36] particularly in association with increased severity of disease. As such, TNF-alpha may be used as a marker of disease progression. In addition, increased circulating concentrations of TNF-alpha may provide a potential target for therapeutic interventions.

Considerable evidence in humans indicates the presence of abnormal endothelial function in patients with CHF, resulting in impaired tissue perfusion, myocardial ischemia, and vascular remodeling. Elevated levels of proinflammatory cytokines, increased vasomotor tone, and reduced vasodilator response to exercise may be responsible for the impairment of endothelium-dependent vasodilatation. Nitric oxide (NO), also called *endothelium-derived relaxing factor (EDRF)*, has important regulatory functions in the cardiovascular system. As with NPs, NO is a functional antagonist of ET and angiotensin II. It is expressed in the vascular endothelium and the myocardium. In heart failure, endothelial release of NO is impaired and myocardial NO synthesis is increased, leading to reduced vasodilatation, negative inotropic and chronotropic effects, and loss of cardiomyocytes. Circulating NO has previously been used as a functional marker of cardiovascular disease in humans. Prospective studies in dogs and cats are needed to determine the exact role of NO as a circulating biomarker of disease.[41,42]

Adrenomedullin is another vasodilating and natriuretic peptide that shows increased plasma concentrations with heart failure. The blood levels of adrenomedullin correlate with the pulmonary artery and pulmonary wedge pressures in patients with CHF and therefore may be used as a marker of pulmonary hypertension. However, its diagnostic importance has not yet been elucidated in companion animals.

199 CHAPTER • 199 Therapy of Heart Failure

Barret J. Bulmer

D. David Sisson

Heart failure may be recognized as a clinical end-point in nearly all cardiac diseases. Because the underlying cause of the development of heart failure varies significantly between species and disease conditions, it is often difficult to define heart failure accurately and concisely. In 1994, a panel of the National Heart, Lung and Blood Institute concluded:

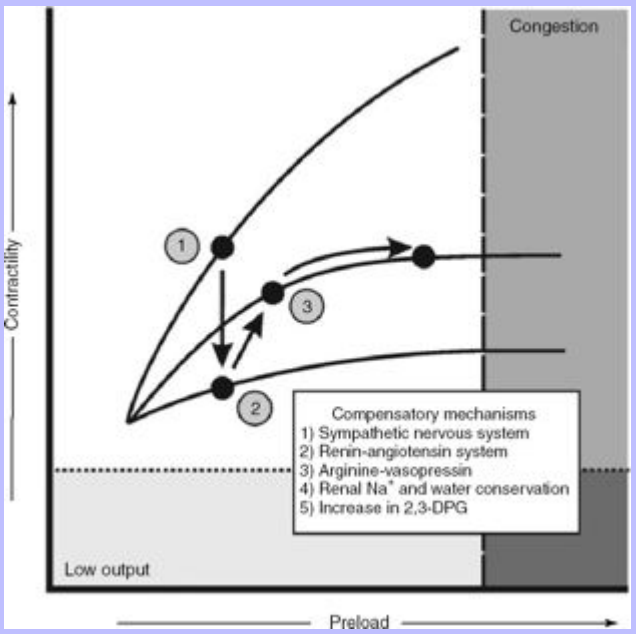
> *Heart failure occurs when an abnormality of cardiac function causes the heart to fail to pump blood at a rate required by the metabolizing tissues or when the heart can do so only with an elevated filling pressure. The heart's inability to pump a sufficient amount of blood to meet the needs of the body tissues may be due to insufficient or defective cardiac filling and/or impaired contraction and emptying. Compensatory mechanisms increase blood volume and raise cardiac filling pressures, heart rate, and cardiac muscle mass to maintain the heart's pumping function and cause redistribution of blood flow. Eventually, however, despite these compensatory mechanisms, the ability of the heart to contract and relax declines progressively, and the heart failure worsens.*[1]

Because all cardiac diseases have the potential to produce heart failure through similar mechanisms, we frequently view their pathophysiology and therapy from a unified perspective. Agents that promote preload and afterload reduction are used to control the clinical signs associated with elevated filling pressures, and neurohormonal modulators are prescribed to blunt the progressive nature of heart disease. This approach allows clinical experience and research to be extrapolated across a wide range of diseases. Although the remainder of this chapter is written primarily from a unified perspective, caution must be exercised to ensure that the variations within cardiovascular diseases are not forgotten.

199.1 PHASES OF HEART FAILURE

Currently, three distinct phases of heart failure are recognized. Phase 1 constitutes the initial cardiac injury. This phase most frequently passes silently, without detectable clinical signs, because compensatory mechanisms (phase 2) are quickly activated (Figure 199-1). Ultimately, myocardial hypertrophy accounts for the long-term stabilization of cardiac output and the normalization of afterload. Unfortunately, the natural history of cardiac disease often is progressive, and the heart's ability to hypertrophy is overwhelmed. The previously beneficial short-term compensatory mechanisms now serve only to increase both preload (contributing to the development of congestion) and afterload (increasing myocardial work and oxygen demand). Often a heart murmur, gallop rhythm, cardiac arrhythmia, or cardiomegaly may be identified during this second phase despite the absence of significant or activity-limiting clinical signs. Phase 3 of heart failure is recognized by the emergence of clinical signs (e.g., exercise intolerance, lethargy, coughing, tachypnea) at rest or with minimal activity. Veterinary patients apparently do not show clinical signs that are recognized by their owners until very late in the disease process. Presumably this may skew our understanding of the natural history of canine and feline cardiovascular disease. This understanding of disease progression is further clouded by the recognition that, depending on the disease process, the first clinical event may be the development of systemic thromboembolism, syncopal episodes, or possibly sudden death.

Figure 199-1 The short-term compensatory mechanisms that help normalize cardiac output during the initial injury often prove detrimental in the face of long-standing cardiac disease.



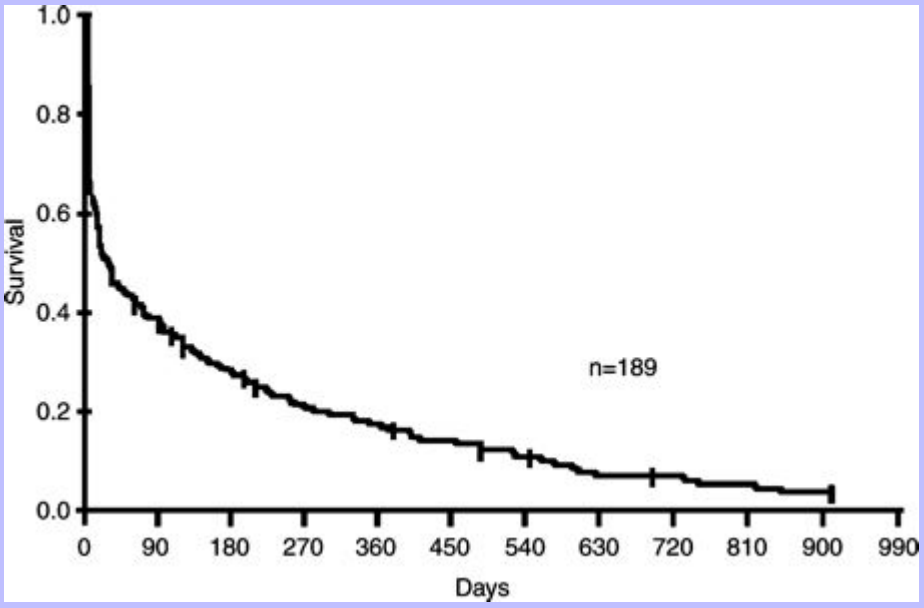
199.2 NATURAL HISTORY OF CARDIOVASCULAR DISEASE

Despite decades of treatment of cardiovascular disease in companion animals, relatively few studies have reported on the survival characteristics of patients afflicted with dilated cardiomyopathy,[2–4] mitral insufficiency,[5] and hypertrophic cardiomyopathy.[6] The spectrum of clinical signs, therapeutic strategies, breed differences, and disease sequelae hampers the formation of any sweeping conclusions regarding the natural history of these cardiovascular diseases; however, some generalities may be recognized. After dilated cardiomyopathy has been diagnosed, the survival curve drops precipitously for the first 3 months, with median survival times from two retrospective studies reported as 27 days and 65 days.[2,3] Months 3 through 6 continue to see a large number of dropouts, although interestingly, the curves appear to flatten markedly at approximately 6 months after the initial diagnosis (Figure 199-2). Whether this represents differences in individual responses to therapy or in the severity of disease at the time of diagnosis is difficult to ascertain.

Analysis of the survival curves for cats with hypertrophic cardiomyopathy presenting with congestive heart failure (CHF) or aortic thromboembolism (ATE) that lived for greater than 24 hours initially showed a steep slope similar to that seen in dogs with dilated cardiomyopathy (Figure 199-3).[6] Approximately 25% of the CHF group and 40% of the ATE group died within 3 months of diagnosis. After 3 months, cats presenting for congestive heart failure began to display a less steep, linear survival curve that concluded in a plateau several years after the diagnosis. The survival curve for cats with ATE also displayed some flattening after the first 3 months, although it ultimately remained linear for the rest of the study period. The median survival times were 563 days and 184 days,

respectively, for cats with congestive heart failure and those with aortic thromboembolism.[6] Cats with subclinical hypertrophic cardiomyopathy were significantly more likely to die of noncardiac disease ($P < 0.001$) and displayed a linear mortality curve for the first 4 years, followed by a prolonged plateau for an additional 4 years.[6]

Figure 199-2 Historically the survival of dogs with dilated cardiomyopathy has been poor, presumably because the disease is significantly advanced at the time of diagnosis. Whether earlier identification of occult DCM, with subsequent administration of neurohormonal antagonists (beta blockers, aldosterone antagonists, ACE inhibitors) or potent positive inotropes (pimobendan), could alter this disease course is uncertain. (From Tidholm A: Survival and prognostic factors in 189 dogs with dilated cardiomyopathy. *J Am Anim Hosp Assoc* 33:4, 1997.)



Interestingly, although mitral insufficiency is the most commonly recognized cardiovascular condition in dogs, the natural history and mortality characteristics after the development of congestive heart failure have received little attention. Investigators for the Long-Term Investigation of Veterinary Enalapril (LIVE) study evaluated the time to treatment failure for dogs with congestive heart failure treated with enalapril and standard medical therapy (furosemide with or without digoxin) versus those treated with placebo and standard medical therapy.[5] In the mitral insufficiency subgroup, the number of dogs remaining in the study randomized to placebo mimicked the survival curve of dogs with dilated cardiomyopathy. A relatively high dropout rate was seen over the first 50 days, followed by a prolonged period of stability. The data for dogs randomized to enalapril did not display this steep dropout rate, but rather formed a linear curve from the time of enrollment until completion of the study.[5]

Figure 199-3 The variable presentation and treatment regimens associated with feline hypertrophic cardiomyopathy make evaluation of survival curves difficult. Not surprisingly, symptomatic cats appear to fare worse than those without clinical signs, many of which eventually died of noncardiac disease. (From Rush JE: Population and survival characteristics of cats with hypertrophic cardiomyopathy: 260 cases [1990–1999]. *J Am Vet Med Assoc* 220:2, 2002.)

199.3 INFLUENCES ON THE NATURAL HISTORY

Unlike in the management of heart disease in humans, veterinary medicine has the profound ability to influence the natural history of cardiovascular disease in companion animals through the use of euthanasia. The ready access to euthanasia in veterinary medicine not only influences patients' survival times, but also may alter the clinician's responsibilities in treating the heart failure. A study by Mallery et al.[7] evaluated the factors that contributed to clients' decision for euthanasia for 38 dogs with congestive heart failure. The most important factors cited were a perceived poor prognosis (37%), recurrent signs of congestive heart failure (26%), and poor quality of life (13%).[7]

Common contributing factors included weakness (76%), anorexia (68%), recurrent clinical signs of congestive heart failure (55%), and a poor prognosis (42%).[7] These findings suggest that the goals of the practitioner should include careful client education before and after initiation of medical therapy, along with efforts to improve the patient's strength, appetite, and quality of life, possibly at the expense of prolonged survival.

199.4 CLASSIFICATION OF HEART FAILURE

Some measure of subjective criteria must be used to classify the degree of disability in veterinary patients in order to optimize the management and understanding of heart failure. Because the human classification system is based on signs and symptoms evident at rest and during exercise, it does not easily correlate with disease in often sedentary veterinary patients. The International Small Animal Cardiac Health Council has devised a classification scheme based on anatomic diagnosis and the severity of clinical signs at rest.

199.4.1 Asymptomatic Patient

Heart disease is detectable, but the patient is not overtly affected and does not demonstrate clinical signs of heart failure. Diagnostic findings could include a cardiac murmur, arrhythmia, or cardiac chamber enlargement detected by radiography or echocardiography. The subcategories of this stage are:

- No signs of compensation (e.g., volume or pressure overload ventricular hypertrophy) are evident.
- Radiographic or echocardiographic evidence of compensation (e.g., volume or pressure overload ventricular hypertrophy) is present.

199.4.2 Mild to Moderate Heart Failure

Clinical signs of heart failure are evident at rest or with mild exercise and adversely affect the quality of life. Typical signs of heart failure include exercise intolerance, cough, tachypnea, mild respiratory distress (dyspnea), and mild to moderate ascites. Hypoperfusion at rest generally is not present.

199.4.3 Advanced Heart Failure

Clinical signs of advanced congestive heart failure are immediately obvious. These include respiratory distress (dyspnea), marked ascites, profound exercise intolerance, and hypoperfusion at rest. In the most severe cases, the patient is moribund and suffers from cardiogenic shock. Death or severe debilitation is likely without therapy.

Many patients present acutely for respiratory distress despite the absence of significant clinical signs before the “inciting” event. Owners may report one to several days of tachypnea with or without coughing, nocturnal dyspnea, lethargy, weakness, and inappetence. Cats with congestive heart failure may present acutely for severe respiratory distress because they were able to hide successfully for several days before the owner could detect a problem. Astute owners may present patients with mild to moderate heart failure for evaluation of exercise intolerance or subtle changes in the respiratory pattern. Patients with right-sided heart failure may be presented for evaluation of unexplained weight gain. At the far end of the spectrum from acute heart failure are patients that are re-evaluated for refractory congestive heart failure despite aggressive medical management. These patients may be re-evaluated for recurrent signs of congestive heart failure (i.e., pulmonary edema, pleural effusion, or ascites), weight loss and inappetence, or profound exercise intolerance and malaise. Effective

management of acute, chronic, and refractory heart failure requires specific aims and strategies that target the appropriate mechanisms.

199.5 TREATMENT STRATEGIES

199.5.1 Management of Acute Decompensated Congestive Heart Failure

Dogs with dilated cardiomyopathy or mitral regurgitation often present with acute onset of coughing, dyspnea, restlessness, orthopnea, and weakness subsequent to the development of severe pulmonary edema and/or low cardiac output. The immediate priorities in these patients are resolution of the pulmonary edema, maintenance of adequate tissue perfusion pressure, and adequate delivery of blood flow to vital tissues. These goals must be achieved quickly, therefore it is important that the practitioner use drugs with proven hemodynamic benefits and a rapid onset of action.

199.5.1.1 Oxygen Supplementation

As left atrial and pulmonary capillary pressures increase and the lymphatics' capacity to remove fluid is overwhelmed, the interstitial space and alveoli become flooded. Because these flooded alveoli lack ventilation and represent areas of functional shunting, oxygen administration must be combined with agents that effectively lower pulmonary venous pressure. Oxygen can easily be administered to compromised patients by provision of an oxygen-enriched environment (i.e., oxygen cage) or by use of nasal insufflation, achieving maximal inspired oxygen concentrations of 40% to 90%, respectively.

199.5.1.2 Reduction of Pulmonary Venous Pressure

Rapid reduction of pulmonary venous pressure is most readily achieved through use of a combination of intravenous (IV) drugs that lower the circulating plasma volume and redistribute the intravascular volume. Intravenous furosemide (2 to 8 mg/kg) should be administered to dogs with severe pulmonary edema to promote natriuresis and diuresis quickly. These large doses may be repeated (initially every 1 to 2 hours) until the respiratory rate and dyspnea start to decline. After stabilization, the dose should be reduced (2 to 4 mg/kg every 8 to 12 hours), because excessive administration may lead to profound dehydration, electrolyte depletion, renal failure, low cardiac output, and circulatory collapse.

Drugs that decrease preload (to combat congestion) and afterload (to decrease myocardial work) are administered concurrently with furosemide. Intravenous sodium nitroprusside is a potent, ultrarapid, balanced vasodilator that seems to reduce pulmonary venous pressure quickly and effectively. When used in animals with congestive heart failure, nitroprusside decreases right atrial and pulmonary capillary wedge pressures and systemic vascular resistance and increases cardiac output.[8] Although hypotension and tachycardia are reported side effects, the reduction in systemic vascular resistance (SVR) is theoretically associated with an increase in cardiac output (CO) that serves to maintain systemic arterial blood pressure (BP = SVR × CO). Nausea, vomiting, and cyanide toxicity during prolonged administration are other reported side effects. Because of its short half-life, nitroprusside, mixed with 5% dextrose, must be administered by constant-rate infusion (CRI). After institution of an initial dose of 1 μg/kg/min, the rate is slowly titrated upward while the blood pressure is monitored. An infusion rate of 2 to 5 μg/kg/min usually is sufficient to decrease afterload, although rarely doses as high as 10 μg/kg/min may be required. If significant hypotension is encountered after administration of nitroprusside, slowing the infusion rate generally is effective at raising the blood pressure to acceptable levels.

199.5.1.2.1

Sodium nitroprusside

Nitroprusside is an intravenous preparation with potent arteriolar and venous vasodilative properties mediated by the formation of nitric oxide and subsequently the second messenger cyclic guanosine monophosphate (cGMP). To some degree, the combination of nitroprusside and dobutamine can be considered short-term “cardiac life support,” used primarily during an attempt to rescue dogs with severe, life-threatening pulmonary edema subsequent to dilated cardiomyopathy. This drug combination's ability to reduce afterload quickly appears to be beneficial also in patients with chronic degenerative valvular disease and pulmonary edema, although management of these cases often can be accomplished less intensively.

Unfortunately, the beneficial hemodynamic profile of nitroprusside is accompanied by a difficult administration protocol that requires intensive monitoring. Because nitroprusside produces an almost immediate and often profound reduction in systemic vascular resistance, continuous blood pressure monitoring throughout administration is recommended. The drug is light sensitive, is given by constant-rate infusion (typically 2 to 5 μg/kg/min), and should not be infused with another agent, which necessitates placement of a second intravenous catheter for administration of dobutamine. These stringent requirements may provide cause for more frequent use of intravenous bipyridines to combat life-threatening heart failure, at least until studies are able to elucidate whether either method produces better results.

If nitroprusside is unavailable, balanced vasodilatation may be attempted through administration of an arterial vasodilator (hydralazine, 0.5 to 2 mg/kg given orally) in combination with a venodilator (nitroglycerin ointment, $^{1}/_{4}$-to $^{3}/_{4}$-inch applied cutaneously every 8 to 12 hours; or isosorbide dinitrate, 0.5 to 2 mg/kg given orally every 8 hours). Although easier to administer, this therapy seems to be less effective at quickly reducing pulmonary venous pressure compared with nitroprusside.

Potent afterload reduction in patients with severe mitral insufficiency and large regurgitant volumes serves to decrease the left ventricular to left atrial pressure gradient and hence the volume of insufficiency. Nitroprusside, or possibly hydralazine, can effectively decrease the volume of mitral regurgitation and lower left atrial pressure in cases of severe CHF subsequent to rupture of the chordae tendineae or the onset of atrial fibrillation. Despite this obvious theoretical advantage, a recent human study showed that mitral regurgitation worsened in four of nine patients with mitral valve prolapse during nitroprusside infusion.[9] This finding highlights the point that adjustments in the therapeutic regimen may be required and should be based on patient response rather than physiologic principles.

199.5.1.3

Augmentation of Systolic Performance

Preload reducing agents, such as furosemide, cannot enhance systolic function and in fact at high doses serve only to decrease cardiac output. Therefore the use of a rapid-acting, intravenous inotropic agent is vital to the management of acute decompensated congestive heart failure in dogs with dilated cardiomyopathy. Although there is debate over whether dogs with mitral valve insufficiency have systolic dysfunction, acutely positive inotropic agents may serve to decrease the regurgitant orifice area and hence the volume of insufficiency.

The short-acting, positive inotropic agents most commonly used to manage decompensated heart failure increase cyclic adenosine monophosphate (cAMP). Dobutamine and dopamine are sympathomimetic agents that bind to $beta_1$ receptors, thereby stimulating adenylyl cyclase activity and production of cAMP. The

bipyridines amrinone and milrinone increase cAMP by preventing its degradation by phosphodiesterase. Both drug classes are capable of rapidly augmenting systolic function during constant-rate intravenous infusions. By increasing cytosolic cAMP, these agents enhance (1) calcium entry into the cell, promoting ventricular contraction; (2) diastolic calcium uptake by the sarcoplasmic reticulum, promoting ventricular relaxation; and (3) peripheral vasodilatation, reducing afterload. It should be remembered that the sympathomimetics also have alpha-agonistic properties that promote vasoconstriction. Unfortunately, both the sympathomimetics and the bipyridines may promote tachycardia and undesirable ventricular arrhythmias. Therefore careful electrocardiographic (ECG) monitoring is required during administration of these drugs, and significant or worsening ventricular arrhythmias may warrant discontinuation of the infusion and institution of antiarrhythmic therapy.

199.5.1.3.1 Sympathomimetics

The sympathomimetics enhance cardiac contractility by complexing with myocardial beta receptors. After substrate binding to an unoccupied beta receptor, a coupled G-protein stimulates the enzyme cyclase to produce cAMP. This second-messenger "effector" system acts by means of protein kinase A to phosphorylate intracellular proteins, including the L-type calcium channel, phospholamban, and troponin I, thereby enhancing ventricular contraction and relaxation. Despite the sympathomimetics' ability to increase cardiac contractility approximately 100% above baseline, not all drugs in this class are suitable for the management of heart failure. The specificity for beta receptor binding depends on the specific agent and dose administered. Sympathomimetics inappropriate for the management of heart failure include the pure beta agonist isoproterenol and the naturally occurring catecholamines norepinephrine and epinephrine. These agents tend to promote tachycardia, arrhythmias, and untoward alterations in systemic vascular resistance.

Dobutamine and dopamine are more appropriate sympathomimetics for the management of heart failure. Although both drugs can enhance cardiac contractility, several drawbacks discourage long-term use: (1) they must be given intravenously, because successful oral administration is precluded by extensive first-pass hepatic metabolism; (2) because of their extremely short half-lives (approximately 1 to 2 minutes), they must be administered by constant-rate infusion; (3) almost any positive inotropic response tends to increase myocardial work and thus the propensity for ventricular arrhythmias; and (4) after 24 to 48 hours of constant-rate infusion, their positive inotropic response is limited by beta receptor downregulation and uncoupling. The tendency for long-term sympathomimetic administration to increase mortality, as documented in humans, appears to relegate these agents to short-term management of acute, life-threatening heart failure.

199.5.1.3.1.1 Dobutamine

Dobutamine is a synthetic analog of dopamine that displays predominately $beta_1$ receptor binding ($beta_1 > beta_2 >$ alpha). Dobutamine is able to increase cardiac contractility and thus cardiac output without causing a profound, concomitant increase in the heart rate. The mechanism underlying the lack of a positive chronotropic response is not well understood, but this characteristic tends to make dobutamine the most appropriate agent for short-term treatment of heart failure. It appears that complexing with vasodilative beta receptors and vasoconstrictive alpha receptors, combined with an increase in cardiac output, maintains arterial blood pressure at near baseline values. If the systolic blood pressure is normal to elevated, dobutamine infusion (slow titration up to 5 to 15 µg/kg/min in 5% dextrose) can be combined with the potent vasodilator nitroprusside in an attempt to decrease internal cardiac work and further enhance forward blood flow. Continuous ECG and blood pressure monitoring

952 953

is recommended during this treatment regimen, and exacerbation of tachycardia or ventricular arrhythmias may necessitate discontinuation of dobutamine.

199.5.1.3.1.2 Dopamine

A precursor of norepinephrine, dopamine can bind myocardial beta receptors in addition to peripherally located dopaminergic, beta$_2$, and alpha receptors. Within the renal, mesenteric, coronary, and cerebral vascular beds, these dopaminergic DA$_2$ receptors are able to promote vasodilatation at low infusion rates of dopamine (1 to 2 μg/kg/min). However, at higher infusion rates (10 to 20 μg/kg/min), these vasodilative properties are over-ridden by an undesirable, alpha-mediated vasoconstrictive response. Also, high doses are accompanied by increases in the heart rate, the likelihood of arrhythmogenesis, the release of norepinephrine, and the myocardial oxygen demand. Dopamine (slow titration up to 1 to 10 μg/kg/min) may be used in situations similar to those in which dobutamine is appropriate (e.g., profound myocardial failure) and may further enhance renal blood flow. For the authors, an increased propensity for the development of tachycardia relegates dopamine to the role of second-choice drug. As with dobutamine, careful ECG and blood pressure monitoring is indicated during dopamine administration.

199.5.1.3.2 Bipyridines

Similar to the sympathomimetics, the bipyridines promote an increase in cardiac contractility by increasing cytosolic cAMP levels. However, rather than directly enhancing the production of cAMP, they increase circulating levels by inhibiting phosphodiesterase III, the enzyme responsible for cAMP inactivation. Unlike the sympathomimetics, the bipyridines do not rely on beta-adrenergic receptors and therefore are less affected by downregulation and uncoupling. Furthermore, because phosphodiesterase inhibitors increase vascular smooth muscle cAMP without displaying affinity for alpha receptors, they are also vasodilators. Because of the bipyridines' combination of positive inotropic and vasodilative properties, the term *inodilators* has come into use for these agents. Because they increase cytosolic calcium and myocardial work, they inherently carry the caveats of tachycardia and ventricular arrhythmias. In fact, the 28% increase in all-cause mortality identified in humans randomized to oral milrinone versus placebo has severely limited further attempts to evaluate agents that act via cAMP-dependent mechanisms.[10]

199.5.1.3.2.1 Milrinone

The phosphodiesterase inhibitor milrinone is substantially more potent than amrinone and is available in an intravenous preparation. Because of its combined positive inotropic and vasodilative properties, milrinone may be used as a substitute for the dobutamine/nitroprusside combination in the management of acute life-threatening heart failure. Despite milrinone's ability to increase measures of fractional shortening after oral administration in dogs, this formulation is no longer available for prescription.[11]

There are no published reports regarding the hemodynamic effects of intravenous milrinone administered to dogs with acute myocardial failure. When administered to normal dogs at an infusion rate of 1 to 10 μg/kg/min, milrinone increased cardiac contractility 50% to 140%.[12] Whether similar doses are efficacious in dogs with heart failure is uncertain, and dosing recommendations currently are difficult to propose. Because CRI milrinone requires 10 to 30 minutes to reach maximal peak effects in normal dogs, it may be prudent to administer a loading dose, followed by constant-rate infusion.

Theoretical administration guidelines after the bolus would be to titrate the infusion rate upward slowly while monitoring the systemic blood pressure and a continuous electrocardiogram. Efficacy may be monitored clinically (e.g., reduction in the respiratory rate, alleviation of orthopnea) or echocardiographically with periodic measures of systolic function.

199.5.1.3.2.2 Amrinone

The effects of amrinone are almost identical to those of milrinone except that it does not appear to be as potent. Although there are no reports of its large-scale use in the management of acute decompensated congestive heart failure, treatment recommendations have been extrapolated from studies of normal dogs. Constant-rate infusions of 10 to 100 µg/kg/min appear to be capable of increasing cardiac contractility by 10% to 80% in awake, normal dogs.[12] Anesthetized dogs showed a 15% increase in the heart rate at an infusion rate of 30 µg/kg/min and a 20% increase at 100 µg/kg/min.[12] This tachycardia may have been induced either directly, through cAMP stimulation, or indirectly, in response to a decrease in blood pressure. The 30 µg/kg/min infusion rate was associated with a 10% decrease in blood pressure, whereas the 100 µg/kg/min rate reduced blood pressure by 30%.[12] After institution of a CRI, amrinone requires approximately 45 minutes to reach peak effect. Therefore, similar to milrinone, it appears most appropriate to administer a slow IV bolus of 1 to 3 mg/kg, followed by a slowly up-titrated CRI of 10 to 100 µg/kg/min. Continuous ECG monitoring should be instituted to allow evaluation for excessive tachycardia or arrhythmogenesis, and the systemic blood pressure should be monitored to avoid hypotension.

199.5.2 Management of Acute Heart Failure Secondary to Diastolic Dysfunction

Cats with hypertrophic cardiomyopathy (HCM) often present with signs of respiratory distress subsequent to the development of pulmonary edema or pleural effusion. Impaired ventricular relaxation produces elevated atrial and venous pressures, with eventual fluid exudation into the alveoli or pleural space. The treatment goals for cats with HCM and heart failure focus on relieving congestion through preload reduction rather than augmenting systolic function or decreasing afterload.

199.6 PROGRESSION OF HEART FAILURE (THE HUMAN EXPERIENCE)

Traditionally heart failure has been perceived as a hemodynamic disorder that promotes weakness, the development of debilitating congestive signs, deterioration of cardiac function, and ultimately death. Although the initial cardiac insult varies, it was historically rationalized that ventricular remodeling and disease progression occur as consequences of the compensatory mechanisms that promote vasoconstriction and fluid retention. It was recognized that diseased hearts operate on a depressed and flattened Frank-Starling curve, such that volume retention and vasoconstriction, rather than promoting cardiac output, merely exacerbated congestive heart failure. The symptoms of heart failure developed as venous pressures breached the lymphatics' ability to remove edema or as blood flow to exercising muscles was severely limited.

If disease progression were solely mediated by hemodynamic alterations, it was hypothesized, drugs capable of “unloading” the heart (e.g., vasodilators and positive inotropes) would retard this progression and improve survival. In the first Veterans Affairs Heart Failure Trial (V-HeFT) completed in 1985, prazosin or a combination of hydralazine and isosorbide dinitrate was used to decrease preload and afterload.[13] Although prazosin was more effective at reducing blood pressure, only the hydralazine/isosorbide dinitrate combination reduced mortality compared with placebo. The discordance between the hemodynamic and prognostic findings could not be

explained by the traditional perception of heart failure. Support for the hemodynamic hypothesis was further undermined by the Prospective Randomized Amlodipine Survival Evaluation (PRAISE) trial completed in December of 1994, which found that administration of amlodipine to patients with severe chronic heart failure had no significant effect on mortality.[14]

Similar to the use of vasodilators to decrease ventricular wall stress and increase cardiac output, potent inotropic drugs capable of increasing cAMP levels were developed with the intent to improve survival. If poor pump performance were responsible for the progressive nature of heart failure, it was hypothesized, these positive inotropes should alter the natural course of cardiovascular disease. The phosphodiesterase inhibitor milrinone, which has potent inotropic and vasodilative properties, in fact was found to alter the course of heart failure but in a fashion opposite that expected. In October of 1990, the Prospective Randomized Milrinone Survival Evaluation (PROMISE) trial was stopped 5 months prior to its scheduled completion date because administration of oral milrinone was found to increase all-cause mortality by 28%.[10] Patients with the severest symptoms (i.e., New York Heart Association [NYHA] class IV), who therefore would be the most likely to receive additional medical therapy, showed a 53% increase in mortality. Administration of the partial beta-agonist xamoterol also failed to improve survival in a study of 516 patients.[15]

These drug trial failures were accompanied in the late 1980s and early 1990s by an evolution in the understanding of the traditional hemodynamic model of heart failure. It still was recognized that hemodynamic alterations accounted for the symptomatic manifestations of cardiac disease, but a new understanding of the condition resulted in the conclusion that the body's compensatory neurohormonal mechanisms contributed to the dilemma of disease progression. Activation of the sympathetic nervous system (SNS) and the renin-angiotensin system (RAS) was found to promote both adverse hemodynamic consequences and direct toxic effects on the myocardium. Cultured mammalian cardiomyocytes exposed to norepinephrine displayed a concentration-dependent decrease in viability that was attenuated significantly by beta-receptor blockade.[16] In addition, norepinephrine was implicated in the provocation of ventricular arrhythmias and the impairment of sodium excretion by the kidneys.[17] Pathophysiologic levels of angiotensin II were found to promote myocytolysis with subsequent fibroblast proliferation, and aldosterone was implicated in the process of myocardial extracellular matrix remodeling.[18,19] These findings established a connection between hemodynamic mechanisms and neurohormonal consequences, which mutually promote a cycle of disease progression. The initial cardiac insult is followed by activation of neurohormonal compensatory mechanisms that produce further hemodynamic alterations and myocardial fibrosis. Cardiac output continues to decline, the compensatory mechanisms continue to be activated, and the disease process proceeds unabated.

This more complete understanding of the neurohormonal systems led to the development and use of drugs designed to antagonize the RAS. A breakthrough in the management of cardiovascular disease came with the utilization of angiotensin-converting enzyme (ACE) inhibitors in the mid to late 1980's. Angiotensin-converting enzyme is capable of degrading vasodilative bradykinin and is responsible for cleaving relatively inactive angiotensin I to the potent vasoconstrictor angiotensin II (AT II). Indirectly ACE is responsible for aldosterone production, because AT II is a primary stimulus for adrenal gland production of mineralocorticoids. Given angiotensin-converting enzyme's critical position in the RAS, it was proposed that ACE inhibition may promote beneficial hemodynamic and neurohormonal antagonistic and antifibrotic actions.

The ACE inhibitor enalapril has been extensively studied in humans with varying stages of heart failure. In three studies,[20–22] compared with placebo or the combination of hydralazine and isosorbide dinitrate, enalapril reduced all-cause mortality in humans with a reduced ejection fraction and heart failure. In another study,[23] compared with placebo, enalapril did not reduce the mortality rate in asymptomatic patients with reduced ejection fraction,

although it delayed the onset of heart failure. Because ACE inhibitors have been shown to alleviate symptoms, improve patients' clinical status, and decrease mortality, the current recommendation is that all humans with heart failure due to left ventricular systolic dysfunction receive an ACE inhibitor.[17] The mortality reductions associated with administration of ACE inhibitors lends support to the theory that disease progression is mediated by factors other than hemodynamics alone.

199.6.1 Management of Stable Compensated Congestive Heart Failure

After stabilization of the acute crisis, during which hemodynamic support is the goal, long-term management of heart failure ensues. The goals for this stage are to combat congestion, improve exercise capacity and quality of life, blunt adverse neurohormonal sequelae, and prolong survival time. Drugs can be administered to promote pump function (positive inotropes), to alter hemodynamics (preload and afterload reducers), and to blunt the adverse sequelae mediated by the body's compensatory mechanisms (neurohormonal antagonists). Numerous studies have been performed in humans to evaluate the benefits or limitations of drugs used to combat congestive heart failure, but the cost of well-designed, multi-institutional studies has precluded large-scale investigation in companion animals. For this reason, theoretical benefit often is extrapolated to dogs and cats; however, the practitioner should exercise caution in making these assumptions.

Triple drug therapy using furosemide and an ACE inhibitor, frequently combined with digoxin, serves as the mainstay of treatment for dogs with congestive heart failure secondary to degenerative valve disease and dilated cardiomyopathy.

199.6.1.1 Diuretics

The importance of appropriate administration of diuretics in the management of heart failure should not be underestimated. Diuretics play a pivotal role because they are the most effective agents for promoting rapid symptomatic benefits, and they are the only agents capable of controlling the fluid retention of heart failure. Although no large-scale trials have been done to evaluate the effect of diuretics on morbidity and mortality, there is little debate that they are a vital class of drug in both the acute and the long-term management of patients with congestive heart failure. Trials that would withhold a diuretic in heart failure would be immoral.

The kidney represents a major target organ for the neurohormonal and hemodynamic alterations that occur with a failing heart. Activation of the sympathetic nervous system, stimulation of the RAS, and intrarenal hemodynamic alterations all contribute to an avid state of sodium and water retention. Dogs with severe heart failure have had a 24% increase in plasma volume.[24] Unfortunately, these dogs are existing on the plateau of a depressed Frank-Starling curve, meaning the increased plasma volume is unable to enhance cardiac output. The premise behind administration of a diuretic, therefore, is to control congestion while maintaining optimal cardiac output. The three primary classes of diuretics are the loop, the thiazide, and the potassium-sparing diuretics. Each acts at a different site in the nephron.

199.6.1.1.1 Loop Diuretics

The loop diuretics (furosemide, torsemide, bumetanide, and ethacrynic acid) constitute the drug class most commonly used to treat heart failure. They inhibit the sodium, potassium, chloride ($Na^+/K^+/2Cl^-$) cotransporter on the luminal surface of the ascending limb of the loop of Henle. This inhibition markedly increases the fractional excretion of Na^+ and Cl^- and prevents establishment of the normal medullary concentration gradient, thereby promoting diuresis. In addition to promoting natriuresis and diuresis,

954 955

furosemide, the most frequently used loop diuretic, appears capable of decreasing pulmonary capillary wedge pressure and promoting venodilatation, prior to the onset of diuresis, through local vascular prostaglandin synthesis.[25,26] The loop diuretics are the most effective agents for controlling the fluid retention of heart failure, and their proven safety, combined with their low cost, makes them a crucial therapeutic weapon.

Furosemide is available in formulations for enteral and parenteral administration. When it is administered intravenously, the onset of action is 5 minutes, the peak diuretic effect occurs within 30 minutes, and the duration of effect is 2 hours. After oral administration, the onset of action occurs within 60 minutes and the peak effect and duration of effect are 1 to 2 hours and 6 hours, respectively.

Furosemide's rapid onset of action explains its presence in most emergency crash carts. Severe pulmonary edema requires intravenous furosemide administration (2 to 8 mg/kg in dogs every 1 to 2 hours; 1 to 2 mg/kg in cats every 1 to 4 hours) to reduce preload rapidly. Although mild electrolyte abnormalities and dehydration may result with high doses, these conditions generally resolve when the pet resumes eating and drinking. After alleviation of the acute crisis, it is best to decrease the furosemide dose to the lowest capable of eliminating congestive signs. The authors have found that most dogs with a previous history of heart failure require 1 to 2 mg/kg given orally once or twice daily. Initially some dogs may be managed with as little as every-other-day therapy; however, as the disease process continues, cardiac output declines and diuretic resistance develops, extremely high doses of furosemide may be required to fend off congestive signs (4 mg/kg given orally three times daily). Periodic evaluation of electrolyte and renal parameters should be performed, especially when furosemide is administered concurrently with an ACE inhibitor and digoxin. It is well recognized that hypokalemia may contribute to ventricular arrhythmias and increase the likelihood of digoxin toxicity.

Bumetanide and torsemide have been reported to have more consistent oral bioavailability than furosemide (ranges of 80% to 100% and 10% to 100%, respectively).[27] The diuretic response occurs more slowly with intravenous torsemide than with furosemide, but torsemide promotes diuresis for a longer period.[28] Whether use of bumetanide or torsemide could allow for a more predictable diuretic response has not been evaluated.

199.6.1.1.2

Thiazide diuretics

The thiazides were among the first effective oral diuretic classes that developed widespread use in clinical practice. They block resorption of Na^+ in the distal convoluted tubule by inhibiting the Na^+/Cl^- cotransporter. The increased delivery of Na^+ to the collecting duct enhances potassium (K^+) and hydrogen (H^+) secretion and may promote the development of hypokalemia and metabolic alkalosis. Compared with loop diuretics, the thiazides are relatively weak; they increase renal sodium excretion from a normal value of about 1% to 5% to 8% of the filtered load. Nonetheless, they appear to promote a synergistic effect when administered with a loop diuretic. Although the combination of loop and thiazide diuretics appears effective at combating refractory pulmonary edema, caution must be exercised to avoid hypokalemia. One strategy to prevent excessive potassium loss is to administer the thiazide every second or third day while continuing daily treatment with furosemide. The two most frequently used thiazide diuretics are chlorothiazide and hydrochlorothiazide. Both drugs show good oral absorption and a relatively rapid onset of action. Chlorothiazide (20 to 40 mg/kg given orally twice daily) promotes diuresis within 1 hour, reaches peak activity at 4 hours, and has a duration of effect of 6 to 12 hours. For hydrochlorothiazide

(*dogs:* 2 to 4 mg/kg given orally twice daily; *cats:* 1 to 2 mg/kg given orally twice daily), onset of action occurs within 2 hours, activity peaks at 4 hours, and the effect lasts 12 hours.

199.6.1.1.3 Potassium-sparing diuretics

Potassium-sparing diuretics formerly were allocated solely to the late stages of heart failure or to patients with hypokalemia, but they recently have come to the forefront in the battle against neurohormonally mediated progression of cardiac disease. This class of diuretics (spironolactone, eplerenone, and triamterene) recently has gained prominence because evidence suggests the presence of "aldosterone escape" in approximately one third of humans treated with ACE inhibitors.[29] The precise mechanisms behind this RAS-independent increase in aldosterone are unknown, although increased potassium levels induced by ACE inhibitors and decreased hepatic clearance may be contributing factors. Tissue pathways for the production of aldosterone have also been identified, although their role in the progression of heart failure is uncertain.

Aldosterone promotes the production of Na^+/K^+ exchangers along the luminal surface of the distal tubule and collecting ducts. In addition to its ability to increase sodium resorption, aldosterone now is recognized to contribute to myocardial fibrosis, augmentation of sympathetic tone, and possibly diuretic resistance. It has been postulated that spironolactone's ability to decrease collagen turnover, and presumably myocardial fibrosis, is responsible for the marked mortality benefits recognized in the Randomized Aldactone Evaluation Study (RALES) trial. Whether dogs and cats will benefit similarly has yet to be determined, but more frequent use of spironolactone in companion animals may be warranted.

Spironolactone is well absorbed from the gastrointestinal tract but has a relatively slow onset of action, peaking at 2 to 3 days after administration. It undergoes rapid hepatic metabolism to pharmacologically active canrenone. Spironolactone is administered to dogs and cats at a dosage of 1 to 2 mg/kg given orally every 12 hours, in conjunction with an ACE inhibitor and a loop diuretic, to combat congestive heart failure.

199.6.1.2 Angiotensin-Converting Enzyme (ACE) Inhibitors

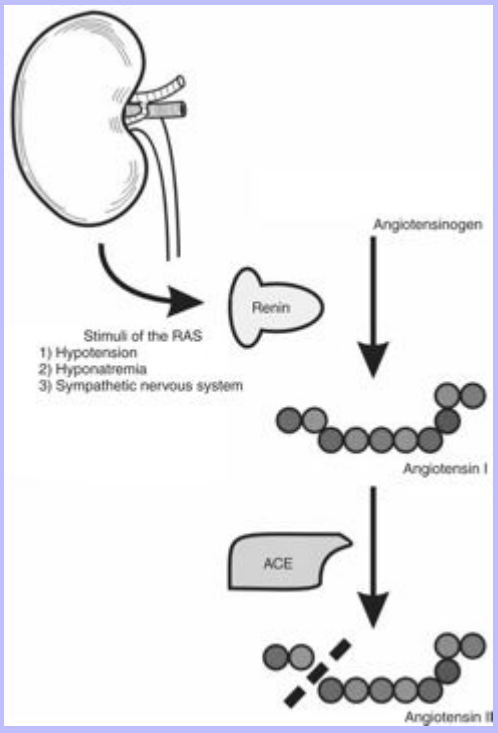
Despite their symptomatic benefits, diuretics should not be used as monotherapy in the management of congestive heart failure because they further activate the renin-angiotensin system.[30,31] Drugs designed to inhibit angiotensin-converting enzyme block the formation of AT II, promote an increase in the circulating levels of bradykinin, and may temporarily reduce circulating aldosterone levels. Although ACE inhibitors are frequently categorized as balanced vasodilators, it appears likely that their beneficial effect on mortality is not mediated purely by hemodynamic alterations.[22] They are relatively weak vasodilators compared with direct-acting arterial vasodilators such as hydralazine, and their ability to promote diuresis is much overshadowed by the less expensive loop diuretics. Rather, it is believed that ACE inhibitors reduce mortality through their ability to blunt the detrimental consequences associated with long-standing activation of the RAS. Their early success has helped spearhead the current pharmacologic trend toward neurohormonal antagonism.

Activation of the neurohormonal cascade often begins with detection of arterial underfilling by mechanoreceptors in the carotid sinus and kidney (Figure 199-4). Regardless of whether this relative "hypotension" occurs secondary to low-output heart failure, severe mitral insufficiency, or profound hypovolemia, the common end-point is activation of the sympathetic nervous system and RAS. Additional

activators of the RAS are reduced sodium delivery to the macula densa and sympathetic stimulation. Release of the protease renin from the juxtaglomerular apparatus promotes conversion of angiotensinogen to angiotensin I. Angiotensin-converting enzyme cleaves the C-terminal dipeptide from angiotensin I, thereby forming the octapeptide angiotensin II. In addition to being a potent vasoconstrictor, AT II has several other properties: (1) it is a primary secretagogue for aldosterone; (2) it potentiates presynaptic norepinephrine release; (3) it stimulates the release of antidiuretic hormone (vasopressin); (4) it promotes renal tubular sodium resorption; and (5) it has been linked to cardiomyocyte necrosis, apoptosis, and progression of ventricular fibrosis.[18,32,33] Angiotensin-converting enzyme is also capable of cleaving the C-terminal dipeptide from bradykinin, therefore it appears to be a regulator of vasoconstrictive/sodium retentive and vasodilative/natriuretic mechanisms. Although tissue ACE and additional enzymatic pathways (e.g., chymase, cathepsin G, tonin, and tissue plasminogen activator) capable of producing AT II have been identified, their significance is unknown at this time.[32]

955
956

Figure 199-4 After the release of renin, angiotensinogen is cleaved to form angiotensin I, which is subsequently cleaved by angiotensin-converting enzyme (ACE) to form angiotensin II. Angiotensin II promotes numerous physiologic actions, including activation of the sympathetic nervous system and production of aldosterone (see Figure 199-12).



ACE-inhibiting compounds are numerous and vary in their chemical structure, potency, bioavailability, and route of elimination. Most ACE inhibitors, excluding captopril and lisinopril, are administered in the form of

prodrugs that require conversion to their active form by hepatic metabolism. Enalapril requires conversion to enalaprilat, and benazepril is metabolized to benazeprilat. Although claims have been made that some formulations produce more profound ACE inhibition, prolonged periods of efficacy, or superior tissue ACE inhibition, the importance of these characteristics is unclear in naturally occurring heart failure.

The degree of ACE inhibition and the duration of action of several agents, including benazepril, captopril, enalapril, lisinopril, and ramipril, have been evaluated in normal dogs.[34] Hamlin and Nakayama[34] documented that benazepril, enalapril, lisinopril, and ramipril were able to achieve similar degrees of ACE inhibition after drug administration (about 75% inhibition at 1.5 hours and about 50% inhibition through 12 hours). Enalapril, lisinopril, and ramipril continued to display significant activity (about 25% inhibition) beyond 24 hours. These researchers also found that captopril was unable to reduce ACE activity substantially, compared with control, beyond the 1.5-hour sample. Whether captopril's inability to suppress ACE activity was a consequence of sample handling or merely an inability to suppress circulating versus tissue ACE is uncertain.[35] Evaluations of enalapril and benazepril in normal cats have identified maximal ACE inhibition of 48% and 98%, respectively, after single-dose administration.[36,37] Benazepril was reported to show greater than 90% ACE inhibition beyond 24 hours.[37]

Excretion of the ACE inhibitors is primarily via the kidneys, although benazepril appears to undergo significant biliary excretion in companion animals (about 50% in dogs and about 85% in cats).[38] When ACE inhibitors have been prescribed for patients with mild renal insufficiency, the recommendation historically has been to reduce both the dosage and frequency interval by approximately 50%. Administration of enalapril to dogs with experimental mild renal insufficiency is associated with a significant increase in the area under the curve (AUC) for the active metabolite enalaprilat.[39] After benazepril was administered to the same dogs, no significant increase was seen in the AUC for benazeprilat. Whether concurrent cardiac disease, with its relatively depressed cardiac output, would be associated with impaired benazeprilat excretion is unclear. Current trends using “standard” doses of enalapril to treat glomerulonephritis and renal insufficiency are difficult to extrapolate to patients with heart failure and renal insufficiency because of their limited ability to increase cardiac output in the face of a reduced rate of glomerular filtration.[40]

956 957

In summary, the merits and limitations of the different formulations are unknown, and only the ACE inhibitor enalapril has been specifically approved in the United States for the treatment of heart failure in dogs. The hypothesized improved safety of using benazepril rather than enalapril in patients with renal insufficiency has not been clinically evaluated in companion animals with cardiac disease.

199.6.1.2.1

Enalapril

Enalapril is one of the few drugs that has been closely evaluated in dogs with naturally occurring congestive heart failure. The first reported placebo-controlled studies in dogs were short-term investigations, the Invasive Multicenter Prospective Veterinary Evaluation of Enalapril study (IMPROVE; 21 days) and the Cooperative Veterinary Enalapril study (COVE; 28 days), both published in 1995.[41,42] These studies enrolled dogs with mitral valve insufficiency or dilated cardiomyopathy (DCM) to evaluate the hemodynamic (IMPROVE) and clinical (COVE) benefits of enalapril. The drug decreased pulmonary capillary wedge pressures in dogs with DCM and improved the heart failure class, pulmonary edema scores, and overall evaluation for both groups of dogs with heart failure. The benefits of these short-term studies were more pronounced for dogs with DCM than for those with mitral valve insufficiency. The COVE investigators found that twice daily oral administration of enalapril (0.5 mg/kg) appeared to

promote more significant improvements than once daily therapy.[42] The LIVE study group followed a subpopulation of dogs from the two short-term studies to evaluate the long-term effects of enalapril administration.[5] These researchers found that dogs treated with enalapril were able to continue the study for longer than those receiving placebo (157.5 versus 77 days, P = 0.006). In contrast to the results of the short-term studies, the beneficial effect was more prominent in dogs with mitral valve insufficiency (P = 0.041) than in those with dilated cardiomyopathy (P = 0.06). An additional study supporting the benefits of ACE inhibitor administration to dogs with heart failure found that enalapril significantly increased the exercise tolerance of dogs with experimentally created mitral insufficiency.[43]

Despite these symptomatic benefits, the hope that early institution of ACE inhibition will delay the onset of heart failure may go unfulfilled. To date, enalapril has been unable to delay the onset of heart failure in asymptomatic cases of mitral insufficiency.[44] Whether ACE inhibitors can reduce mortality in dogs or cats with heart failure has yet to be determined; even so, preliminary evidence reported in 2003 looks supportive, although not conclusive, for cats with diastolic dysfunction.[45]

199.6.1.2.2

Benazepril

Similar to enalapril, benazepril is a prodrug that must undergo hepatic metabolism to produce the active compound, benazeprilat. Oral administration of benazepril has produced variable and conflicting degrees of ACE inhibition. An initial study reported that peak plasma benazeprilat concentrations were achieved 2 hours after oral administration.[46] The percentage of ACE inhibition after a single dose of 0.5 mg/kg of benazepril administered to normal dogs was 99.7% after 2 hours, 95.2% after 12 hours, and 87.3% after 24 hours. Similar results were found for the same intervals at doses of 0.25 mg/kg (97.8%, 89.2%, and 75.7%) and 1 mg/kg (99.1%, 94.0%, and 83.1%). Maximal ACE inhibition after 15 doses was attained in dogs receiving 0.25 mg/kg of benazepril once daily (96.9% at 2 hours, 92.5% at 12 hours, and 83.6% at 24 hours). A second study, which also evaluated a single dose of 0.5 mg/kg of benazepril in normal dogs, showed ACE inhibition of 81% at 1.5 hours, 37% at 12 hours, and 10.3% at 24 hours.[34] Prolonged administration of benazepril was not evaluated. A final study, in which 0.5 mg/kg of benazepril was administered orally once daily to dogs with mitral insufficiency, showed ACE inhibition to be 33.3% at 1 week, 28% at 2 weeks, and 42.7% at 4 weeks.[47]

Based on these conflicting results, the current dosing recommendations are broad (0.25 to 0.5 mg/kg given orally once or twice daily). Whether benazepril is clinically more effective or safer than enalapril for dogs and cats with congestive heart failure remains unclear.

199.6.1.2.3

Adverse effects

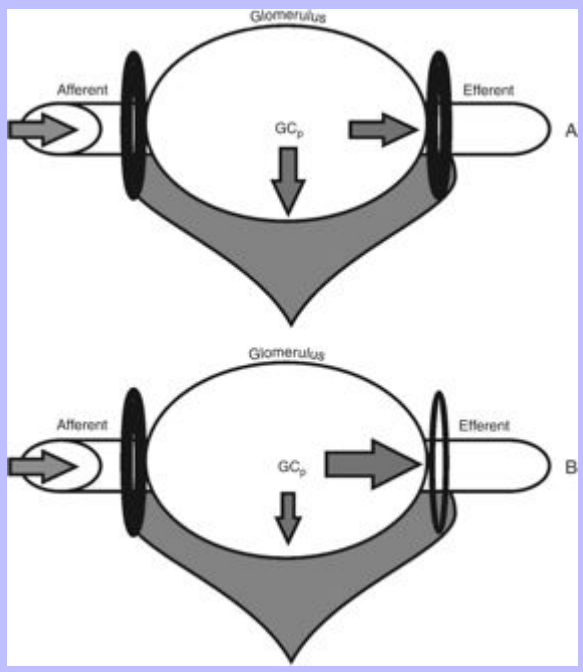
The mechanism by which ACE inhibitors exert their beneficial properties (e.g., inhibition of angiotensin II production) also lends to the potential for adverse consequences. Although infrequently encountered, complications may include systemic hypotension, azotemia, and hyperkalemia.

ACE inhibitors reduce systemic vascular resistance by decreasing circulating levels of angiotensin II and increasing circulating levels of bradykinin. In patients with severe heart failure in which an increase in cardiac output is unable to sustain systemic blood pressure, symptomatic hypotension may develop. Although this complication is infrequent, its likelihood increases with concomitant overzealous use of diuretics. Unfortunately, the clinical signs associated with severe low-output heart failure and systemic

hypotension are very similar (e.g., weakness, exercise intolerance, and possibly stupor), a fact that lends emphasis to an important point: if a patient appears refractory to medical management, the blood pressure should be evaluated before more aggressive measures to combat heart failure are instituted.

A second adverse effect attributed to ACE inhibitors' unique ability to decrease angiotensin II production is a reduction in the glomerular filtration rate (GFR) and the development of azotemia. The GFR is determined by the glomerular capillary pressure (GC_P). Based on the knowledge that pressure is equal to the product of flow and resistance ($P = Q \times R$), it can be ascertained that the GFR ultimately is determined by renal plasma flow and the degree of efferent arteriolar vasoconstriction (Figure 199-5). In cases of heart failure in which renal plasma flow is diminished, the glomerular filtration rate is supported by the ability of ATII to constrict the efferent renal arteriole. ACE inhibitors' ability to depress production of AT II promotes efferent renal arteriolar vasodilatation and hence a reduction in the GFR. The failing heart cannot further increase cardiac output, and an acute bout of azotemia may subsequently develop. A recent study evaluating early institution of enalapril therapy in dogs with compensated mitral valve insufficiency found that dogs allocated to an ACE inhibitor were not at a more significant risk of developing azotemia compared with dogs receiving placebo.[48] In the authors' experience, mild increases in blood urea nitrogen (BUN) and creatinine occur frequently after institution of therapy with an ACE inhibitor and furosemide. However, the development of severe azotemia, necessitating discontinuation of the ACE inhibitor or a reduction in its dosage, occurs infrequently. This complication seems to occur most often in patients with severe heart failure that require aggressive diuretic administration to control congestive signs. Prior to institution of enalapril therapy, the authors evaluate the baseline biochemical parameters and perform a second measurement of the BUN, creatinine, and electrolytes 5 to 7 days after the start of treatment. If patients become anorectic or develop gastrointestinal signs during this time, we instruct the owners to discontinue all drugs and immediately present the animal for veterinary attention.

Figure 199-5 Glomerular capillary pressure (GC_p), and therefore the glomerular filtration rate (GFR), is determined by cardiac output and the relative resistances imparted by the afferent and efferent renal arterioles. Compared with normal **(A)**, ACE inhibitors preferentially dilate the efferent renal arteriole **(B)** and may therefore decrease the GFR and promote the development of azotemia. It appears this consequence is most frequent in patients with low output heart failure that require large doses of diuretics to control their congestive signs.



Hyperkalemia may be encountered during therapy with ACE inhibitors as the result of a reduction in the GFR and a decline in circulating aldosterone levels. In the absence of aldosterone, sodium loss is favored and potassium levels rise. This complication appears to occur infrequently, presumably because most of the potent diuretics have potassium-wasting properties and tend to prevent the development of hyperkalemia. The authors have rarely encountered an increase in potassium that necessitated a dosage reduction for or discontinuation of an ACE inhibitor. There is concern that the addition of spironolactone may potentiate hyperkalemia, therefore periodic electrolyte monitoring is prudent in patients receiving an ACE inhibitor and a potassium-sparing diuretic.

199.6.1.2.4

Drug interactions

Because aspirin inhibits cyclo-oxygenase and decreases prostaglandin formation, some have questioned whether administration of aspirin may negate some of the beneficial vasodilative properties exerted by ACE inhibitors.[49] An additional concern is that aspirin's ability to reduce renal prostaglandin formation may worsen the ACE inhibitor–induced reduction in the GFR.[50] A recent retrospective analysis of six long-term, randomized trials of ACE inhibitors found that aspirin did not significantly alter the beneficial effects of ACE inhibitors in CHF.[50] Whether other commonly prescribed, nonsteroidal anti-inflammatory agents blunt the potentially beneficial vasodilative properties of ACE inhibitors is uncertain.

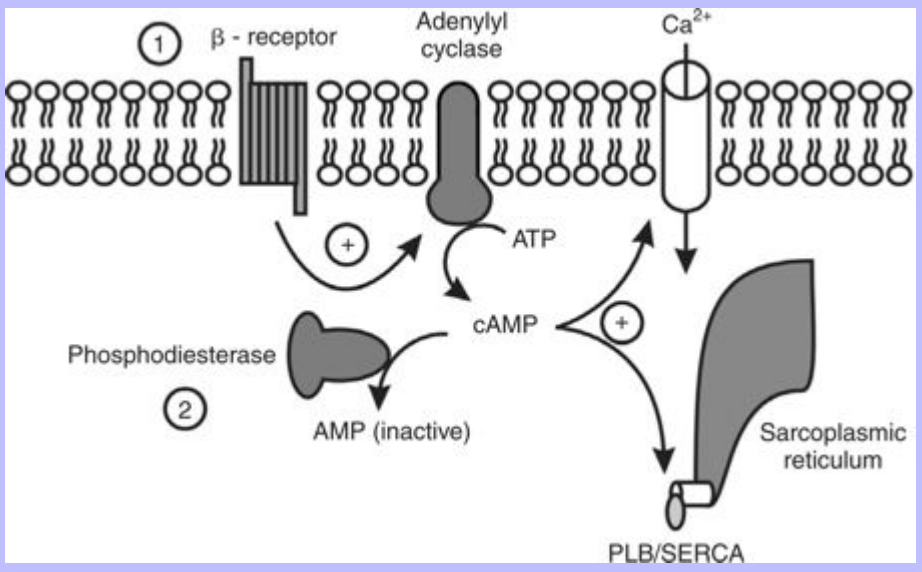
199.6.1.3

Positive Inotropes

Agents capable of increasing cardiac contractility can improve a patient's strength and exercise capacity, thereby potentially enhancing the pet's quality of life. Ideally, these compounds would concurrently promote mortality benefits by improving cardiac efficiency and limiting the activation of endogenous compensatory mechanisms (with their detrimental long-term consequences). Unfortunately, to date most of the potent agents available to augment systolic function act by means of “upstream,” cAMP-dependent mechanisms that have shown negative effects on survival.

Membrane-associated adenylate cyclase is the enzyme responsible for cAMP production, and phosphodiesterase III is responsible for its degradation. Therefore mechanisms to increase cAMP concentrations may take one of two pathways (Figure 199-6): beta agonists increase production of cAMP, and phosphodiesterase inhibitors increase cytosolic cAMP by inhibiting its breakdown. Acting through protein kinase A, cAMP promotes phosphorylation of the L-type calcium channel to increase calcium release from the sarcoplasmic reticulum (SR). The increased systolic Ca^{2+} concentration (1) deinhibits the troponin complex to promote actin and myosin interaction and (2) increases the activity of myosin ATPase.[51] These mechanisms serve to increase both the total force developed and the rate at which the force is developed. Protein kinase A also exerts beneficial lusitropic effects by promoting phosphorylation of (1) the regulatory SR membrane phosphoprotein, phospholamban, to enhance diastolic calcium uptake and (2) troponin I, to increase the rate of cross-bridge detachment and relaxation.[51] Paradoxically, despite these beneficial properties, long-term administration of agents capable of increasing cAMP has been linked to increased mortality rates in patients with heart failure.[10] The increased Ca^{2+} concentrations are believed to contribute to the development of arrhythmias and to increase myocardial energy consumption and oxygen demand, thereby worsening the outcome. These findings lend support to the premise that downregulation and uncoupling of beta receptors, along with upregulation of adenylate cyclase inhibitory proteins, serve as compensatory protective mechanisms rather than primary biochemical abnormalities. Current investigations are evaluating agents capable of enhancing systolic performance “downstream” from cytosolic Ca^{2+} in the hopes of avoiding excessive mortality.

Figure 199-6 The beta-agonists (*1*) dobutamine and dopamine promote their positive inotropic and lusitropic effects through activation of adenylyl cyclase, with a subsequent amplification of cAMP production. The phosphodiesterase inhibitors (*2*) amrinone, milrinone and, to some degree, pimobendan blunt the degradation of cAMP, thereby promoting similar positive inotropic and lusitropic effects that should not be blunted by beta-receptor downregulation. Phosphorylation of the sarcolemmal L-type calcium channel is responsible for the positive inotropic action, whereas phosphorylation of phospholamban (PLB), with ensuing deinhibition of the sarcoplasmic reticulum calcium ATPase (SERCA), accounts for the enhanced diastolic function. Phosphorylation of troponin I (not shown) further enhances diastolic function by altering the cross-bridge kinetics between actin and myosin.



199.6.1.3.1

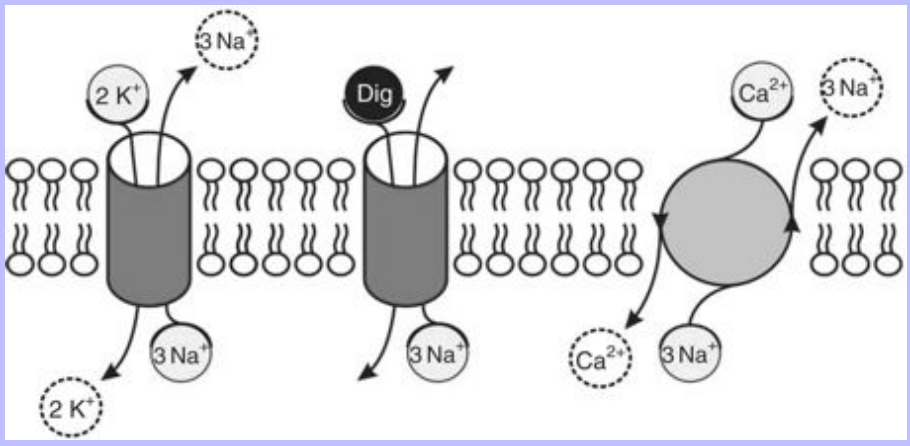
Digitalis glycosides

The digitalis glycosides are the only readily available class of inotropic agents that act independently of the cAMP second-messenger system. This characteristic imparts a degree of safety to the glycosides, with regard to their neutral effect on mortality, but simultaneously limits their inotropic potency.[52] Because of digoxin's potential positive inotropic effects and rate-controlling properties for atrial fibrillation, there is little debate that it is indicated in the treatment of dilated cardiomyopathy; however, there is substantial debate over its role in the management of mitral valve insufficiency. The authors' rationale for the use of

digoxin (0.003 mg/kg given orally twice daily) in dogs with mitral valve insufficiency is primarily its neurohormonal antagonism effect rather than pump support. Inhibition of the Na^+/K^+ ATPase pump in the vagal afferents sensitizes the baroreceptors to the prevailing blood pressure, which may decrease sympathetic outflow and renin-angiotensin activity.[17] Although the findings are purely anecdotal, the authors have had and continue to have cases in which the addition of digoxin to background therapy of furosemide and enalapril has produced clear symptomatic improvement.

The cardiac glycosides inhibit the action of the Na^+/K^+ ATPase pump by competitively binding to the extracellular potassium site (Figure 199-7). This antagonism promotes an increase in the intracellular sodium concentration, with its subsequent exchange for calcium via the reversible Na^+/Ca^{2+} pump. The net result is an increase in cytosolic calcium levels and enhanced cardiac contractility. Inhibition of the Na^+/K^+ ATPase pump further sensitizes the baroreceptors (blunting sympathetic discharge), inhibits renal tubular resorption of sodium (promoting mild diuresis), and increases the delivery of sodium to the distal tubules (inhibiting renin release).[17]

Figure 199-7 The Na^+/K^+ ATPase pump contributes to maintenance of the resting membrane potential by actively pumping three Na^+ ions out across the sarcolemmal membrane and two K^+ ions into the cell. The pump therefore is capable of maintaining both an electrical and a chemical gradient. Digoxin competitively binds the K^+ binding site on the extracellular surface, thereby inhibiting sodium efflux by means of this mechanism. The excessive intracellular Na^+ reverses the Na^+/Ca^{2+} exchanger and ultimately promotes an influx of Ca^{2+} and efflux of Na^+. The increased calcium transport augments calcium-induced calcium release from the sarcoplasmic reticulum, enhancing contractility.



Despite these theoretical benefits, digitalis has been unable to alter the natural course of heart failure.[52] The Digitalis Investigation Group (DIG) enrolled 6800 human patients in a placebo-controlled study to evaluate whether digoxin administration affected mortality or morbidity.[52] Digoxin did not reduce overall mortality but did reduce the rate of hospitalization for worsening heart failure (26.8% versus 34.7%, P <0.001). Subgroup analysis revealed that patients in class III or class IV heart failure showed the greatest benefit from digoxin administration. Compared with results from agents not related to glycosides, including dobutamine and milrinone, the findings of this investigation did not demonstrate excess mortality. It is unlikely that a similar study evaluating the efficacy of digoxin will ever be performed in dogs because of the extreme sample size needed to detect these small differences. One study reported that four of 10 dogs with dilated cardiomyopathy showed echocardiographically identifiable improvements in cardiac contractility after treatment with digoxin.[53] Whether the 7% increase in fractional shortening was a true increase in contractility or merely occurred subsequent to rate control (250 beats per minute [bpm] pretreatment versus 145 bpm post-treatment) is uncertain, but digoxin appears to be a relatively weak inotropic agent in dogs with heart failure. Nonetheless, it is the only oral inotropic agent that is readily available in the United States.

959

960

Therapeutic levels of digitalis increase parasympathetic tone, while blunting sympathetic activation, to promote slowing of the sinus node and increased atrioventricular (AV) node refractoriness with decreased conduction velocity. This property makes them useful in the management of DCM complicated by atrial fibrillation, because the other negative chronotropes (e.g., beta blockers, Ca^{2+} channel blockers) acutely depress systolic function. Digitalis is further indicated for the management of symptomatic DCM with sinus rhythm or left to right shunting lesions complicated by myocardial failure. Although digoxin is not always considered a mainstay of therapy for the management of mitral insufficiency, the authors continue to use it in cases of heart failure subsequent to chronic degenerative valve disease (CDVD). Although some of these mitral insufficiency patients fail to attain symptomatic benefit from digoxin therapy, the drug's low cost and safety when used appropriately continue to make it a useful agent. Digoxin is an inappropriate agent to use for rate control in cases of hypertrophic cardiomyopathy in which the primary abnormality is diastolic rather than systolic dysfunction. Any positive inotropic response predisposes HCM patients to the development or worsening of systolic anterior motion of the mitral valve.

199.6.1.3.1.1

Digoxin

Digoxin is the digitalis glycoside most commonly used in dogs, and it appears to be the most suitable glycoside for cats with systolic dysfunction. The bioavailability of digoxin after oral administration of the tablet form is approximately 60%.[12] The digoxin elixir shows better bioavailability after oral administration (about 75%) and is easier to dose appropriately for small dogs. After absorption, digoxin has a relatively long and variable serum half-life in dogs, with reports ranging from 23 to 39 hours.[12] In cats the duration is even more uncertain, with reports of mean half-lives ranging from 33.5 hours to 57.8 hours, with even longer half-lives during prolonged administration. Because approximately five half-lives are required to attain steady-state concentrations of a drug, digoxin cannot be expected to produce rapid symptomatic or rate-controlling benefits. Digoxin predominately undergoes renal excretion, although a small amount (approximately 15%) is metabolized by the liver. Renal failure significantly reduces the clearance of digoxin and profoundly increases the serum concentration, often to the point of intoxication. Patients with renal failure that require a cardiac glycoside should be given *digitoxin* because it undergoes hepatic elimination.

Determining the appropriate dose of digoxin to attain therapeutic levels yet avoid digitalis intoxication can be a frustrating endeavor. Traditionally, small dogs (less than 20 kg) have been treated with 0.005 to 0.008 mg/kg given orally twice daily, and larger dogs have been treated based on body surface area, with 0.22 mg/m^2 given orally twice daily. The intent with these doses was to attain a therapeutic digoxin level of 1 to 2 ng/mL. The DIG trial found that human mortality varied directly with serum digoxin levels, even within this "therapeutic" range. A new trend has emerged from that data whereby the human medical profession has aimed to keep trough levels of digoxin at 0.5 to 1 ng/ml. Whether these recommendations hold true for dogs is uncertain, but aiming for the low end of the reference range appears to be appropriate. The authors currently institute digoxin therapy at a dosage of 0.003 mg/kg given orally twice daily. If the digoxin level is subtherapeutic 5 to 7 days after initiation of therapy, the dosage is increased by 25%, and the serum level is rechecked a week later. This regimen is continued until therapeutic levels have been attained.

A number of factors may influence the distribution of digoxin, creating a need for special consideration and monitoring. The principal reservoir for digoxin is skeletal muscle, therefore dosing recommendations should be based on lean body mass. Obese dogs require lower doses of digoxin than thin dogs, and the dosing requirement for dogs that experience marked muscle loss tends to decline. Patients with right-sided heart failure and large volumes of ascites need dosage reductions because digoxin does not distribute into free abdominal fluid.[12] After institution of digoxin therapy, it is most appropriate to alter the dosing scheme based on the serum digoxin level, the response to therapy, and evidence of intoxication.

A number of drug interactions also are possible with digoxin. The best recognized interaction is between digoxin and the class Ia antiarrhythmic quinidine. When these drugs are combined, serum digoxin levels increase because quinidine displaces digoxin from the Na^+/K^+ ATPase pump and reduces its renal clearance through inhibition of P-glycoprotein. The binding of digoxin with myocardial Na^+/K^+ ATPase is "tighter" than that with skeletal muscle, therefore the net effect of this drug combination is an increase in the likelihood of digitalis intoxication. It is recommended that these agents not be used together. Fortunately, no interactions have been reported between digoxin and the more frequently used class I anti-arrhythmics procainamide and mexiletine. Most of the other reported drug interactions, with amiodarone, verapamil, nifedipine, propafenone and, to a lesser extent diltiazem, occur because of inhibition of P-glycoprotein. Any agent that alters renal blood flow or hepatic microsomal enzymes has the potential to disturb digoxin's pharmacokinetics.

Similar to quinidine, the extracellular potassium concentration can influence digoxin binding to the Na^+/K^+ ATPase pump. The hypokalemia often associated with anorexia or large doses of a diuretic leaves more receptors exposed for digoxin attachment, thereby increasing the likelihood of digitalis intoxication. With hyperkalemia, more receptors are bound, and digoxin is displaced from the Na^+/K^+ ATPase. Hypercalcemia and hypernatremia promote digoxin's inotropic and toxic properties, whereas decreased calcium and sodium concentrations have the opposite effects.

Since it was recognized that taurine deficiency was responsible for most cases of feline DCM, the number of cats receiving digoxin has declined over the past decade. The authors still encounter an infrequent case of DCM unrelated to taurine deficiency, and some cases of restrictive cardiomyopathy have such poor systolic function that digoxin is indicated. Cats appear to tolerate the tablet form of digoxin better than the alcohol-based elixir. The recommended dose is one fourth of a 0.125 mg tablet given orally. Dosing intervals are as follows: (1) cats weighing 3 kg or less: every 48 hours; (2) cats

weighing 4 to 5 kg: every 24 to 48 hours; (3) cats weighing 6 kg or greater: every 24 hours. Because of the variable half-life of digoxin in cats, the authors typically monitor serum levels 7 to 10 days after initiation of therapy.

199.6.1.3.2 Digitalis toxicity

Without a doubt, digoxin is a toxic substance when excessive amounts accumulate. This narrow therapeutic index highlights the need for careful client and veterinary attention when digoxin is part of a treatment regimen. In the authors' experience, when digoxin therapy is instituted at a dosage of 0.003 mg/kg given orally twice daily, with uptitration based on serum digoxin concentrations, the incidence of digitalis toxicity is low both clinically and biochemically.

Clients should be informed of the most common manifestations of digoxin intoxication and given concise instructions on what to do if clinical signs develop. Continuing drug administration and waiting until the next recheck is not an appropriate step; the authors recommend discontinuation of all drugs followed by an immediate veterinary evaluation. It should be emphasized that the three regions frequently affected by excessive digoxin accumulation are the myocardial, gastrointestinal, and central nervous systems. Gastrointestinal manifestations, which often precede central nervous system (CNS) and myocardial toxicity, commonly include anorexia and vomiting, presumably from a direct chemoreceptor triggering effect exerted by digoxin. The serum concentration at which gastrointestinal signs develop is extremely variable. Some dogs have digoxin-associated anorexia at subtherapeutic drug concentrations, whereas others do not show any evidence of toxicity even with serum concentrations well above the therapeutic range. It can be difficult to determine whether the anorexia is associated with digoxin administration, azotemia secondary to a decreased GFR or renal insufficiency, poor diet palatability, or worsening heart failure. A biochemical profile, serum digoxin determination, and thoracic radiographs should be obtained in any digoxin-treated dog with heart failure that suddenly develops anorexia. In the absence of complicating factors such as azotemia or pulmonary edema, the authors temporarily discontinue digoxin administration even if the serum level is within the therapeutic range. If the pet's appetite returns (suggesting digoxin-associated anorexia), a lower digoxin dose may be instituted or the drug may be discontinued all together. Digoxin does not provide enough mortality benefit or positive inotropic response to warrant administration in the face of profound anorexia or other complications.

960
961

Although the myocardial complications may be more difficult for owners to recognize, they often are the most serious. Digoxin toxicity may induce almost every known cardiac arrhythmia, including both bradyarrhythmias and tachyarrhythmias. First-and second-degree AV block, sinus bradycardia, and sinus arrest are presumably influenced by digoxin's parasympathomimetic properties. Life-threatening ventricular tachyarrhythmias may develop as a consequence of cellular calcium overload. Excessive calcium precipitates late afterdepolarizations, whereby oscillations within the diastolic membrane potential periodically reach threshold and produce a pre-mature complex. The slowed conduction and altered refractory period may then precipitate re-entry, yielding ventricular tachycardia. Obviously, determining whether the ventricular arrhythmia is associated with digoxin administration or is a manifestation of the underlying disease process may be difficult, but in general, discontinuation of digitalis is indicated.

The CNS alterations mediated by digoxin toxicity may include depression, disorientation, or delirium. Again, determining whether such clinical signs are attributable to digitalis intoxication or progression of the underlying disease process often is difficult. These patients should be evaluated for hypotension, in addition to having their serum digoxin levels measured.

199.6.1.3.2.1 Treatment of digitalis toxicity

The aggressiveness with which digoxin toxicity is treated depends on the manifestation of intoxication rather than the serum digoxin level. Gastrointestinal disturbances can frequently be managed by discontinuation of the drug. Dogs with bradyarrhythmias are often asymptomatic, and withdrawal of digoxin is the only therapeutic alteration required. In the rare case of symptomatic patients, short-term administration of atropine may be required while the toxic digoxin concentrations expire. The most aggressively managed complication of digitalis intoxication is ventricular tachyarrhythmias.

The class Ib antiarrhythmic drug lidocaine is the first-choice agent for acute management of digitalis-induced ventricular tachycardia. It is effective at targeting late afterdepolarizations without substantially affecting the sinus rate or AV nodal conduction. An initial bolus of 2 to 4 mg/kg is administered intravenously over 1 to 2 minutes, followed by a constant-rate infusion to suppress the arrhythmias. Lidocaine should be administered conservatively to cats because they are more sensitive to the neurotoxic side effects. Although infrequently used, phenytoin also appears efficacious for the treatment of digoxin-induced arrhythmias.

Because hypokalemia may precipitate digoxin toxicity and limit the efficacy of antiarrhythmic agents, it is important to evaluate the serum potassium concentration and to correct underlying deficits. Because of its ability to bind competitively the Na^+/K^+ ATPase pump, potassium can displace digoxin from the myocardium, thereby decreasing the likelihood of toxicity.

The development of a specific antibody fragment for cardiac glycosides has enabled production of an "antidote" for severe digoxin intoxication. Digibind® (GlaxoSmith Kline, Durham NC) complexes with the digoxin molecule and inhibits binding to the Na^+/K^+ ATPase pump, quickly resolving drug intoxication. Unfortunately, this drug is expensive, and its use in clinical practice therefore is limited.

199.6.2 Deficiencies of the Triple Drug Regimen

199.6.2.1 Early Institution of Therapy

Despite the relative safety and symptomatic benefit of triple drug therapy (i.e., furosemide, enalapril, and digoxin), this regimen has limitations. A possible ineptitude of this combination for the early treatment of cardiac disease is the mechanism by which ACE inhibitors promote their beneficial response. It is logical that, for these drugs to blunt the adverse consequences of the renin-angiotensin system, the system must be activated. In response to RAS activation after cardiac injury, the heart hypertrophies to normalize cardiac output and wall stress. Within physiologic limits, this hypertrophy, possibly combined with the inhibitory effects of circulating atrial natriuretic peptide, may be able to restore the renin-angiotensin system to resting levels.

Studies that have evaluated activation of the RAS in normal dogs, in dogs with asymptomatic dilated cardiomyopathy, and in dogs with symptomatic dilated cardiomyopathy lend support to this hypothesis.[54,55] In a study by Koch et al.,[54] 23 dogs were evaluated; nine dogs had asymptomatic DCM, eight had symptomatic DCM, and six had severe congestive heart failure subsequent to DCM. Sixteen giant breed dogs without evidence of cardiac disease were used to establish the neuroendocrine control values. In dogs with asymptomatic dilated cardiomyopathy, the plasma renin activity and aldosterone concentrations were not

significantly different from those in control dogs (1.48 versus 0.89 and 35 versus 61, respectively). In dogs with symptomatic DCM and congestive heart failure, significant activation of the neurohormonal axis was seen compared with normal dogs and those with asymptomatic DCM. Plasma renin activity and aldosterone concentrations increased substantially between dogs with functional class III and class IV heart failure (3.8 versus 30.8 and 123 versus 600, respectively). Tidholm et al.[55] further evaluated activation of the neurohormonal systems of 45 dogs: 15 dogs with DCM and radiographic evidence of heart failure, 15 dogs with DCM without evidence of heart failure, and 15 age-, breed-, and gender-matched control dogs. They, too, found that in dogs with asymptomatic DCM, plasma renin activity, aldosterone concentrations, and N-terminal (NT)-pro atrial natriuretic peptide levels were not significantly different from those in control dogs. Dogs with DCM and congestive heart failure showed significant differences in all three variables compared with normal dogs and those with asymptomatic DCM.

Investigation of the effects of mitral valve insufficiency on the circulating neurohormonal system has also proved interesting, with some conflicting results. Pedersen et al.[56] evaluated the plasma renin and aldosterone concentrations of 18 Cavalier King Charles spaniels with asymptomatic or mildly symptomatic mitral insufficiency. Compared with 18 Cavalier King Charles spaniels without signs of heart disease, the plasma renin levels (median 3.44 versus 2.51, P = 0.03) and aldosterone concentrations (median 53 versus 27, P = 0.03) were significantly higher in dogs with valvular insufficiency. Haggstrom et al.[57] repeatedly evaluated 11 Cavalier King Charles spaniels with mitral insufficiency at 6-month intervals until signs of decompensation developed. The dogs did not receive cardiac medications during the study, and their diets remained the same throughout. The time of decompensation was considered the end-point of the study (situation 2), and the two most recent study periods (at 4.6 ± 2.2 months [situation 1] and 11.7 ± 1.8 months [situation 0]) prior to decompensation completed the three periods analyzed. The investigators found that N-terminal atrial natriuretic peptide (ANP) concentrations increased significantly from situation 0 to situation 1 and were further increased from situation 1 until the time of decompensation (situation 2). Plasma aldosterone concentrations were not significantly different from situation 0 to situation 1 but were found to decrease significantly at the time of decompensation (P <0.01). Plasma angiotensin II concentrations were not significantly different between situation 0 and situation 1 or between the beginning of the study and the end of the study, but similar to the aldosterone levels, angiotensin II was significantly decreased between situation 1 and situation 2 (P <0.05). The investigators concluded that the reductions in circulating angiotensin II and aldosterone at the onset of decompensation likely occurred subsequent to the elevation in ANP levels. Atrial natriuretic peptide has been reported to directly inhibit the release of renin and aldosterone and to promote a reduction in intravascular volume, thereby limiting RAS activation in the early stages of decompensation.[57] However, significant, long-term elevation of ANP in cases of severe heart failure may promote receptor downregulation, attenuating the inhibitory activity on the renin-angiotensin system.[58] Renal hypoperfusion and enhanced elimination of ANP may further blunt the counterbalancing activity of ANP, possibly allowing the RAS to accelerate the progression of heart failure unabated.[58]

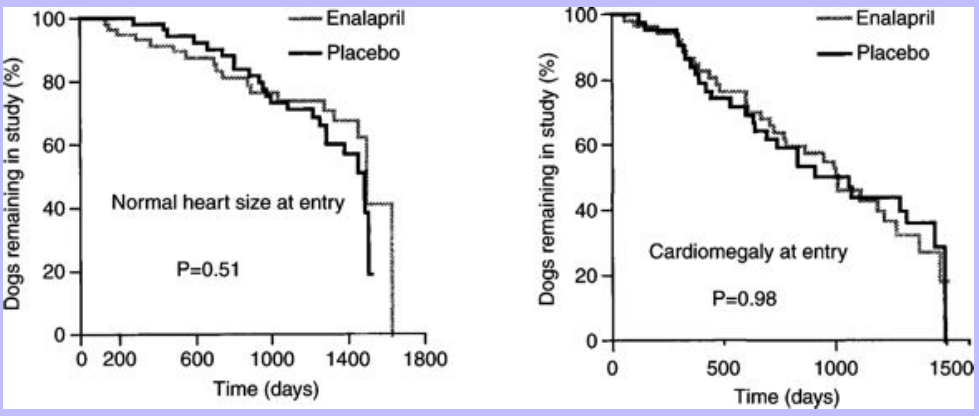
961 962

Although it was determined that systemic, circulating RAS is not activated at the onset of heart failure in Cavalier King Charles spaniels or in asymptomatic dogs with DCM, recognition that local tissue pathways exist for the RAS may still support early institution of ACE inhibition. Canine ventricular myocytes have been recognized locally to contain the constituents of the RAS that may promote ventricular remodeling in an autocrine fashion.[59] Dogs subjected to rapid ventricular pacing to induce heart failure were compared with control dogs that were instrumented but not paced. Using reverse-transcriptase polymerase chain reaction (RT-PCR) and Western blot testing, Barlucchi et al.[59] found significant differences in canine myocyte RAS activity between control and failing hearts. Angiotensinogen expression was increased 2.5-fold (P <0.001), renin was increased 3.6-fold (P <0.001), the two forms of ACE identified at 134 and 170

kDa were increased 1.45-fold ($P < 0.005$) and 1.44-fold ($P < 0.002$), respectively, and the AT_1 receptor subtype of angiotensin II was increased 1.7-fold ($P < 0.001$) after 4 weeks of pacing. Angiotensin II levels measured by enzyme-linked immunosorbent assay (ELISA) were increased 2.2-fold ($P < 0.004$) in dogs subjected to pacing, whereas no significant differences were seen in chymase expression ($P = 0.28$) or the expression of the myocyte AT_2 receptor subtype of angiotensin II ($P < 0.06$).[59]

These findings point out one of the most challenging questions in the treatment of cardiac disease in companion animals: when is the appropriate time to initiate therapy? Although ACE inhibitors have proved efficacious at delaying the onset of heart failure in humans with asymptomatic left ventricular dysfunction, no similar published studies exist to support this conclusion in dogs and cats.[23] A double-blind, placebo-controlled study of 229 Cavalier King Charles spaniels with asymptomatic mitral regurgitation found that enalapril was unable to delay the onset of heart failure (Figure 199-8).[44] Although this study has been criticized on some counts (e.g., inadequate dose of ACE inhibitor [0.25 to 0.5 mg/kg daily], use of a single breed with a disease course that may not be representative of all dogs, and insufficient statistical power), it nonetheless was a 4.5-year endeavor that remains the largest published evaluation of therapy aimed at delaying the onset of heart failure in dogs with asymptomatic mitral regurgitation. These findings cannot completely exclude the potential for other ACE inhibitors to delay the onset of heart failure in cases of mitral insufficiency or the possible benefit of early institution of ACE inhibition in dogs with DCM or cats with HCM; however, while awaiting study findings on those questions, the authors will continue to delay institution of ACE inhibitor therapy until cardiac disease has progressed to a point where diuretics are needed to control congestion.

Figure 199-8 Early institution of enalapril therapy was unable to delay the onset of congestive heart failure in a study of 229 asymptomatic Cavalier King Charles spaniels. (From Kvart C: Efficacy of enalapril for prevention of congestive heart failure in a study of 229 cases of asymptomatic myxomatous valve disease and asymptomatic mitral regurgitation. *J Vet Intern Med* 16:1, 2002.)



199.6.2.2 Therapeutic Efficacy in Dilated Cardiomyopathy versus Mitral Insufficiency

Activation of the renin-angiotensin system occurs subsequent to one of three major stimuli: decreased renal perfusion pressure, reduced sodium delivery to the macula densa, or sympathetic activation.[60] Therefore many cardiovascular and systemic disease processes may promote renin release, with eventual production of angiotensin II. Despite the potential for ACE inhibitors to blunt angiotensin II formation, they may have variable efficacy in alleviating the clinical signs of heart failure, depending on the underlying disease process.

The potential for discrepancies in response to ACE inhibitor therapy seemed apparent in the IMPROVE and COVE studies, which evaluated enalapril in the management of heart failure subsequent to dilated cardiomyopathy or mitral regurgitation (MR).[41,42] In both studies, dogs with DCM appeared to show a more dramatic response compared with those that had MR. After 28 days of enalapril therapy, the dogs with DCM showed significant improvement, compared with animals receiving placebo, in the class of heart failure, pulmonary edema scores, overall evaluation, mobility, attitude, activity, demeanor, cough (total, night, normal activity, and exercise), and appetite scores.[42] Dogs with MR allocated to enalapril showed significant improvement only in overall evaluation, mobility, activity, and cough (total).[42] It was noted that a longer study may have identified further significant improvements in patients with mitral regurgitation.

962

963

Subsequently, a longer term study was performed in an effort to determine the effects of enalapril on the survival of dogs with heart failure.[5] Dogs with DCM or MR that had developed congestive heart failure were enrolled and randomly allocated to enalapril or placebo in addition to receiving standard medical therapy. The dogs were followed until death, treatment failure (defined as deterioration of condition requiring additional medications), or termination of the study. In contrast to the short-term investigations, dogs with mitral insufficiency randomized to enalapril remained in this study significantly longer than those randomized to placebo (mean, 159.5 days versus 86.6 days, $P = 0.041$), whereas the DCM subgroup showed no significant differences (mean, 142.8 days versus 56.5 days, $P = 0.06$).[5]

Although no steadfast conclusions can be drawn from the differences between the short-and long-term studies, these findings highlight the difficulty in extrapolating across disease conditions. Furthermore, they should show the pitfalls of extrapolating results from human studies, in which the vast majority of patients have left ventricular dysfunction secondary to coronary artery disease or myocardial infarction. Until further studies can better elucidate the benefits or detriments of current veterinary medical management, practitioners must continue to rely on anecdotal evidence, presumption, and clinical judgment.

199.6.2.3 Failure to Target Other Neurohormonal Pathways

An additional limitation of triple drug therapy is the failure to target two of the neurohormonal modulators that perpetuate cardiomyocyte necrosis and ventricular fibrosis. Studies have shown that adrenergic stimulation decreases cardiomyocyte viability by means of cAMP-mediated calcium overload and that aldosterone promotes myocardial hypertrophy and fibrosis, autonomic imbalance, and electrolyte imbalances that may precipitate arrhythmias.[16,61]

199.6.3 Potential therapeutic strategies

199.6.3.1 Aldosterone antagonists

The neurohormonal hypothesis of heart failure gains further support from the fact that the aldosterone antagonist spironolactone has proved efficacious in the management of severe heart failure in humans. Studies have recognized that small concentrations of aldosterone can stimulate cardiac fibroblast expression of type I and type III collagen, thereby promoting myocardial fibrosis.[19] Although ACE inhibitors are considered effective at reducing aldosterone levels by inhibiting the formation of aldosterone's primary secretagogue, angiotensin II, there is mounting evidence of a phenomenon called *aldosterone escape*.[29] Increased potassium levels induced by ACE inhibitors and decreased hepatic clearance may contribute to this RAS-independent increase in aldosterone.[19] It also has become apparent that local tissue pathways for the production of aldosterone exist in extra-adrenal sites, although the importance of these tissue pathways has not been clarified.[19] Because aldosterone impairs normal vasodilative responses, promotes myocardial fibrosis, potentiates the sympathetic nervous system, and influences electrolyte transport, a recent strategy to target heart failure has been the administration of aldosterone antagonists.[61]

Addition of the aldosterone antagonist spironolactone to the baseline therapy of patients with severe heart failure produced a 30% reduction in mortality and a 35% reduction in the frequency of hospitalization for worsening heart failure.[62] Although identification of the mechanism by which spironolactone exerts its beneficial effects was not the aim of the Randomized Aldactone Evaluation Study (RALES) group, a small substudy of 261 participants suggests that limitation of aldosterone-stimulated collagen synthesis is the major contributor.[63] In a recent model of experimental heart failure created in dogs, the aldosterone antagonist eplerenone was able to attenuate the development of interstitial fibrosis and cardiomyocyte hypertrophy while increasing capillary density.[64] Although the frequency and likelihood of aldosterone escape are unknown in dogs treated with ACE inhibitors, it seems prudent to consider spironolactone administration for patients treated with enalapril. Currently the optimal dosing scheme for dogs is unknown; however, the authors combine spironolactone (2 mg/kg given orally twice daily) with their standard therapy (furosemide and enalapril with or without digoxin) to further combat the detrimental consequences of aldosterone. Whether this is the optimal regimen or whether spironolactone promotes symptomatic or survival benefit in dogs with heart failure is unknown at this time.

199.6.3.2 Beta-blockers

Similar to what happens in humans, in dogs with congestive heart failure the body activates the sympathetic nervous system and RAS in an effort to maintain homeostasis. Unfortunately these short-term compensatory mechanisms promote adverse hemodynamic and biochemical alterations that ultimately contribute to weakness, debilitating congestive signs, deterioration of cardiac function, and ultimately death. The IMPROVE and COVE investigators identified the short-term utility of enalapril in combating dilated cardiomyopathy, and since then ACE inhibition has become routine therapy.[41,42] Although it has not been evaluated in controlled clinical trials, the loop diuretic furosemide appears to have a potent effect in alleviating the congestive clinical signs that frequently accompany heart failure. The efficacy, safety, and affordability of furosemide have made it a mainstay in the management of heart failure. Because systolic dysfunction is the primary phenotypic manifestation of dilated cardiomyopathy, the authors' ideal therapy

would further use an agent that augments systolic performance without promoting adverse events. In humans, long-term administration of beta agonists and phosphodiesterase inhibitors is marred by the resultant increase in mortality and in hospitalizations for heart failure. Whether these findings would also be reflected in large-scale canine trials is unknown, but the historical adverse events have caused pharmaceutical companies to abandon their marketing in the United States. Thus digoxin is the primary positive inotrope available to improve systolic function. Although it has been reported to produce echocardiographically identifiable improvements in fractional shortening in some dogs, it remains a relatively weak positive inotrope.[53]

Just when some investigators had given up on the search for a safe positive inotropic agent, new investigations have identified a drug class that increased measures of systolic performance while decreasing mortality and hospitalizations. Surprisingly, this class of drugs is the beta blockers.

Agents that antagonize beta receptors act by interfering with the endogenous neurohormonal system. The primary integrator of the neurohormonal response to arterial underfilling appears to be the sympathetic nervous system.[19] Excessive catecholamine levels promote a daunting number of detrimental effects: peripheral vasoconstriction, impaired sodium excretion by the kidneys, myocardial hypertrophy with impaired coronary flow, provocation of arrhythmias, apoptosis, and myocytolysis.[17] Some researchers suggested that blockade of this primary integrator may retard the unrelenting nature of heart failure, whereas others were reluctant to blunt the effects (e.g., positive inotropic and chronotropic) of this potentially beneficial system. The proponents of beta blockade contended that these potential benefits are already self-limited by internalization and degradation of beta receptors in response to elevated circulating levels of norepinephrine. To settle the controversy, large-scale, placebo-controlled trials were conducted to identify the potential benefits of antiadrenergic therapy. In these studies, the second-generation beta blockers bisoprolol and metoprolol and the third-generation beta blocker carvedilol were shown to reduce mortality substantially in patients with a reduced ejection fraction.[65–67] Because the study protocols included stringent observation, slow upward drug titration, and recruitment of patients with stable rather than decompensated heart failure, most of the patients enrolled in these trials were able to tolerate the short-term negative inotropic effects associated with beta blocker administration. With long-term administration, at 4 to 12 months of treatment beta blockers were found to induce a time-dependent process of reverse remodeling in which systolic function improved as myocardial hypertrophy regressed and the ventricular geometry normalized.[68] Among the medications used to treat heart failure, this improvement in intrinsic systolic function appears to be unique to beta blockers. Based on these results, beta blocker administration currently is recommended for humans with stable heart failure secondary to systolic dysfunction.[17]

963

964

The primary types of beta blockers evaluated thus far have been those that selectively inhibit the $beta_1$ receptor (metoprolol and bisoprolol) and that antagonize $beta_1$, $beta_2$, and $alpha_1$-adrenergic receptors (carvedilol). Although carvedilol blocks peripheral vasodilative $beta_2$ receptors, it concurrently blocks vasoconstrictive $alpha_1$-adrenergic receptors, thereby enhancing its tolerance in patients afflicted with systolic dysfunction. In patients with mild to moderate heart failure, the reported tolerance for $beta_1$-selective antagonists ranges from 79% to 100%, whereas carvedilol is tolerated by approximately 92% of patients.[68] The most recent carvedilol study was performed in patients with stable NYHA class IV heart failure and an ejection fraction of less than 25%. Despite the severity of their disease, at 4 months 65% of patients assigned to carvedilol were receiving the target dose of their assigned medication.[67]

The safety and efficacy of beta blockers in the management of heart failure have been more critically evaluated in controlled drug trials than has any other class of drugs. A meta-analysis of 18 published double-blind, placebo-controlled trials involving primarily NYHA class II and class III heart failure that were conducted through 1998 revealed persuasive positive effects on mortality, hospitalization, and the ejection fraction. Beta blockers reduced the risk of death by 32% and the risk of hospitalization for heart failure by 41% while increasing the ejection fraction by 29%.[69] Patients assigned to beta blockers were 32% more likely to show improvement in their heart failure class and 30% less likely to experience worsening heart failure.[69] Large-scale trials of bisoprolol, metoprolol, and carvedilol have been reported since 1998, in which mortality reductions of 34%, 34%, and 35%, respectively, were identified.[65–67] These impressive findings have led to small-scale investigations into the management of canine heart failure with carvedilol. While the results of those trials are awaited, new treatment strategies for the management of canine dilated cardiomyopathy and degenerative mitral valve disease can be hypothesized.

199.6.3.3 Beta-Blockers for the management of DCM

The management of canine dilated cardiomyopathy is often frustrating and unrewarding. Two retrospective analyses have shown median survival times of 65 days and 27 days, and 1-year survival probabilities of 37.5% and 17.5% have been reported.[2,3] The prognosis for Doberman pinschers appears even worse, with a reported median survival time of 6.5 weeks and a 1-year survival probability of 3%.[4] Survival times may since have improved with more robust use of ACE inhibitors, but dilated cardiomyopathy seems to progress much more rapidly in dogs than in humans. Approximately 25% of human patients referred to major medical centers with newly diagnosed dilated cardiomyopathy die within 1 year, and the 5-year survival rate is 50%.[70]

This discrepancy between humans and dogs in the rate of disease progression poses a problem for the management of DCM in dogs. As previously described, beta blockers have proved to be one of the most effective agents for combating heart failure, because their antiadrenergic properties offset the toxic and hemodynamic derangements induced by norepinephrine. Unfortunately, therapy for 1 to 3 months appears to be necessary before any improvement in systolic function is recognized, and administration for up to 18 months is needed for reversal of maladaptive remodeling with reduction in left ventricular volumes.[71] It therefore seems that many dogs with dilated cardiomyopathy would not live long enough to reap the beneficial effects of beta blockers. The percentage of dogs that would tolerate the short-term negative inotropic effects induced by beta blockade also is uncertain.

A potential remedy for this situation may be concurrent, low-dose administration of a positive inotropic agent during the uptitration and early target phases of beta blocker therapy. The phosphodiesterase inhibitor and calcium sensitizer pimobendan may satisfactorily fulfill this role. A study evaluating the effectiveness of carvedilol therapy compared with a combination of carvedilol and pimobendan found that withdrawal of therapy because of worsening of heart failure occurred less often in the combination group.[72]

Similar to amrinone and milrinone, pimobendan is able to improve cardiac contractility, promote ventricular relaxation, and induce vasodilatation by increasing cAMP levels. However, pimobendan also has calcium-sensitizing properties that increase contractility by enhancing the interaction between troponin C and the prevailing cytosolic calcium level. Compared with agents that increase cAMP, a calcium sensitizer has several benefits: (1) it lowers the risk of induction of arrhythmias; (2) it reduces cell injury and death caused by calcium overload; (3) it exerts its effects without increasing energy demands; and (4) it has the

potential to reverse systolic dysfunction in the face of acidosis and myocardial stunning.[73] In a study of humans with heart failure, pimobendan was able to increase exercise capacity significantly without increasing oxygen consumption.[74] Proarrhythmic effects were not identified during 24-hour electrocardiography, but a trend toward increased mortality was seen in the patients assigned to pimobendan. Enrollment criteria excluded any patients treated with beta blockers, therefore whether combination therapy may have reduced the trend toward increased mortality is speculative. Nonetheless, the concept of combining a novel positive inotropic agent with a slowly titrated beta blocker may very well deserve attention. Unfortunately, pimobendan currently is not available in the United States, and the use of beta blockers in the management of DCM should be considered purely investigational.

199.6.3.4 Beta-blockers for the management of chronic degenerative valve disease

The authors currently manage CDVD with furosemide, an ACE inhibitor, and digoxin, with the addition of spironolactone in moderate to severe cases. This combination directly targets excessive plasma volume and the renin-angiotensin system while indirectly combating activation of the sympathetic nervous system. A new concept may include the addition of a beta blocker to antagonize directly the detrimental consequences of adrenergic activation. A recent study evaluated the hemodynamic effects of the ACE inhibitor lisinopril versus a combination of lisinopril and the beta blocker atenolol in the treatment of experimental mitral regurgitation.[75] Lisinopril was found to reduce significantly left ventricular end-diastolic pressure, pulmonary capillary wedge pressure, and end-diastolic stress, but it had no marked effect on forward stroke volume or left ventricular contractility. Three months after the addition of atenolol to this regimen, forward stroke volume and left ventricular contractility had returned to normal. Whether this effect occurred subsequent to an additional 3 months of ACE inhibition or was mediated by the beta blockade is uncertain. Regardless, this study suggests that direct adrenergic antagonism may prove beneficial in the management of CDVD, and further studies may be warranted.

964

965

199.6.4 Management of Refractory Congestive Heart Failure

Over time, many patients become refractory to standard medical therapy as disease progression continues or if a concurrent systemic disease process develops that exerts detrimental effects on the cardiovascular system (e.g., hyperadrenocorticism, hypothyroidism, renal failure, systemic hypertension, neoplasia, anemia, pneumonia, or pulmonary thromboembolism). Infrequent causes of an acute bout of decompensation include the development of hemodynamically important arrhythmias, sudden rupture of chordae tendineae, or splitting of the left atrial wall subsequent to severe mitral insufficiency and elevated left atrial pressure. For these reasons, any patient that continues to show clinical signs of congestion or low cardiac output despite appropriate medical therapy should be closely re-evaluated. After determining whether the owner is administering the prescribed drugs at the appropriate intervals, the practitioner should obtain an ECG, thoracic radiographs, complete blood count, biochemical profile, and blood pressure measurement. Echocardiography often is warranted to characterize the severity of valvular insufficiency, the extent of chamber enlargement, and the degree of systolic dysfunction.

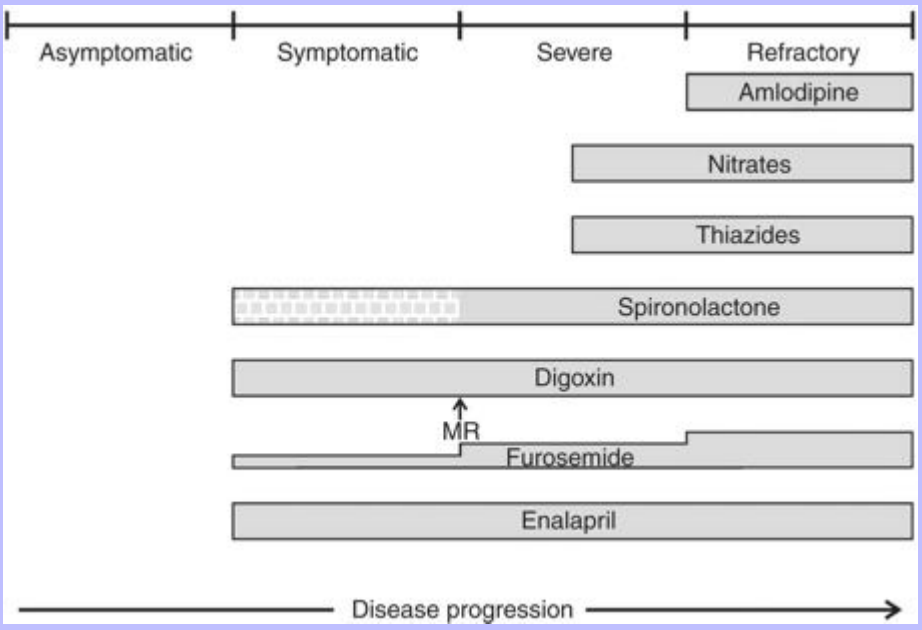
If an underlying disease process is identified, it should be managed appropriately before institution of therapy with new cardiac drugs. Attempts should be made to suppress significant ventricular arrhythmias; agents capable of slowing conduction through the atrioventricular node (e.g., calcium channel blockers or beta blockers) may be required to help control the ventricular response rate in the face of atrial fibrillation. Potent afterload reduction with nitroprusside or hydralazine often is required to combat the effects of ruptured chordae tendineae. Left atrial tears are difficult to manage.

If no underlying disease process is identified, several strategies may be used to manage these refractory patients (Figure 199-9). Afterload reduction using arterial vasodilators, preload reduction using additional diuretics or venodilators, or additional neurohormonal blockade using beta blockers or spironolactone may be warranted. The route of diuretic administration may be modified, or positive inotropic agents periodically may be given intravenously. The inherent risks and complications of treatment are greatest in patients with refractory heart failure, and referral to a specialist is wiser than embarking on an unconventional treatment protocol.

199.6.4.1 Vasodilators

Vasodilators promote smooth muscle relaxation of the arterioles (arterial vasodilators), veins (venodilators), or arteries and veins (balanced vasodilators). Although these drug classes promote a similar therapeutic end-point, vasodilatation, a variety of mechanisms are involved in achieving their effect.

Figure 199-9 Although therapy must be tailored on a case-by-case basis, the authors traditionally do not start medical therapy in asymptomatic patients. As the disease progresses over time and compensatory mechanisms overwhelm traditional ACE inhibitor, diuretic, and digoxin therapy, other strategies must be used to combat congestive and low-output signs. Currently the optimal time for institution of therapy with aldosterone antagonists is uncertain.



Heart failure is associated with activation of the sympathetic nervous system and renin-angiotensin system. In the face of decreased cardiac output, these systems promote arteriolar vasoconstriction to maintain

adequate perfusion pressure and venoconstriction to enhance venous return to the heart. Unfortunately, the arteriolar vasoconstriction further increases the workload of the failing heart; more energy must be expended to overcome high systemic vascular resistance, and less energy is available to expel blood into the aorta. Stroke volume (and hence cardiac output [CO]) decreases, but systemic vascular resistance (SVR) continues to increase in an effort to maintain blood pressure (BP = CO × SVR). The increase in preload promoted by venoconstriction also proves detrimental because the diseased heart, operating on the plateau of the Frank-Starling curve, is unable to further hypertrophy or increase its contractility. Ventricular end-diastolic pressures begin to rise, leading to the eventual formation of edema.

Based on these hemodynamic sequelae, it seemed apparent that a reduction in afterload and/or preload ultimately would reduce mortality. Interestingly, the first V-HeFT study found that prazosin, the agent most capable of reducing blood pressure, was unable to reduce mortality compared with placebo.[13] The combination of hydralazine and isosorbide dinitrate reduced mortality, but in the V-HeFT II trial, enalapril was more effective than the combined vasodilators at preventing death.[22] This beneficial effect was seen despite the inability of the ACE inhibitor to reduce blood pressure. Obviously blood pressure and systemic vascular resistance are not synonymous, but these findings have detracted from the use of potent afterload reducers in the routine management of heart failure. Venodilators may still be effective at reducing the development of edema, but the problem of drug tolerance has limited their use to animals with refractory heart failure.

199.6.4.1.1

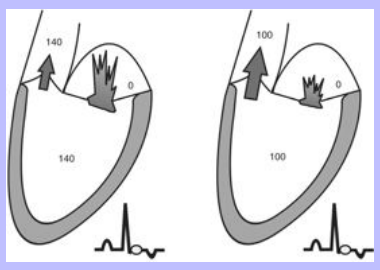
Amlodipine

Amlodipine is a second-generation, dihydropyridine (DHP) calcium channel blocker that primarily produces arteriolar vasodilatation and is used in the treatment of systemic hypertension. Unlike the non-DHPs diltiazem and verapamil, amlodipine has little effect on conduction through the atrioventricular node, and its negative inotropic properties appear to be offset by a reduction in afterload. Although amlodipine was unable to reduce mortality in an evaluation of 1153 patients with left ventricular dysfunction and severe heart failure (P = 0.07), it did reduce the mortality rate by 31% (P = 0.04) in the subgroup of patients with nonischemic DCM.[14] Despite this mortality benefit, 14 of the 209 patients with DCM assigned to amlodipine developed pulmonary edema (compared with 2 of 212 patients assigned to placebo). The mechanism involved in this development was uncertain.

965

966

Figure 199-10 Left ventricular systolic pressure is influenced by the systemic vascular resistance, therefore agents capable of reducing afterload have the potential to decrease the volume of mitral insufficiency while increasing the effective forward stroke volume.



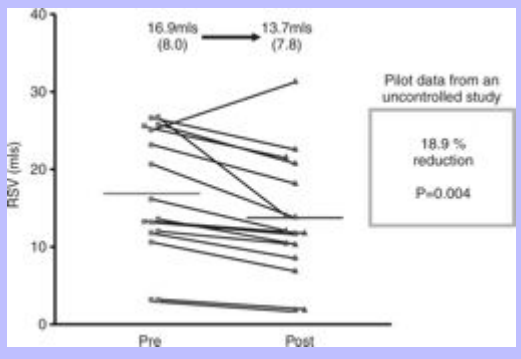
An interesting application of amlodipine therapy may be for severe mitral valve insufficiency. A reduction in systemic vascular resistance (and hence the systolic left ventricular to left atrial pressure gradient) may serve to decrease the volume of mitral valve insufficiency (Figures 199-10 and 199-11). Potential benefits of amlodipine are its 30-hour half-life and peak effect in 4 to 7 days after institution of therapy to dogs. This slow onset of action may give the baroreceptors time to reset, thereby avoiding sympathetic activation and reflex tachycardia. The effective dose of amlodipine seems to vary; a common strategy is to institute therapy at a low dose (0.05 mg/kg given orally once daily), followed by slow titration up to 0.2 mg/kg until a reduction in blood pressure is achieved. Because of the drug's long half-life, the authors typically monitor blood pressure weekly, using uptitration until the target blood pressure is attained.

199.6.4.1.2

Hydralazine

Hydralazine is a direct-acting arterial vasodilator that promotes vasodilatation through an unknown mechanism. It was studied in the 1980s for the management of CDVD in dogs and was found to produce substantial decreases in mean arterial blood pressure, total systemic resistance index, and pulmonary capillary wedge pressure.[76] Since that time, hydralazine appears to have been pushed aside by the ACE inhibitors in the management of uncomplicated heart failure. This trend likely resulted from the commonly encountered side effects of hydralazine (i.e., symptomatic hypotension, anorexia, vomiting, and diarrhea), the presence of elevated aldosterone levels seen after hydralazine therapy compared with captopril, and the significant results of the V-HeFT II trial.[77]

Figure 199-11 After administration of the calcium channel blocker amlodipine, the regurgitant stroke volume in dogs with mitral insufficiency was significantly reduced (by 18.9%). Although these data look promising, it should be noted that this study had no control population, the echocardiographer was not blinded, and no data evaluation of the neurohormonal consequences of afterload reduction was performed. (Courtesy Dr. Mark Oyama, University of Illinois College of Veterinary Medicine, Urbana-Champaign.)



Hydralazine is still used in the acute management of decompensated heart failure when nitroprusside is unavailable (or impractical to use) because of its rapid onset of action. Similar to amlodipine, the reduction in systemic vascular resistance may reduce the volume of mitral insufficiency and promote an increase in the forward stroke volume. In contrast to amlodipine, the peak vasodilative effect of hydralazine occurs within 3 hours and subsides within 12 hours. Unfortunately, this same characteristic may result in reflex tachycardia and further stimulation of the sympathetic nervous system and RAS. A study by Haggstrom et al.[31] identified significant increases in heart rate and plasma aldosterone and angiotensin II concentrations, as well as evidence of fluid retention, in Cavalier King Charles spaniels with mitral insufficiency that were treated with hydralazine monotherapy for 3 weeks. These findings suggest that ACE inhibitors should be used concurrently with hydralazine if chronic afterload reduction is warranted.

For the management of fulminant congestive heart failure, hydralazine may be administered at a dosage of 2 mg/kg given orally twice daily to dogs with a systolic blood pressure above 100 mm Hg. The authors recommend blood pressure monitoring, with the twin goals of avoiding hypotension and monitoring therapeutic efficacy. Ideally the increase in effective cardiac output will counterbalance the hydralazine-mediated reduction in systemic vascular resistance, preventing the development of symptomatic hypotension.

967

199.6.4.1.3 Nitrates

The nitrates, which include nitroglycerin, isosorbide dinitrate and isosorbide mononitrate, and nitroprusside, are a class of vasodilators that promote the formation of nitric oxide. Although nitroprusside administered intravenously is a potent balanced vasodilator, topical and oral administration of nitroglycerin and oral administration of isosorbide dinitrate and isosorbide mononitrate appear to promote primarily venodilatation. The premise behind venodilatation is to promote redistribution of the circulating blood volume from the heart and pulmonary vasculature to the systemic venous circulation. This reduction in preload should decrease ventricular end-diastolic, atrial, and pulmonary capillary pressures, shifting the Frank-Starling curve to the left and alleviating pulmonary edema. Currently the efficacy of nitrates in the management of chronic heart failure is uncertain and may be limited by *nitrate tolerance*, the phenomenon in which continued drug exposure reduces the agent's effectiveness.

199.6.4.1.3.1 Nitroglycerin

A 2% topical formulation of nitroglycerin combined with furosemide and oxygen (with or without hydralazine) is frequently used in the management of acute heart failure. Anecdotal recommendations have called for application of nitroglycerin cream to a clipped or hairless region ($^1/_2$ to 2 inches every 6 to 8 hours for dogs; $^1/_4$-inch every 6 to 8 hours for cats) to promote continuous transdermal absorption and venodilatation. Studies evaluating the absorption of cutaneously applied nitroglycerin, the optimal site for topical administration, and the efficacy of this therapy for dogs or cats with heart failure have not been reported. There is a report that nitroglycerin applied to the auricular pinna promotes splenic vasodilatation in normal anesthetized dogs, but by no means should nitroglycerin replace furosemide as the primary agent for reducing preload and alleviating pulmonary edema.[78]

199.6.4.1.3.2 Isosorbide dinitrate and isosorbide mononitrate

Isosorbide dinitrate and its major metabolite, mononitrate, are orally administered venodilators that may help reduce preload and hence pulmonary edema. Similar to nitroglycerin, the orally administered nitrates have not been extensively studied in naturally occurring heart failure. However, Adin et al.[79] were unable to document circulatory redistribution after a single dose of isosorbide mononitrate in normal dogs or in those with heart failure. Whether nitrates can regress cardiac remodeling in naturally occurring heart failure remains to be investigated.[80]

Although their efficacy is unknown, isosorbide dinitrate (0.5 to 2 mg/kg given orally twice daily) and isosorbide mononitrate (0.25 to 2 mg/kg given orally twice daily) occasionally are used in the management of refractory heart failure or in combination with hydralazine or amlodipine for patients unable to tolerate ACE inhibitors. Whether dosing-free intervals are required to combat the development of nitrate tolerance for dogs and cats is unknown.

199.6.4.2 Triple Diuretic Therapy

Although twice-daily administration of a loop diuretic appears to be the regimen most frequently used to manage congestive heart failure, there are physiologic benefits to altering the dosing frequency or combining agents from different classes. Although not a true component of diuretic resistance, the activity of the nephron in the absence of therapeutic diuretic concentrations must be kept in mind. The loop diuretics currently available are not long-acting formulations. Therefore the original diuretic effects have dissipated well before the administration of a second daily dose. During this time, when it is not inhibited, the $Na^+/K^+/2Cl^-$ pump promotes avid sodium resorption, possibly to a degree that negates any previous natriuretic effect.[27] This highlights the point that, in cases of worsening heart failure, three times daily dosing of furosemide may be more beneficial than merely increasing the twice daily dose. In cases of right-sided heart failure, in which oral drug absorption may be impaired, changing the type of administration to the subcutaneous or intramuscular route may prove beneficial. Administration of a diuretic by means of a constant-rate infusion may prove the most beneficial during emergency treatment of heart failure, although frequent, moderate doses likely achieve a similar end-point.

No matter the dosing interval or the route of administration, the segments of the nephron distal to the loop of Henle are capable of producing diuretic resistance. Increased solute exposure to the distal nephron promotes hypertrophy and increased resorptive capacity of the early distal tubule, the connecting tubule, and the cortical collecting duct.[81] Although the exact mechanisms are unclear, aldosterone has been implicated as promoting this process.[81] Strategies to combat diuretic resistance associated with long-standing administration of a loop diuretic include (1) addition of a thiazide diuretic to encourage diuresis in the hypertrophied region and/or (2) addition of an aldosterone antagonist to target the proposed hypertrophic mechanism. This synergistic nephron blockade, using multiple agents with activity in different regions of the nephron, may allow a reduction in the dose of furosemide required to control the patient's congestive signs. In the authors' experience, furosemide and spironolactone, combined with conservative doses of hydrochlorothiazide, have palliated the congestive signs of many heart failure patients. However, this more aggressive diuretic management predisposes the patient to the development of electrolyte abnormalities and a reduction in cardiac output and the GFR unless care is taken to avoid overzealous volume contraction. Outpatients should be carefully and periodically evaluated through biochemical profiles to make sure that adverse effects are avoided.

Additional factors that can contribute to diuretic resistance include (1) poor cardiac output, which impairs delivery of the diuretic to its site of action; (2) prominent activation of the renin-angiotensin system; and (3) hypokalemia, which may impair the efficacy of the diuretic. If concern exists about diuretic resistance, care should be taken to optimize the ACE inhibitor dose, to correct electrolyte imbalances, and to combat low-output conditions.

199.6.4.3 Dietary Sodium Restriction

Historically, sodium restriction has been recommended for patients with cardiovascular disease to decrease the delivery of sodium to and its resorption in the distal tubule.[82] This recommendation was in place well before any of the current understanding of the renin-angiotensin system developed, and it therefore may need to be reevaluated.

It currently is recognized that reduced sodium concentrations at the macula densa serve as a stimulus for renin release and subsequent production of angiotensin. A study of Cavalier King Charles spaniels with mild asymptomatic mitral valve insufficiency showed that a low-sodium diet (17 mg/kg/day) was associated with higher plasma renin activity and aldosterone concentrations than a control diet (96 mg/kg/day).[83] In light of the concern that activation of neurohormonal pathways promotes the progressive nature of cardiovascular disease, the authors currently do not use sodium restriction in asymptomatic patients. Whether symptomatic patients receive clinical benefit from sodium restriction is uncertain, but one study found that dogs with mitral valve insufficiency that were fed a low-sodium diet (24 mg/kg/day) had significantly smaller left atrial and left ventricular dimensions than they did when fed a moderate-sodium diet (42 mg/kg/day).[84] Only a small number of dogs with dilated cardiomyopathy were enrolled in the study, but no significant differences in their echocardiographic parameters were seen between the two diets. Despite ACE inhibitor therapy, greater than 70% of the dogs enrolled in the study had increased baseline concentrations of ANP and increased plasma renin activity and aldosterone concentrations; however, the dietary modifications were not associated with significant alterations from baseline.[84]

967
968

Whether exclusively feeding a low-sodium diet to patients with heart failure is feasible often hinges on the palatability of the diet and the willingness of the owner to abandon treats and table scraps. Although uncertain of its clinical benefit or potential detriment, the authors often recommend a low to moderate-sodium diet for patients with refractory heart failure. As evidenced by the study by Mallery et al.,[7] anorexia is a large contributing factor (68%) in the decision for euthanasia; therefore caution, education, and a willingness to abandon the regimen must accompany the prescription of a potentially less palatable, sodium-restricted diet.

199.6.5 Management of Heart Failure Secondary to Diastolic Dysfunction

199.6.5.1 Maintenance Therapy

After stabilization, furosemide is switched to oral administration and the dose is decreased (6.25 mg given twice daily) to prevent excessive preload reduction, dehydration, and hypokalemia. In cases of hypertrophic cardiomyopathy, additional drugs may be instituted to reduce the heart rate and improve diastolic filling. Drugs frequently used in the management of HCM include the beta blocker atenolol and the calcium channel blocker diltiazem. Calcium channel blockers theoretically can exert a beneficial effect in the management of HCM by modestly reducing the heart rate and contractility, thereby diminishing myocardial oxygen demand.

Diltiazem may promote a direct positive lusitropic effect, and verapamil may partially reduce coronary endothelial dysfunction compared with propranolol.[85,86] Atenolol (6.25 to 12.5 mg given orally every 12 to 24 hours) appears to exert better rate control and more consistently alleviates left ventricular outflow tract obstruction compared with diltiazem. Beta-adrenergic blockade may also prevent myocardial fibrosis by inhibiting catecholamine-induced cardiotoxicity and may combat ventricular arrhythmias by decreasing myocardial oxygen consumption. One theoretical disadvantage of the use of beta blockers in the management of diastolic dysfunction is that phospholamban is an inhibitory protein that controls the rate of diastolic calcium uptake into the sarcoplasmic reticulum. Beta-adrenergic stimulation phosphorylates phospholamban and removes this inhibitory effect. Beta blockade may prevent this phosphorylation (and therefore decrease diastolic calcium uptake) and further impair the active process of ventricular relaxation.

Similar to beta blockers, with their proposed neurohormonal benefits, ACE inhibitors likely are beneficial in the management of feline HCM. The authors have seen cats with symptomatic cardiomyopathy show marked neurohormonal activation.[87] With this finding, and with the frequent requirement for furosemide to control pulmonary edema, it appears prudent to use enalapril (1.25 to 2.5 mg given orally every 12 to 24 hours) in the management of diastolic dysfunction. Although there is concern that afterload reduction may precipitate dynamic left ventricular outflow tract obstruction, recent data suggest that ACE inhibitors can be used safely in cats with systolic anterior motion of the mitral valve.[88]

199.7 FUTURE PROSPECTS CURRENTLY UNDER INVESTIGATION

199.7.1 Medical Therapy

199.7.1.1 Search for a Safe Positive Inotropic Agent

A class of drugs currently receiving attention in the management of congestive heart failure is the calcium sensitizers. These agents can augment systolic performance by enhancing calcium binding to troponin C or by affecting the cross-bridge turnover kinetics without increasing cytosolic calcium levels.[89] A potential drawback to clinical use of pure calcium sensitizers would be the enhanced reactivity of troponin C with diastolic cytosolic calcium levels, which would slow the process of myocardial relaxation.[73] In an attempt to avoid this potential diastolic dysfunction, most of the agents under investigation today use a combination of phosphodiesterase (PDE) inhibition and calcium sensitization. Because these drugs produce both calcium sensitization and PDE inhibition, it becomes difficult to determine whether the positive inotropic action stems from enhanced reactivity of troponin C and Ca^{2+} or cAMP-mediated phosphorylation of phospho-proteins, or a combination of the two.

In an effort to elucidate the mechanisms of the positive inotropic effects of pimobendan, EMD 53998, levosimendan, and OR-1896, a group of investigators sought to determine whether these drugs were capable of increasing left ventricular contractility (+dP/dt) without altering the myoplasmic Ca^{2+} transient.[90] Each agent was administered at variable concentrations, and subsequently +dP/dt, myocardial calcium transients, phosphorylation of key intracellular phosphoproteins, and myocardial cAMP levels were measured. The investigators found that low concentrations of levosimendan and OR-1896 were capable of increasing left ventricular contractility without affecting Ca^{2+} transients or myocardial cAMP levels and without promoting significant phosphorylation of troponin I and C proteins.[90] Administration of low concentrations of pimobendan or EMD 53998 produced more pronounced increases in Ca^{2+} transients compared with

increases in left ventricular contractility. As the administration dose increased, all of the agents caused an increase in +dP/dt that was associated with further increases in myocardial cAMP levels and phosphorylation of intracellular phosphoproteins.[90] The investigators therefore concluded that pimobendan, EMD 53998, and higher doses of levosimendan and OR-1896 exerted positive inotropic properties through PDE inhibition–mediated responses rather than through calcium sensitization.[90] These researchers felt that their results lent support to the premise that low-dose levosimendan and OR-1896 were capable of augmenting left ventricular contractility by increasing the response of the myofilaments to the prevailing calcium concentrations.[90]

It should be noted that these conclusions are far from universally accepted. Other investigators, including Endoh,[73] have found that pimobendan can elicit a positive inotropic effect even in the presence of carbachol, a muscarinic receptor agonist that is useful for differentiating cAMP-mediated effects from those classified as calcium sensitization. Endoh's report[73] found that although levosimendan appears to have calcium-sensitizing properties, it must rely on simultaneous activation of cAMP-mediated signaling processes.[73]

The varying results of these studies show that the precise mechanisms by which the calcium sensitizers exert a positive inotropic effect is uncertain and that long-term controlled studies are required to evaluate the effects of these drugs on the heart rate, arrhythmogenesis, and sudden death.

199.7.1.1.1 Pimobendan

Despite its questionable calcium-sensitizing properties, pimobendan currently is the most investigated agent in this drug class. Similar to other agents in this class, pimobendan combines calcium sensitization and PDE inhibition to circumvent any diastolic dysfunction. However, this same property carries the potential for cAMP-dependent increases in arrhythmogenesis. Despite its predominantly cAMP-mediated inotropic effect, pimobendan can increase cardiac contractility to a degree similar to that of dobutamine but at a lower oxygen cost for contractility.[91] Although pimobendan appears to lower myocardial oxygen consumption, the stigma associated with positive inotropic agents, especially those that increase cAMP concentrations, may have doused early enthusiasm for pimobendan in the United States. Although not available in the United States, pimobendan currently is available in Canada, Europe, and Japan and has undergone several small to medium-sized investigations in humans and dogs.

968
969

Multiple pimobendan trials have been completed in humans with heart failure.[74,92] The results of these trials have been variable, pointing out both apparent beneficial effects and questionable, undesirable side effects.

A recent placebo-controlled study has been published that evaluated pimobendan therapy (0.3 to 0.6 mg/kg/day) in a small number of Doberman pinschers and cocker spaniels with dilated cardiomyopathy.[93] The addition of pimobendan to standard therapy with digoxin, enalapril, and furosemide was associated with a significant improvement in the heart failure class. The cocker spaniels allocated to placebo and to pimobendan showed statistically similar median survival times (537 days versus 1037 days, $P = 0.77$), whereas the Doberman pinschers allocated to placebo had significantly shorter median survival times than those given pimobendan (50 days versus 329 days, $P < 0.02$).[93]

This small study highlighted several findings. The first interesting finding is that cocker spaniels with dilated cardiomyopathy appear to have the potential for long-term survival. At the conclusion of the

4-year study, six of the 10 cocker spaniels were still alive (two in the pimobendan group and four in the placebo group). Three of the four dogs that had died (one in the placebo group and two in the pimobendan group) were euthanized for noncardiac disease; the fourth dog, allocated to pimobendan, died suddenly within 1 month of diagnosis. The study was too small to allow assessment of the propensity of pimobendan to exacerbate arrhythmias, but the drug may have contributed to the cocker spaniel's sudden death.

Another interesting aspect of this study is that although positive inotropic therapy may prolong survival in Doberman pinschers with DCM, it may be prudent to randomize patients with atrial fibrillation (AF) separately from those without this condition. Historically Doberman pinschers with atrial fibrillation have had an abysmal 2.9-week median survival time.[4] The pimobendan randomization happened to allocate three Doberman pinschers with AF into the placebo group and only one into the pimobendan group. This may have negatively affected survival in the placebo group, but it should be noted that the Doberman with atrial fibrillation that was treated with pimobendan survived for 37 weeks.[93]

The observed reduction in heart failure class associated with pimobendan therapy likely will prompt further investigations into this agent. Whether pimobendan administration to dogs produces a trend toward increased mortality, as identified in the Pimobendan in Congestive Heart Failure (PICO) trial, is uncertain.[74] Whether the combination of low-dose pimobendan and a beta blocker would have synergistic properties in dogs with dilated cardiomyopathy is uncertain but is an interesting concept. The study by Mallery et al.[7] continues to pose the question of whether a small but significantly increased incidence of sudden death in dogs should preclude the availability of an agent with the potential to enhance their quality of life.

199.7.1.2 Angiotensin II Receptor Antagonists

The beneficial effects of ACE inhibitors have largely been attributed to these drugs' ability to decrease the formation of angiotensin II and increase circulating levels of bradykinin. However, alternative, ACE-independent pathways for the production of angiotensin II, including tissue plasminogen activator, cathepsin G, tonin, and chymase, may enable AT II "escape" even with administration of ACE inhibitors.[32] A study of patients treated with a variety of ACE inhibitors identified angiotensin II "reactivation" in 15% of patients.[29] This process occurred in the face of both high and low levels of ACE activity, which suggests that alternate pathways were responsible for the production of angiotensin II. As a potential strategy for offsetting these alternate angiotensin II–generating pathways, agents capable of directly antagonizing the AT II receptors were developed.

Two subtypes of angiotensin II receptors have been identified in humans: angiotensin II type 1 (AT_1) and angiotensin II type 2 (AT_2). Although these receptors belong to the same family, some researchers have suggested that their biologic activities differ markedly (Figure 199-12).[32] AT_1 receptors are found primarily in the adrenal glands, vascular smooth muscle cells, kidney, and heart, where they mediate almost exclusively all the known actions of angiotensin II on blood pressure and osmoregulation.[32] AT_2 receptors are expressed in high density during fetal development; in adults they are found less abundantly in the adrenal medulla, uterus, ovary, and vascular endothelium and in areas of the brain. AT_2 receptors appear to mediate biologic processes that counteract the trophic, AT_1-mediated responses.[32] Agents capable of blocking the AT_1 receptor subtype were developed with the aim of achieving more complete angiotensin II

antagonism than is obtained with ACE inhibitors. Also, selectively targeting the AT_1 receptor subtype would still allow for the potentially beneficial actions mediated by the AT_2 receptors and avoid common side effects, predominantly coughing, associated with ACE inhibitor therapy in humans. It is believed that the increased circulating levels of bradykinin promoted by ACE inhibitors contribute to these drugs' side effects, but it must be noted that this same property, which is lacking in AT II receptor antagonists, may contribute to the ACE inhibitors' success in the management of heart failure.

Efforts to determine whether ACE inhibitors or angiotensin II receptor antagonists were superior or noninferior quickly followed the development of the latter agents. An early study, the Evaluation of Losartan in the Elderly (ELITE) trial, lent support to the premise that ATII receptor blockade may yield mortality benefits compared with ACE inhibitors.[94] Other studies that examined various subgroups followed. Mortality and morbidity end-points were examined to determine whether AT II inhibitors are preferable to ACE inhibitors.[94–96]

The results of ELITE II and the Valsartan Heart Failure Trial (Val-HeFT) suggest better tolerability of AT II inhibitors compared with ACE inhibitors, but these studies provide no data to support the superiority of AT II inhibitors in the management of heart failure subsequent to systolic dysfunction. The proposed significant benefit behind combination therapy with AT II inhibitors and ACE inhibitors identified in Val-HeFT is limited after the ACE inhibitor–naïve subgroup is removed from the analysis.[97] Of additional concern was the fact that valsartan, compared to placebo, had an adverse effect on mortality (P = 0.009) in patients previously treated with ACE inhibitors and beta blockers.[96] Although these results cannot be extrapolated to veterinary medicine and because clinical trials have not been performed in dogs or cats with naturally occurring heart failure, the current utility of angiotensin II receptor antagonists appears limited.

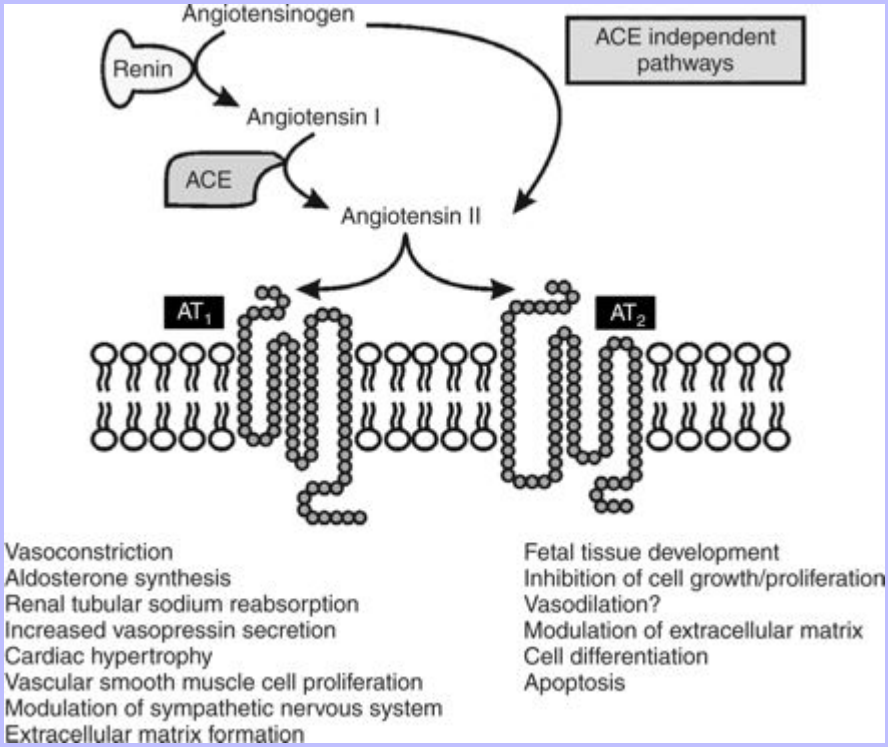
199.7.1.3

Neutral Endopeptidase Inhibitors

With the success of the ACE inhibitors established, research interests quickly shifted to additional, potentially beneficial neurohormonal pathways. Based on the recognition that ANP can promote natriuresis and diuresis and can directly inhibit the release of renin and aldosterone, new agents were developed in an effort to increase ANP's circulating concentration. Neutral endopeptidase (NEP) is an enzyme that inactivates several substrates, including natriuretic peptides, angiotensins, and bradykinins.[98] It was hypothesized that drugs capable of inhibiting NEP may prove beneficial in the management of congestive heart failure as single agents or in combination therapy. Early studies of the NEP inhibitor ecadotril given to dogs with pacing-induced heart failure showed increased urine output, sodium clearance, and renal sodium excretion compared with dogs given placebo.[98] Another short-term study of ecadotril identified a dose and time-dependent reduction in left ventricular end-diastolic pressures in dogs with experimental heart failure produced by repeated coronary embolization.[99] Long-term administration of ecadotril (3 months) in dogs with left ventricular dysfunction produced by sequential intracoronary microembolizations was recently reported to attenuate left ventricular remodeling and progressive left ventricular dysfunction compared with dogs receiving placebo.[100]

969
970

Figure 199-12 The formation of angiotensin II may follow ACE-dependent or ACE-independent pathways. Despite the potential for angiotensin II receptor blockers to promote more complete antagonism, current studies in humans have found them no better than traditional ACE inhibitors at combating heart failure.



Despite these findings, NEP inhibitors administered as single agents appear to have fallen out of the research arena. A communication on behalf of the International Ecadotril Multi-Centre Dose-Ranging Study reported findings from a study of 279 patients with chronic heart failure randomized to placebo or one of four doses of ecadotril.[101] The study's primary aim was to evaluate the safety and tolerability of ecadotril at doses of 50–400 mg twice daily. Two patients randomized to the highest dose of ecadotril developed pancytopenia at 47 and 53 days, and died rapidly of sepsis. The presence of a thioester group within the compound suggested an idiosyncratic ecadotril-induced aplastic anemia that was potentially dose related.[101] Lower doses of ecadotril were not associated with adverse reactions. Although the study was not powered to exclude symptomatic benefit, patient-reported symptoms and quality of life-scores were unable to reveal any overall symptomatic benefit during the administration of ecadotril.[101] A similar, smaller pilot study from the United States evaluating 50 patients randomized to placebo or ecadotril, 50 to 400 mg twice daily, did not identify any adverse sequela but again there were no changes identified in signs and symptoms of heart failure, NYHA class, or patient self-assessment of symptoms.[102]

199.7.1.4 Vasopeptidase Inhibitors

Although it is difficult to determine the reasons for the relative lack of efficacy seen in the small pilot studies of ecadotril, the problem may have been that the drug increased not only natriuretic peptide levels but also the levels of circulating angiotensin II. More recently a group of drugs that can inhibit NEP and ACE, the so-called *vasopeptidase inhibitors*, has been developed.

Omapatrilat has been the most rigorously evaluated vasopeptidase inhibitor in several trials for the management of congestive heart failure. No significant difference was seen in the primary end-point of combined risk of death or hospitalization for heart failure requiring intravenous treatment (P = 0.187) between omapatrilat and ACE inhibitors.[104] To date, the inability of vasopeptidase inhibitors to provide substantial benefit compared with the proven efficacy of ACE inhibitors may limit their clinical utility.

199.7.1.5 Endothelin Antagonists

Endothelin, a peptide released from endothelial cells, has powerful vasoconstrictive activity. Currently three peptides, endothelin-1, endothelin-2, and endothelin-3, and two receptor subtypes, ET_A and ET_B, have been identified. In principle, endothelin-1 promotes vasoconstriction by complexing with the ET_A receptor and vasodilatation by binding to the ET_B receptor, but this is somewhat species dependent. In addition to its vasodilative properties, the ET_B receptor may promote vasoconstriction in some regional blood vessels, including the mesenteric and coronary vasculature.[105]

Although endothelin's name suggests that it is produced only in vascular endothelial cells, the genes that encode the three peptides have been identified in varying patterns in vascular smooth muscle cells, cardiac myocytes, renal tubular epithelial cells, bronchial epithelial cells, glial cells, pituitary cells, macrophages, and mast cells.[105] Therefore the importance of endothelin may extend well beyond simple vasoconstriction and include additional pleiotropic effects on many nonvascular tissues. Although endothelin is suspected of being linked to systemic hypertension, pulmonary hypertension, vascular remodeling, and acute renal failure, the emphasis of this discussion is on potential applications of endothelin to the progression of heart failure.[105]

Heart failure, through increased filling pressures and decreased peripheral perfusion, promotes activation of numerous neurohormonal reflexes to maintain cardiac output and circulatory homeostasis. Activation of the RAS and SNS and the release of arginine vasopressin are recognized to increase the concentration of circulating vasoconstrictors (i.e., angiotensin II, norepinephrine, and vasopressin) and to promote maladaptive remodeling. Furthermore, it has been shown that these compensatory mechanisms enhance the production of endothelin.[105] Increased endothelin binding to the ET_A receptors promotes vasoconstriction and smooth muscle cell proliferation, thereby further diminishing cardiac performance through afterload mismatch. Studies have also shown that the ET_B receptors become upregulated and can promote vasoconstriction and cardiac fibrosis in the presence of heart failure.[106] These findings have raised the possibility of administration of ET_A receptor antagonists or a combination of ET_A/ET_B receptor antagonists to combat heart failure.

970

971

Chronic administration of endothelin antagonists to laboratory animals with experimental heart failure and acute administration to humans with heart failure resulted in beneficial hemodynamic profiles. In rats with heart failure induced by coronary artery ligation, the combination of an ACE inhibitor and an endothelin

(ET_A) antagonist lowered the systolic blood pressure and the left ventricular end-systolic and left ventricular end-diastolic pressures significantly more than the ACE inhibitor or endothelin antagonist alone.[107] However, the drug combination did not significantly improve survival or reduce left ventricular weight and collagen density compared with rats randomized to an ACE inhibitor alone. Endothelin antagonism without the benefit of ACE inhibition did not result in a survival benefit compared with untreated rats with heart failure.

Despite these promising hemodynamic profiles, early evidence suggests that chronic nonselective and ET_A-selective antagonism of endothelin receptors is of limited benefit in patients with severe heart failure. The Endothelin Antagonist Bosentan for Lowering Cardiac Events in Heart Failure (ENABLE) trial evaluated the nonselective endothelin antagonist bosentan, which has proved beneficial in pulmonary hypertension, for the management of humans with NYHA class IIIb-IV heart failure and an ejection fraction of less than 35%. The patients randomized to Bosentan appeared to have an increased early risk of worsening heart failure requiring hospitalization.[108]

These studies appear to highlight the fact that hemodynamic benefit may not equate with clinical benefit. Whether lower doses of the endothelin antagonists and slow uptitration might prove beneficial is unresolved at this time; however, the results of studies to date may have curtailed the momentum for the use of endothelin antagonists in the management of chronic heart failure.

199.7.2 Interventional Therapy

199.7.2.1 Passive Ventricular Constraint

In the early 1990s an experimental “ventricular assist” technique was developed in which a patient's native skeletal muscle was wrapped around the failing ventricles to provide cardiac support. The latissimus dorsi, connected to a synchronizable burst stimulator, was used in an effort to increase cardiac contractility and hence functional status.[110] The utility of dynamic cardiomyoplasty held promise because it alleviated the need for cardiac bypass, donor organs, and immunosuppression, which are required for cardiac transplantation. The feasibility of dynamic cardiomyoplasty in dogs was subsequently documented, and researchers found a potential for improved contractile function even during contractions that were not assisted by myostimulation of the latissimus dorsi.[111]

Although dynamic cardiomyoplasty has failed to gain prominence in the management of heart failure, the potential for limiting ventricular dilatation by means of passive constraint has prompted further study. The premise is that passive ventricular constraint may significantly slow or stabilize the remodeling process that accompanies heart failure. Because the constraint is passive and does not require myostimulation, a synthetic wrap could be used, simplifying the surgical procedure.[112,113]

Despite the potential benefit of passive ventricular constraint in these models, the fact remains that veterinary patients tend to be presented for evaluation after severe cardiac dysfunction has already developed. New diagnostic modalities may allow for earlier detection of occult cardiac disease, but the variable nature of disease progression could still complicate the determination of which patients should be fitted with a cardiac support device. At this time, further studies are required to evaluate the efficacy of passive ventricular constraint in severe cardiac dysfunction, and diagnostic tests allowing early detection of cardiac disease must be developed.

199.7.2.2 Ventricular Resynchronization

Although systolic dysfunction classically is believed to be a myocardial phenomenon, the important role the cardiac conduction system plays in maintaining optimal cardiac performance is often forgotten. The normal conduction pathway modulates the contraction rate, the mechanical efficacy of atrial systole, and the co-ordination of the ventricular chambers.[114] In humans the presence of an intraventricular conduction delay, typically in a left bundle branch block pattern, promotes disco-ordinate contraction, with early activation of the septal wall followed by delayed lateral contraction at higher stress.[114] The presence of this conduction defect has been associated with a 60% to 70% higher risk of all-cause mortality and has remained an independent risk factor after adjustment for age, underlying cardiac disease, severity of heart failure, and treatment with ACE inhibitors or beta blockers.[115] The problem of ventricular discordance has long been recognized in patients with artificial ventricular pacemakers, and efforts to approximate the ventricular activation sequence more closely (i.e., by pacing the right ventricular outflow tract rather than the apex) have been shown to increase cardiac output.[116–118]

Recently a similar approach, called *cardiac resynchronization therapy* (*CRT*), has been used in patients with congestive heart failure and intraventricular conduction delay. Biventricular pacing or univentricular pacing of the left ventricular free wall has improved the contractile index $+dP/dT_{max}$ and arterial pulse pressure within a single beat of commencement of pacing.[114] The proposed benefits of CRT include a reduction in end-systolic and end-diastolic volumes and the ability to promote reverse remodeling. Ventricular resynchronization has been associated with increased systolic function despite a decline in myocardial oxygen consumption.[114] This contrasts with traditional cAMP-dependent inotropic therapy and may explain the ability of biventricular pacing to improve functional patient status while promoting mortality benefits. Unfortunately, the ability of CRT to improve heart failure class and reduce mortality in veterinary medicine may be limited by the low prevalence of intraventricular conduction disturbances in dogs with dilated cardiomyopathy.

199.7.2.3 Stem Cells and Cellular Transplantation

Historically it has been recognized that cardiac and neural tissues lack the large postnatal regenerative capacity seen in the epithelial layers of the skin, intestinal and pulmonary mucosal linings, and connective tissues. Therefore the ability to repopulate areas of ischemic myocardium with cells capable of promoting angiogenesis or areas of fibrosis with cells that contribute to contractile function could prove curative.

Numerous cell types have been identified that may serve as potential sources for tissue grafting, including skeletal myoblasts, fetal cardiomyocytes, smooth muscle cells, embryonic stem cells and bone marrow–derived stromal and hematopoietic stem cells.[120] Because of the complex electrophysiologic, structural, and contractile properties of myocardial cells, cardiomyocytes appear to be the ideal donor cells. The difficulty lies in harvesting and transplanting enough cells to mitigate the degree of cardiac dysfunction. The isolation of pluripotent stem cells from mouse blastocysts in 1981 may have provided the key to an endless vault of viable, transplantable cardiomyocytes.[120]

The promise of stem cells lies in their capacity for prolonged self-renewal and their potential to differentiate into one or more cell types. Embryonic stem (ES) cells display wide-ranging plasticity, which allows them to form derivatives of all three germ layers. Their ability to undergo near endless cell doublings while retaining

971
the capacity to differentiate into various cell types further advances their therapeutic potential. However, beyond the ethical considerations involved in the use of human embryonic stem cells (which veterinary practitioners may not face), many other hurdles must be overcome. One of the most important obstacles is defining a methodology to generate reproducible, spontaneous cardiomyocyte-differentiating stem cells with sufficient purity for clinical purposes.[120] Emerging evidence suggests that an unknown combination of growth factors, transcription factors, feeder layers, and physical properties is involved in early cardiomyocyte differentiation.[120] Delivery systems such as intracoronary catheterization techniques, intramyocardial injection, transendocardial delivery by means of catheter-based systems, and intravenous administration are currently being evaluated and refined to optimize the long-term survival of the grafted cells, to ensure the delivery of a critical mass of viable cells, and to promote the appropriate alignment with the host cells.[120] These steps are vital to the functional and structural integration of stem cells in the host tissue.[120] The immunogenicity of embryonic stem cells poses yet another challenge.

972
Stem cells are not confined to embryos; rather, small numbers of stem cells can be harvested from adult bone marrow. These adult mesenchymal stem (MS) cells maintain an undifferentiated phenotype in culture and appear to have the capacity for multilineage differentiation.[121] The potential benefits of autologous adult MS cells, including ease of attainability, lack of immunogenicity, and absence of ethical objections, have prompted widespread research into their use in the management of cardiovascular disease. It remains to be seen whether repopulation of the myocardium with these cells is feasible in veterinary medicine and whether a sufficient number of viable cells to enhance systolic function can be delivered.

John D. Bonagura

200.1 DEFINITION

The term *congenital heart disease* includes morphologic and functional abnormalities of the heart and adjacent great vessels that are present at birth. These abnormalities are defined as congenital even if they are not discovered until much later in life. Congenital heart disease arises from altered or arrested embryonic development of the rudimentary heart. The eventual consequences of such a failure can include gross anatomic alterations and/or inability of the heart to perform its normal functions of maintaining normal venous and arterial pressures and providing adequate perfusion of the tissues with oxygenated blood.

200.2 CLINICAL APPROACH TO CONGENITAL HEART DISEASE

Malformations of the heart and great vessels constitute a relatively small but clinically important percentage of cardiovascular disorders in dogs and cats.[1a,14a*] The types of defects, pathogenesis, and etiology of disease that afflict animals and humans are remarkably similar, and most of the diagnostic and therapeutic methods used in veterinary cardiology have been adapted from those used in the management of children and adults with congenital heart disease. Although absolute diagnosis and evaluation of congenital heart disease may require echocardiography or cardiac catheterization, a complete physical examination, electrocardiography, and chest radiographs provide a wealth of information that can be used to make a provisional diagnosis and to guide the formulation of an appropriate treatment plan. To this end, every veterinarian should be familiar with the most common congenital diseases and should be able to counsel owners regarding the prognosis, the treatment options, and the impact on breeding programs.

200.3 HISTORY AND PHYSICAL EXAMINATION

The diagnostic approach for animals with congenital heart disease is similar to that used to evaluate animals with acquired disease. In this regard, the evaluation should always include a careful history and complete physical examination. When assembling the history, the clinician should take care to note the breed of the patient, because many congenital diseases have a suspected or proven genetic basis, and most have breed predilections. Whenever possible, the health records of the sire, dam, and any siblings should be reviewed. Additional testing (e.g., electrocardiography, radiography, and echocardiography) usually is advisable, depending on the client's expectations, the nature and severity of the disease, and the medical or surgical treatment options available.

200.3.1 History

The breed and age should always be considered in the evaluation of animals suspected of having congenital heart disease. Table 200-1 shows the breed predilections reported for canine cardiac defects in North America and Europe.[1c-6c] These associations support the suspected genetic basis of many malformations. Gender predispositions to congenital heart disease are weak or poorly established in dogs except for the higher prevalence of patent ductus arteriosus in females.[1a,4a,8a] In cats, Siamese, Burmese, and Asian shorthair breeds may be predisposed to some defects, and male kittens seem to be affected more often than females.[2c,36a]

Consideration of gender predilection, however, has little influence on the evaluation of individual patients. Age may be an important factor in the interpretation of the results of initial examinations. Most defects are detectable shortly after birth, but the severity of the hemodynamic abnormalities may change significantly during the first 6 to 12 months of life. For example, the lesion of congenital subaortic stenosis may not be present at birth, but it can develop during the first 2 months of life and can increase in severity during the first year of life.[2a,9a] Similarly, the consequences of left-to-right shunting defects may not be fully manifested until pulmonary vascular resistance and right heart pressures decrease to the low levels of a normal adult, several weeks after birth. Some defects appear to be severe in the very young but have relatively modest consequences in adulthood.

Table • 200-1 Canine Breed Predilections for Congenital Heart Disease

BREED	DEFECTS
Basset hound	PS
Beagle	PS
Bichon fries	PDA
Boxer	SAS, PS, ASD
Boykin spaniel	PS
Bull terrier	MVD, AS
Chihuahua	PDA, PS
Chow chow	PS, CTD
Cocker spaniel	PDA, PS
Collie	PDA
Doberman pinscher	ASD
English bulldog	PS, VSD, TOF
English springer spaniel	PDA, VSD
German shepherd	SAS, PDA, TVD, MVD
German shorthair pointer	SAS
Golden retriever	SAS, TVD, MVD
Great Dane	TVD, MVD, SAS
Keeshond	TOF, PDA
Labrador retriever	TVD, PDA, PS
Maltese	PDA
Mastiff	PS, MVD
Newfoundland	SAS, MVD, PS
Pomeranian	PDA
Poodle	PDA
Rottweiler	SAS
Samoyed	PS, SAS, ASD
Schnauzer	PS
Shetland sheepdog	PDA
Terrier breeds	PS
Weimaraner	TVD, PPDH
Welsh corgi	PDA
West Highland white terrier	PS, VSD
Yorkshire terrier	PDA

AS, Aortic stenosis; *ASD,* atrial septal defect; *CTD,* cor triatriatum dexter; *MVD,* mitral valve dysplasia; *PDA,* patent ductus arteriosus; *PPDH,* peritoneopericardial diaphragmatic hernia; *PS,* pulmonic stenosis; *SAS,* subaortic stenosis; *TOF,* tetralogy of Fallot; *TVD,* tricuspid valve dysplasia; *VSD,* ventral septal defect.

Most animals with congenital heart defects are asymptomatic when first examined; these patients are recognized when a heart murmur is detected during a routine examination. Dogs and cats with hemodynamically severe regurgitant, obstructive, or shunting defects may appear completely normal to the owner during the first 6 to 12 months of life, therefore it should not necessarily be concluded from an unremarkable history that the underlying defect is mild. For instance, dogs with severe subaortic stenosis may not demonstrate any clinical signs prior to sudden and unexpected death. Similarly, young animals with patent ductus arteriosus and imminent cardiac failure often appear normal to the owner until pulmonary edema becomes life-threatening and causes dyspnea. Additional clinical signs that may develop with severe defects include failure to grow at a normal rate or to a normal size, exertional fatigue, abdominal distention (ascites), episodic weakness or syncope, or cyanosis.

200.3.2 Physical Examination

The ability to detect and decipher heart murmurs and abnormal transient heart sounds is an invaluable skill that cannot be overemphasized in the evaluation of patients with congenital heart disease. The typical characteristics of the heart murmurs associated with the most common congenital defects are listed in Table 200-2. Descriptions of the acoustic properties of the various murmurs and an algorithm for differentiating their causes are presented in Chapter 55. When a heart murmur is first detected, the examiner must determine whether it is pathologic or innocent, because normal puppies and kittens often have benign heart murmurs. Innocent murmurs are usually of low intensity (grade I-II/VI), protosystolic or midsystolic in timing, and best heard at the left heart base. They often vary in intensity according to changes in the heart rate or body position. Innocent murmurs usually but not invariably diminish or resolve by 6 months of age; however, soft systolic innocent murmurs can persist well into adulthood, especially in large-breed dogs.

Cardiac murmurs caused by congenital disease are typically louder (grade III-VI/VI) and of longer duration than innocent murmurs, often obscuring the normal heart sounds. Murmurs of this description are unlikely to be innocent, and additional diagnostics are warranted; however, the examiner is cautioned not to correlate the intensity of the murmur with the severity of the suspected underlying defect. The murmur associated with patent ductus arteriosus or a small ventral septal defect is often very intense, even when the volume of the shunted blood is relatively modest. The murmurs of some lesions, notably atrial septal defects and mild subvalvular aortic stenosis, are easily misinterpreted as innocent. In animals with large septal defects, including severe atrioventricular valve dysplasia and some forms of serious cyanotic heart disease, the heart murmur may be soft or even inaudible. Although a cardiac murmur of any grade indicates the possibility of congenital heart disease, common sense, guided by the patient's clinical circumstances and the owner's wishes, should dictate the vigor of the diagnostic evaluation.

Abnormalities of the arterial pulse, mucous membranes, jugular veins, or precordial impulse may support a suspicion of congenital heart disease. Hyperkinetic and bounding (“waterhammer”) arterial pulses are characteristic of lesions that cause abnormal diastolic runoff of aortic blood and low arterial diastolic pressure, such as patent ductus arteriosus or severe aortic regurgitation. Hypokinetic pulses are typical of moderate to severe left ventricular outflow obstruction (i.e., subaortic stenosis) or of other severe defects accompanied by low left ventricular output. Visible cyanosis develops when the partial pressure of arterial oxygen falls below 45 mm Hg and reduced (unoxygenated) arterial hemoglobin reaches 5 g/dL. Cyanosis in animals with congenital heart disease is usually caused by a systemic to pulmonary (right-to-left) shunt at the level of the heart or great vessels. Distended jugular veins indicate elevated central venous pressure, which is usually caused by an abnormality of the right side of the heart, such as tricuspid valve dysplasia or pulmonic stenosis. A precordial impulse of increased strength or area often indicates enlargement of the underlying ventricle or ventricles. The presence of a precordial thrill defines the most intense cardiac murmurs (grade V-VI/VI). The focus of this vibration is synonymous with the point of maximal acoustical intensity and is characteristic of the associated underlying defect.

973

974

Table • 200-2 Auscultatory Findings in Congenital Heart Disease

LESION	TIMING	FEATURES	POINT OF MAXIMUM INTENSITY	COMMENTS
Atrial septal defect	Systolic (diastolic)	Ejection (diastolic rumble)	Left base	Systolic murmur ends prior to S_2, which is usually split; murmur (or murmurs) due to relative pulmonic (tricuspid) stenosis
(Sub)aortic stenosis	Systolic*	Ejection (crescendo-decrescendo)	Left base	Often nearly as loud at the right base; diastolic murmur of aortic regurgitation may also occur
Mitral valve dysplasia†	Systolic	Regurgitant (holosystolic)	Left apex	May radiate widely
Patent ductus arteriosus	Continuous	Machinery	Left base	Murmur peaks at S_2, often radiates to right base and thoracic inlet
Pulmonary hypertension (Eisenmenger's syndrome)	None (systolic)	Split S_2 (ejection)	Left base	Accentuated and split S_2; systolic murmur of tricuspid regurgitation or blowing, decrescendo diastolic murmur of pulmonic regurgitation may also occur
Pulmonic stenosis	Systolic	Ejection (crescendo-decrescendo)	Left base	Occasional systolic ejection sound; blowing, decrescendo diastolic murmur of pulmonic regurgitation may occur
Tetralogy of Fallot	Systolic	Ejection (crescendo-decrescendo)	Left base	Murmur due to pulmonic stenosis; may be soft or absent with pulmonary artery hypoplasia
Tricuspid valve dysplasia†	Systolic	Regurgitant (holosystolic)	Right midprecordium	Often low pitched and rumbling
Ventricular septal defect	Systolic*	Regurgitant (holosystolic)	Right base	Often higher pitched and more cranially located than tricuspid regurgitation; may also be loud at left base

PMI, Point of maximum intensity.

* At time a diastolic murmur of aortic regurgitation may also be present.

† Mitral stenosis and tricuspid stenosis are rare but may cause diastolic murmurs over the affected valve and ventricle.

200.4 LABORATORY TESTS

Even though a strong clinical suspicion of congenital heart disease may arise based on the history and physical examination, definitive diagnosis of an animal with a cardiac murmur usually requires additional studies. In this regard, an electrocardiogram, thoracic radiographs, and echocardiography are usually required. The results of these studies often dictate the performance of subsequent diagnostic procedures, such as blood gas determinations, cardiac catheterization, and angiography. Distinctive laboratory abnormalities may occur in animals with cyanotic heart disease (i.e., tetralogy of Fallot, reversed patent ductus arteriosus) and may include

arterial hypoxemia, hypocarbia, metabolic acidosis, and erythrocytosis. However, in most cases hematologic testing is not an important part of the evaluation for congenital heart disease. Although serum biochemical test results may be abnormal in the presence of congestive heart failure or concurrent organ disease, the biochemical profile and urinalysis results typically are normal.

200.5 ELECTROCARDIOGRAPHY

In most animals with congenital heart disease, an electrocardiogram (ECG) can provide helpful information, mainly through its ability to detect cardiac chamber enlargement. Although a normal ECG does not rule out heart disease, an abnormal ECG indicating left-or right-sided enlargement in a young animal can strongly suggest a short list of likely cardiac defects. For instance, an ECG indicating a rightward shift in the mean electrical axis and right ventricular hypertrophy immediately suggests the possibilities of pulmonic stenosis, tetralogy of Fallot, or tricuspid valve dysplasia. Such an ECG would be rare in dogs with predominantly left-sided disease, such as mitral dysplasia or subaortic stenosis. Conduction delay with right mean electrical axis deviation and widening of the QRS complex (partial or complete right bundle branch block) can indicate pronounced right ventricular enlargement, congenital right bundle branch block, or the presence of both abnormalities. An ECG should be recorded whenever a rhythm disorder is suspected. Serious congenital heart defects often result in cardiac arrhythmias, some of which require specific treatment or some modification of diagnostic or therapeutic plans. Supraventricular arrhythmias, such as atrial tachycardia and atrial fibrillation, are prone to occur in animals with congenital defects that cause marked atrial enlargement, such as mitral or tricuspid valve dysplasia. Ventricular arrhythmias are common in disorders resulting in arterial hypoxemia, extreme hypertrophy of the ventricular myocardium, or reduced myocardial perfusion. Relevant examples include pups with tetralogy of Fallot or subvalvular aortic stenosis. Rhythm disorders with a genetic basis are being recognized with increasing frequency in juvenile and adult cats and dogs (see Chapter 202).

974
975

200.6 CARDIAC IMAGING

200.6.1 Radiography

Radiographs of the thorax assist in the determination of cardiac size, identification of chamber or great vessel enlargement, assessment of the pulmonary circulation, and detection of congestive heart failure. Much of radiographic interpretation is subjective in nature, and distinguishing left heart, right heart, or bilateral enlargement in young animals is relatively difficult.[1] There is a general tendency to overinterpret the size of the right heart in neonates because of normal right ventricular prominence. This can lead to the erroneous diagnosis of pulmonic stenosis in a young animal with an innocent heart murmur. Further confusing the examiner, the ventricular apex can be shifted rightward on the dorsoventral or ventrodorsal view, contributing to the illusion of right heart enlargement in a normal animal. Despite these pitfalls, thoracic radiographs provide a reasonably sensitive and specific indication of heart size and the severity of disease, especially when the underlying disease is one of volume overload (i.e., patent ductus arteriosus, tricuspid dysplasia). This is not the case for congenital diseases characterized by pressure overload (i.e., pulmonic stenosis, subvalvular aortic stenosis), in which concentric hypertrophy is better appreciated with echocardiography. Measurement of the radiographic cardiac silhouette, using a vertebral heart scoring system similar to that used in adult dogs, provides objective criteria for the interpretation of heart size. In one study, using the lateral radiographic projection, the sum of the long and short axis cardiac dimensions averaged 10 ± 0.5 vertebrae (as measured caudally from the fourth thoracic vertebra) in healthy 3-month-old pups and did not change significantly as the dogs reached 6, 12, and 36 months of age.[2]

Inspection of the great vessels often provides additional information about the underlying cardiac defect. Aneurysmal dilatation of the proximal ascending aorta is typical for subvalvular aortic stenosis and aortic insufficiency, whereas dilatation of the proximal descending aorta is typical of patent ductus arteriosus. Dilatation of the main pulmonary artery can develop as a consequence of pulmonic stenosis or insufficiency, increased pulmonary blood flow caused by a left-to-right shunt, or pulmonary hypertension. Assessment of the size and symmetry of more peripheral pulmonary arteries and veins can help identify pulmonary overcirculation or undercirculation, as well as pulmonary venous congestion. Left-to-right shunts potentiate pulmonary blood flow, increasing the number, diameter, and prominence of the pulmonary arteries and veins, whereas right-to-left shunts reduce pulmonary flow, resulting in diminished prominence and reduced diameters of the pulmonary arteries and veins. Animals with decompensated or impending congestive heart failure may show selective widening of the caudal vena cava (right heart failure) or pulmonary veins (left heart failure). The typical radiographic findings of the common congenital heart defects are specifically addressed in their respective sections of this chapter.

200.6.2 Echocardiography

Echocardiography is an extremely powerful noninvasive diagnostic tool and has reduced the need for invasive cardiac catheterization and angiography to establish a definitive diagnosis of congenital heart disease. The various congenital heart diseases exert excessive pressure or volume loads (or both) on specific chambers of the heart, resulting in concentric or eccentric hypertrophy, respectively (or both). These patterns of hypertrophy can be easily recognized and quantified by two-dimensional and M-mode echocardiography.[3] Doppler echocardiography can be used to examine cardiac blood flow, which is often disturbed by the presence of congenital disease.[3] By relying on the shift of ultrasound frequencies reflected by moving objects (e.g., red blood cells), Doppler ultrasound allows the examiner to measure the velocity and direction of blood flow and to distinguish turbulent from laminar flow. Doppler ultrasound information can be viewed as a spectral display or can be superimposed on two-dimensional images as a color flow map. Spectral Doppler is used primarily to quantify the velocity of blood flow. An electronic cursor is positioned parallel to the direction of flow, and the resulting Doppler study displays blood flow velocity in a graphic format. Blood flow toward or away from the transducer location is displayed above and below the baseline, respectively. Maximal velocity of flow is measured from the peak of the Doppler signal and can be converted to units of pressure (mm Hg) using the modified Bernoulli equation:

$$\text{Pressure gradient between two cardiac chambers (mm Hg)} = 4 \times \text{Maximal velocity (m/s)}^2$$

The Bernoulli equation allows the examiner to estimate the hydrostatic (blood) pressure difference between individual cardiac chambers. This information is particularly important for quantifying the severity of disease with obstructive lesions (e.g., subaortic stenosis). As the severity of a lesion worsens, pressure in the ventricle increases to produce the required cardiac output. This increase in pressure translates into a higher blood flow velocity across the area of obstruction. Proper alignment of the cursor with respect to the direction of flow is crucial to the accuracy of spectral Doppler studies. The cursor must be positioned within 20 degrees of parallel along the main direction of blood flow to ensure accurate measurements.[4]

Range-gated or *pulsed wave Doppler* allows interrogation of blood cell velocities in specific locations by having the operator direct a depth-range "gate" (which is superimposed over a two-dimensional image) to the region of interest. This mode provides accurate information about the exact anatomic site of the abnormal flow and the relative direction of flow. It is limited to the measurement of relatively low velocities because of a sampling phenomenon called *aliasing* (related mainly to the sampling rate), in which velocities greater than a

known limit (the *Nyquist limit*) appear to reverse direction and cause an ambiguous display. *Continuous wave Doppler* uses two crystals (a constant transmitter and a constant receiver) to achieve very high sampling rates and to allow recording and measurement of very high velocities along the directed ultrasound beam. The velocities of all cells along the beam line are recorded and displayed, a technique that allows the high flow velocities across stenotic or insufficient valves to be displayed and measured but prevents precise localization of the abnormal flow. Pulsed wave and continuous wave Doppler are therefore complementary; the pulsed wave mode is used to identify and localize a lesion, and the continuous wave mode is used to measure any high velocities.

975

976

Color flow Doppler images consist of range-gaited, color-encoded velocity data that are superimposed on two-dimensional images. Laminar flow toward or away from the transducer is displayed as red or blue, respectively, with lighter hues of each color representing higher velocities. Turbulent flow is often displayed as a mosaic pattern of green, light blue, or yellow, but different color patterns can be selected by the user as a matter of personal preference. Color flow Doppler is conveniently used to identify and localize areas of high velocity and turbulent blood flow, which allows the operator to survey the heart quickly and identify regional flow disturbances. When areas of high velocity or turbulent flow are discovered, the examiner can focus attention on the two-dimensional anatomy of that region and perform more detailed, quantitative Doppler interrogations of blood flow in that area.

Echocardiographic contrast agents, composed of highly reflective air-agitated saline or other gas-containing microbubbles, can be used to enhance Doppler studies by amplifying weak signals from small jets that are otherwise difficult to interrogate. When Doppler technology is not available, contrast agents are used as sonographic targets to improve the detection of shunting lesions (especially right-to-left shunts) and other cardiac defects. Contrast echocardiography is a useful tool when Doppler technology is not available, and it can also enhance Doppler studies.

Experienced examiners have found that evaluation of patients suspected of having congenital disease is facilitated if the echocardiographic study is performed in a stepwise fashion, with particular attention paid to the pattern of cardiac hypertrophy, the identification and quantification of high-velocity and turbulent blood flow, and the detection of anatomic lesions particular to each type of congenital disease.[3]

200.7 OTHER IMAGING MODALITIES

Single-pass or blood pool radionuclide scanning studies can also be used to detect and quantify congenital shunts, but such methods are generally limited to university teaching hospitals. Computed tomography (CT) and magnetic resonance imaging (MRI) offer particular advantages in the evaluation of specific congenital heart diseases. MRI, for example, is an effective method of evaluating the aortic arch and related vascular anomalies in humans. However, because of their expense and limited availability to veterinarians, these modalities are infrequently used to evaluate animals with congenital heart disease.

200.8 CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Cardiac catheterization is an invasive hemodynamic and angiographic procedure performed for diagnostic or therapeutic reasons. Prior to the widespread use of echocardiography, cardiac catheterization was considered the gold standard for diagnosis and evaluation of congenital heart disease. Much of the anatomic and hemodynamic information gathered during cardiac catheterization can now be obtained noninvasively with two-dimensional and Doppler echocardiography. For this reason, cardiac catheterization is reserved mainly for attempts to repair certain congenital defects (e.g., balloon valvuloplasty for pulmonic stenosis and device occlusion of patent

ductus arteriosus) or to clarify ambiguous anatomic lesions when surgery is contemplated. In selected cases, diagnostic cardiac catheterization is warranted to verify pressure estimates derived from Doppler echocardiographic studies, to collect blood for oximetry, to measure cardiac output, or to examine structures not accessible to echocardiographic interrogation, such as the peripheral pulmonary or systemic vasculature.

200.8.1 Hemodynamic Measurements

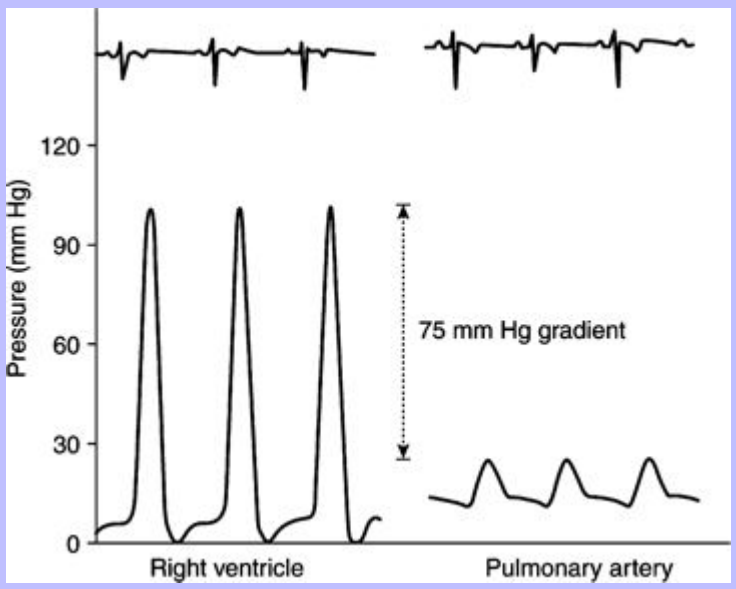
For selective catheterization of the heart, the operator introduces specially designed catheters into a peripheral vessel and guides them into specific cardiac chambers or great vessels to measure intracardiac and vascular pressures, cardiac output, and oxygen content (oximetry). Such studies are performed before angiographic imaging, because all radiopaque contrast agents can alter vascular tone and cardiac performance. Vascular and intra-cardiac pressures are measured either by attaching the proximal end of fluid-filled catheters to a pressure-sensing transducer or by using specially designed catheters with microtransducers incorporated into the distal end. Pressures are displayed and saved with a digital or an analog physiologic recorder.

The peak systolic pressure in the left ventricle and aorta is approximately four times that in the right ventricle and pulmonary artery. Because the systemic and pulmonary circulations are connected in series and cardiac output from the left and right ventricles is balanced, it can be appreciated that pulmonary vascular resistance is much lower than systemic vascular resistance. Blood flowing through the heart moves from areas of high to low resistance and therefore from areas of high to low pressure. For instance, left ventricular systole produces a small, instantaneous pressure gradient between the left ventricle and the aorta, causing opening of the aortic valve and commencement of left ventricular outflow. It is important to note, however, that once the aortic valve is open, the pressures in the ventricle and aorta quickly equalize. In contrast, a pressure gradient during systole is maintained between the left ventricle and left atrium because of the intervening and closed mitral valve. Should the aortic valve not open completely, pressure between the left ventricle and the aorta does not equalize, and a pressure gradient (increased pressure proximal to the obstruction, relative to the pressure distal to the obstruction) is maintained during the entirety of systole. This pressure gradient is needed to maintain normal flow through the stenotic aortic valve. Thus an intracardiac pressure gradient is indicative of an obstructive lesion, and its severity correlates with the magnitude of the obstruction. A systolic pressure gradient between the right ventricle and main pulmonary artery, consistent with pulmonic stenosis, is shown in Figure 200-1. Pressure, resistance, and flow (cardiac output) are interrelated so that the magnitude of a pressure gradient across obstruction varies with flow; it can be diminished by heart failure, anesthesia, or hypovolemia and can be increased by exercise, anemia, or excitement. The configuration of the pressure waveforms is also altered in predictable ways by congenital heart defects. In dogs with severe subvalvular aortic stenosis, the slope of the aortic pressure rise and the peak systolic pressure are decreased. In cases of patent ductus arteriosus, diastolic runoff of aortic blood into the pulmonary artery reduces the systemic diastolic pressure, and the pulse pressure (the difference between the peak systolic and diastolic pressures) increases.

Elevation of end-diastolic pressure is a subtle but important abnormality that can be identified by a ventricular pressure recording. This important abnormality may be caused by volume overloading from regurgitant valvular lesions or left-to-right shunts, by increased diastolic ventricular stiffness associated with ventricular concentric hypertrophy or myocardial fibrosis, or by pericardial disease. Substantial increases in ventricular end-diastolic pressures (i.e., greater than 15 to 20 mm Hg) herald the development of overt congestive heart failure (i.e., edema, effusion, ascites). Pressures in the right atrium (measured directly) and left atrium (estimated by measuring pulmonary wedge pressure) increase as an unavoidable consequence of high ventricular end-diastolic pressure. Stenosis of the atrio-ventricular (AV) valves is characterized by elevated atrial and normal ventricular diastolic pressure, which produces a measurable diastolic pressure gradient

across the affected valve. Transmission of ventricular systolic pressure to the atria across an incompetent AV valve results in ventricularization of the atrial pressure tracing and elevated mean atrial pressure.

Figure 200-1 Intracardiac pressure tracing from a 1-year-old mixed breed dog made during catheterization of the right heart and pulmonary artery. The pulmonary artery pressures are normal. A systolic pressure gradient of 75 mm Hg exists between the right ventricle and pulmonary artery, indicating the presence of an obstruction to right ventricular outflow (in this case, valvular pulmonic stenosis). A small diastolic pressure gradient also exists between the pulmonary artery and right ventricle; this is caused by diastolic closure of the pulmonic valve and is a normal finding. The ECG displays a deep S wave, which is often found in animals with pulmonic stenosis and secondary right ventricular hypertrophy.



Flow through the heart (cardiac output) can be measured by means of cardiac catheterization using a variety of indicator-dilution techniques or by combining measurements of the oxygen content of arterial and mixed-venous blood (oximetry) and oxygen consumption in respiratory gases. The most commonly performed technique, thermodilution, involves injection of an indicator (temperature, in the form of cold saline solution) and subsequent downstream measurement of its dilution over time (the change in the temperature of the blood). Cardiac output measurements are used to quantify cardiac performance, to calculate the pulmonary or systemic vascular resistance (R = Pressure/Flow), and to help define the severity of obstructing lesions. *Oximetry*, the measurement of blood oxygen content or saturation, is used mainly to detect and quantify cardiac shunts. Blood samples are sequentially drawn from the great vessels and right and left cardiac chambers and processed through a blood gas analyzer. The oxygen content in chambers and vessels on the

ipsilateral sides of the heart should be roughly equivalent. A substantial change in oxygen content indicates mixing of blood from the two sides of the heart and the presence of a shunt. For instance, when oxygen saturations are recorded from the right atrium, ventricle, and pulmonary artery, a significant increase between chambers (usually greater than 5%) indicates the presence of a left-to-right shunt just proximal to the site of the step-up. Conversely, when oxygen saturations are recorded from the left side of the heart, a significant decrease indicates the presence of a right-to-left shunt. The magnitude of change in oxygen saturation directly correlates with the degree of cardiac shunting, and the severity of the shunt lesion can be calculated.

200.8.2 Angiography

For selective angiographic studies of animals with congenital heart disease, a bolus of radiopaque contrast solution is injected into a specific location in the heart or vessels, and its transit through the circulation is visualized by fluoroscopy. This allows identification of any anatomic abnormalities and alterations in the normal pattern of blood flow. Multiple injection sites are often used to define a lesion completely. In some instances angiograms are performed with the patient in both lateral and sternal or dorsal recumbence to provide images from multiple orientations. For shunts and obstructive lesions, contrast is injected into the chamber just proximal to (upstream from) the site of the suspected defect, whereas for valvular insufficiency lesions, the contrast is injected into the chamber just distal to (downstream from) the lesion. Commonly performed injections include those made into (1) the right ventricle, to identify pulmonic stenosis, tricuspid dysplasia, right-to-left shunting ventricular septal defects, tetralogy of Fallot, transposition of the great vessels, (pseudo)truncus arteriosus, right-to-left shunting patent ductus arteriosus, and abnormalities of the pulmonary vascular tree; (2) the left ventricle, to identify subaortic stenosis, mitral dysplasia, left-to-right shunting ventricular septal defects, transposition of the great vessels, aorticopulmonary windows, and left-to-right shunting patent ductus arteriosus; (3) the main pulmonary artery, to identify anomalous pulmonary venous drainage, aorticopulmonary windows, left-to-right shunting atrial septal defects, and mitral valve stenosis; and (4) the aortic root, to identify aortic insufficiency, aorticopulmonary windows, anomalous coronary arteries, aortic coarctation, left-to-right shunting patent ductus arteriosus, and bronchoeso-phageal or other collateral pulmonary vessels. Angiograms can be recorded on videotape or multiple radiographic plates, or they can be stored digitally to optical or magnetic media.

200.8.3 Therapeutic Procedures

In the current era, cardiac catheterization plays an important role in the treatment of several types of congenital heart disease. Specialized catheters with inflatable balloons on the distal tip can be used to dilate stenotic valves or narrowed vessels. Catheters can also be used to deliver embolization devices to close shunting defects, such as patent ductus arteriosus. The electrical activity of the heart can be mapped and arrhythmias can be abolished using radiofrequency waves generated from an appropriately positioned catheter (see Treatment of Arrhythmias.)

A primary advantage of catheter-based therapy over traditional surgical approaches (thoracotomy) is the minimally invasive nature of cardiac catheterization. The evolution and clinical application of specific therapies are discussed further in later sections of this chapter.

200.9 ETIOLOGY AND PREVALENCE OF CONGENITAL HEART DISEASE

200.9.1 Etiology

Congenital cardiac malformations may be caused by a large number of genetic and environmental factors, and in most cases a single causative agent cannot be conclusively proven. The possible interaction of the potential toxicologic, nutritional, infectious, and genetic factors makes it difficult to answer the question posed by many clients, "Why did my pet get this congenital disease?" The observation that certain congenital defects display a species and/or breed predilection suggests that many defects have a heritable basis (see Table 200-1). This hypothesis has been unequivocally demonstrated for several specific defects in certain dog breeds.[5–7] Most of these studies indicate a simple mendelian basis for transmission, indicating that identifiable genetic factors contribute to malformations during development of the embryonic heart, giving rise to each specific type of congenital heart disease. Additional genes with additive effects may produce a discrete phenotype once a mendelian trait has been inherited.[8–11] Regrettably, the complexity and uncertainty surrounding the exact mode of inheritance of many defects makes it difficult to counsel breeders about the breeding of individual dogs. Although recent attempts have been made to identify dogs with congenital heart disease before breeding, these efforts are often confounded by the limited sensitivity and specificity of currently available screening methods. A normal physical examination does not equate with genetic normalcy, soft murmurs are difficult to interpret, and echocardiographic screenings often yield similarly equivocal findings. Even with careful attention to pedigree and the results of breeding trials, it can be very difficult to affect the overall prevalence of a specific defect in a large population. Progress in this regard hinges on the development of economical tests that can detect the genes responsible for the congenital defect.

200.9.2 Prevalence

Surveys in North America indicate that the overall prevalence of congenital heart disease in dogs is 0.46% to 0.85% of hospital admissions. For 40 years, patent ductus arteriosus (PDA), subvalvular aortic stenosis (SAS), and pulmonic stenosis (PS) have topped the list of most commonly reported congenital defects in dogs. Hospital surveys of congenital heart defects in the United States have been reported by Patterson and Detweiler in dogs and by Liu and by Harpster in cats.[2a,12a,14a,36a] In the largest survey of dogs from the 1960s, 325 malformations were detected in 290 dogs, and the overall prevalence in a university hospital population was 6.8 per 1000 dogs.[1a,2a,14a] The frequency of diagnosis was approximately 28% for PDA, 20% for PS, 14% for aortic stenosis, 8% for persistent right aortic arch, 7% for ventricular septal defect, and less than 5% for tetralogy of Fallot, persistent left cranial vena cava, and atrial septal defects. In a 1989 survey of 339 cases of congenital cardiac defects in dogs in the United Kingdom, the most common diagnoses were subaortic stenosis (32%), PDA (20%), mitral valve dysplasia (14%), PS (12%), and ventricular septal defect (8%). A more recent report by Buchanan[1c,9b] that includes prevalence information from a North American database of more than 1300 cases indicates that patent ductus arteriosus is still most frequently reported (31.7% of cases), but subaortic stenosis (22.1%) now exceeds pulmonic stenosis (18.3%) in prevalence.

The shifting popularity of some dog breeds over time influences the regional or global prevalence of a particular defect. For example, the growing popularity of golden retrievers may increase the number of dogs diagnosed with subvalvular aortic stenosis. Harpster's review of congenital heart disease in cats summarizes data from the literature, from Angell Memorial Animal Hospital (Boston), and from the Animal Medical Center (New York City). The prevalence of congenital heart defects in cats was 0.2% to 1% of hospital

admissions. Of the reported diagnoses, the most commonly diagnosed defects included atrio-ventricular septal defects (24%, including ventricular septal defect, atrial septal defect, and endocardial cushion defect), atrioventricular valve dysplasia (17%), endocardial fibroelastosis (11.5%), PDA (11%), aortic stenosis (6%), and tetralogy of Fallot (6%). Males were affected nearly twice as often as females.[36a]

200.10 CLASSIFICATION OF CONGENITAL HEART DISEASE

A number of schemes have been devised for classifying congenital heart defects. The system presented in Box 200-1 emphasizes the nature of the cardiac overload and the physiologic consequences rather than the embryologic basis for maldevelopment. It should be apparent that some lesions fit into more than one category. Some of the lesions listed are very rare, and some have been reported only in conjunction with other defects.

200.11 DEFECTS THAT CAUSE PRIMARILY VOLUME OVERLOAD

200.11.1 Systemic to Pulmonary (Left-to-Right) Shunts

200.11.1.1 Patent Ductus Arteriosus

The circulation in the fetus differs from that in the adult. In fetal animals the ductus arteriosus develops from the left sixth embryonic arch and extends from the pulmonary artery to the descending aorta, where it diverts blood from the nonfunctional fetal lungs back into the systemic circulation. Prior to birth, the ductus diverts approximately 80% to 90% of the right ventricular output back to the left side of the circulation. After parturition and the onset of breathing, pulmonary vascular resistance falls, flow in the ductus reverses, and the resulting rise in arterial oxygen tension inhibits local prostaglandin release, causing constriction of the vascular smooth muscle in the vessel wall and functional closure of the ductus arteriosus. Although the ductus may be probe patent in puppies less than 4 days of age, it usually is closed securely 7 to 10 days after birth.[4a,41a,42a] Persistence of a PDA beyond the early neonatal period is the first or second most commonly diagnosed congenital cardiac defect in dogs.[37a,61a] Cats are also affected but much less commonly than dogs.

200.11.1.1.1 Pathogenesis

Failed ductal closure in dogs is characterized by distinct histologic abnormalities in the ductal wall. The normal fetal ductal wall contains a loose, branching pattern of circumferential smooth muscle throughout its length. In prenatal puppies bred to have a high probability of PDA, varying portions of the ductal wall are comprised of elastic fibers rather than contractile smooth muscle fibers. According to the work of Patterson et al., increasing genetic liability to PDA results in "extension of the noncontractile wall structure of the aorta to an increasing segment of the ductus arteriosus, progressively impairing its capacity to undergo physiologic closure."[4a] It is tempting to speculate that some defect prevents one or more of the series of processes that permits smooth muscle cells to proliferate in the wall of the ductus prior to birth. In the defect's mildest form, the ductus closes at the pulmonary arterial end only and a blind, funnel-shaped outpouching of the ventral aspect of the aorta, called a *ductus diverticulum*, results. This hidden form *(forme fruste)* of incomplete ductal closure can be diagnosed only by angiography or necropsy, but it indicates that the dog possesses genes for this defect.[4a,39a,40a] Increasing genetic liability results in a tapering, funnel-shaped ductus arteriosus that remains patent after the early natal period and

that allows blood to flow from the high-pressure aorta to the low-pressure pulmonary artery (Figure 200-2), thereby creating varying amounts of left-to-right shunting. The most severe but least common form is the cylindrical, nontapering ductus with persistent, postnatal pulmonary hypertension (Eisenmenger's syndrome) and bidirectional or right-to-left shunting (see Figure 200-2). Based on the breeding studies of poodle-type dogs, Patterson et al. concluded that the mode of transmission of PDA in dogs is most likely polygenic, but other mechanisms of inheritance are possible. For additional information on the morphology and pathogenesis of PDA, the reader is referred to several outstanding reviews of the subject.[12–14]

200.11.1.1.2 Pathophysiology

The direction of flow through the PDA is determined by the relative resistances of the pulmonary and systemic vascular beds; in the vast majority of cases, it is directed from left to right (from the aorta to pulmonary artery). This results in a continuous cardiac murmur, increased pulmonary blood flow, and volume overloading of the left atrium and left ventricle. Because of the relatively high resistance of the systemic circulation after birth, aortic blood pressure is greater than pulmonary pressure, and blood shunts continuously across the PDA during both systole and diastole. For a given pressure gradient, the magnitude of shunting is determined by the morphology (effective resistance) of the ductus arteriosus. In most cases the ductus is widest at the aortic end and tapers to its narrowest (flow limiting) region at the point of attachment to the pulmonary artery. Increased left ventricular stroke volume and rapid runoff of blood from the aorta to the low pressure pulmonary circulation via the PDA causes increased aortic systolic and decreased aortic diastolic pressures. The resulting widened arterial pulse pressure offers a hemodynamic explanation for the bounding or hyperkinetic (waterhammer, Corrigan's) arterial pulse detected in dogs with substantial shunts.

200.11.1.1.2.1

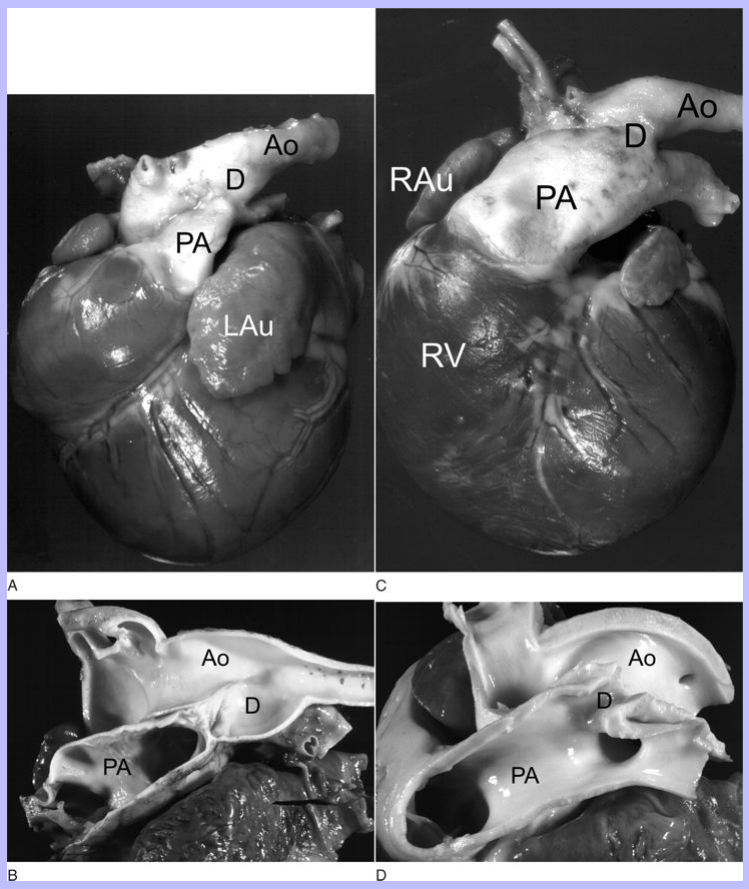
Box • 200-1 Classification of Congenital Defects According to Pathophysiology

Canine	Feline
Defects primarily causing volume overload	
Systemic to pulmonary (left-to-right) shunting	
Common	Common
Patent ductus arteriosus	Ventricular septal defect
Ventricular septal defect	Patent ductus arteriosus
Uncommon	Atrial septal defect
Atrial septal defect	Endocardial cushion defect
Endocardial cushion defect	Uncommon
(Pseudo) truncus arteriosus	Truncus arteriosus
Valvular regurgitation	Valvular regurgitation
Common	Common
Mitral dysplasia	Mitral dysplasia
Tricuspid dysplasia	Tricuspid dysplasia
Uncommon	
Pulmonic insufficiency	
Aortic insufficiency	
Defects primarily causing pressure overload	
Common	Common
Pulmonic stenosis	Dynamic subaortic stenosis
Subaortic stenosis	Uncommon
Uncommon	Pulmonic stenosis
Valvular aortic stenosis	Pulmonary artery branch stenosis
Coarctation and interruption of the aorta	Fixed subaortic stenosis
Cor triatriatum dexter	Valvular aortic stenosis
	Cor triatriatum dexter
	Cor triatriatum sinister
Defects primarily causing cyanosis	
Common	Common
Tetralogy of Fallot	Tetralogy of Fallot
Uncommon	Endocardial cushion defect
Pulmonary to systemic shunting (ventral septal defect [VSD])	Uncommon
Pulmonary to systemic shunting (patent ductus arteriosus [PDA])	Pulmonary to systemic shunting (VSD)
Tricuspid atresia/right ventricular hypoplasia	Pulmonary to systemic shunting (PDA)
Double outlet right ventricle	Double outlet right ventricle
Transposition of the great vessels	Truncus arteriosus
Truncus arteriosus	
Aorticopulmonary window	
Miscellaneous cardiac and vascular defects	
Common	Common
Peritoneopericardial diaphragmatic hernia	Peritoneopericardial diaphragmatic hernia
Persistent right aortic arch	Endocardial fibroelastosis
Persistent left cranial vena cava	Uncommon
Uncommon	Persistent right aortic arch
Endocardial fibroelastosis	Anomalous right atrium
Pericardial defects	
Anomalous pulmonary venous return	
Double aortic arch	

Retroesophageal left subclavian artery
Situs inversus

All vascular structures involved in the transport of the shunted blood enlarge to accommodate the extra volume flow. Increased volume flow causes dilatation of the proximal aorta and main pulmonary artery and overcirculation of the pulmonary vascular bed. Dilatation of the left atrium and eccentric hypertrophy of the left ventricle develop in proportion to the volume flow of the shunt. This mechanism permits compensation for a variable period, but if the shunt is large, myocardial failure (cardiomyopathy of volume overload) develops, together with progressive elevation of left ventricular end-diastolic pressure and overt pulmonary edema. Because the left-to-right shunt occurs at the level of the great vessels, the right ventricle and atrium never handle the shunted blood, and these structures remain normal unless pulmonary vascular resistance and pulmonary arterial pressure increase.

Figure 200-2 Gross pathology of patent ductus arteriosus (PDA). **A,** Left-sided view of the heart of a 9-week-old Australian shepherd with a left-to-right PDA, demonstrating the anatomic location of the ductus *(D)* between the descending aorta *(Ao)* and the main pulmonary artery *(PA)*. The left auricle (*LAu*) is enlarged. **B,** Cutaway view of a left-to-right PDA in a dog. The ductus is funnel shaped, tapering toward the PA end. **C,** Left-sided view of the heart of a dog with a right-to-left shunting PDA. Note the enlargement of the right ventricle *(RV)* and right auricle *(RAu)*. The pulmonary artery *(PA)* is enlarged. **D,** Cutaway view of a right-to-left shunting PDA in a dog. Note the cylindrical nature of the ductus *(D)* and the fact that the anatomic location of the ductus is distal to the aortic branches that supply the cranial portion of the body.



In a small percentage of cases, the lumen of the PDA remains wide open after birth. The absence of a restrictive ductal orifice allows aortic pressure to be transmitted to the pulmonary circulation, precluding the normal postnatal decline in pulmonary vascular resistance. In this circumstance the aortic and pulmonary artery pressures equilibrate, and the right ventricle remains concentrically hypertrophied after birth. In Patterson's colony of dogs, this pattern of pulmonary hypertension and reversed (right-to-left) shunting developed within the first few weeks of life.[39a] These observations fit the usual clinical presentation of most dogs diagnosed with a *reversed PDA*, in which the animal usually has no history of a continuous murmur and no evidence of left ventricular enlargement or a large left-to-right shunt earlier in life. Most dogs with reversed PDA flow have diminished pulmonary blood flow, a normal to small left ventricle, and marked concentric hypertrophy of the right ventricle. On rare occasions, dogs with a moderate to large left-to-right shunting PDA experience a gradual increase in pulmonary resistance and gradual reversal of the direction of shunting, typically at several months to several years of age. These dogs often have a history of prior left heart failure. Substantial residual left ventricular (LV) enlargement is evident on thoracic radiographs and by echocardiography. Pulmonary blood flow is reduced, but right ventricular hypertrophy is less pronounced than in dogs in which the direction of shunting is reversed at an early age. The precise pathogenesis of pulmonary hypertension is not completely understood, but anatomic descriptions of the pulmonary vasculature are similar in humans and animals. Histologic changes within small pulmonary arteries include hypertrophy of the media, thickening of the intima and reduction of lumen dimensions, and development of plexiform lesions of the vessel wall.[60a,61a,15] Most of these changes are considered to be irreversible, precluding surgical correction of the reversed PDA.

200.11.1.1.3

Clinical findings

The clinical features of PDA have been thoroughly characterized in both a breeding colony and in clinic populations.[1a,4a,10c,16,37a-53a] Compared with male dogs, female dogs have a substantially greater risk of developing a PDA (2.49 per 1000 versus 1.45 per 1000).[2a] The Chihuahua, collie, Maltese, poodle, Pomeranian, English springer spaniel, keeshond, bichon frise, and Shetland sheepdog are most frequently affected, although other breeds, such as the Cavalier King Charles spaniel, may also be predisposed. Many other breeds, including larger dogs, such as the German shepherd, Newfoundland, and Labrador retriever, may also be prone to PDA in some regions. Although severely affected pups and kittens may appear stunted, thin, or tachypneic from left heart failure, most are reported to be asymptomatic and developing normally at the time the condition is discovered. Clinical signs are rarely recognized within the first few weeks of life, and most dogs are not diagnosed until the initial examination at 6 to 8 weeks of age.

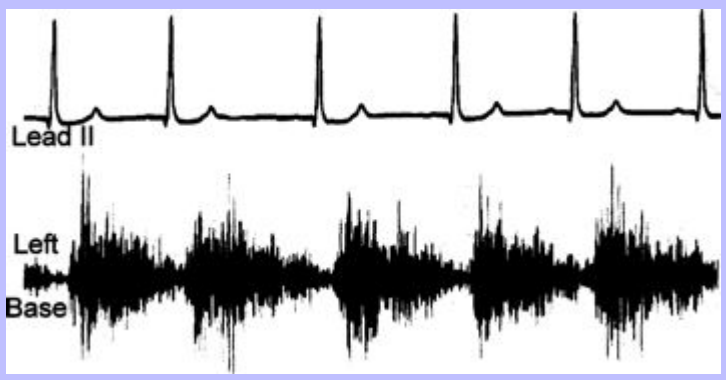
200.11.1.1.4

Left-to-right shunting patent ductus arteriosus

A thorough physical examination and chest radiographs usually suffice to suggest the diagnosis. Mucous membranes are pink in the absence of heart failure. The precordial impulse is often exaggerated and more diffuse than normal as a result of left ventricular enlargement. A thrill may be palpated at the heart base, and a continuous murmur is best heard in the same location (Figure 200-3). The murmur's point of maximum intensity is located over the main pulmonary artery at the dorsocranial left heart base and may radiate cranially to the thoracic inlet and to the right base, where it is almost always softer.[5a,16,39a,47a] Often only a systolic murmur is audible over the mitral area. This murmur may simply represent radiation of the loudest portion of the continuous murmur from the heart base to this location, or it may indicate that secondary mitral regurgitation has developed as a consequence of severe left ventricular

dilatation. In cats, the continuous murmur of a PDA may be heard best somewhat more caudoventrally than in affected dogs. Increased LV stroke volume and rapid diastolic runoff through the PDA combine to produce peripheral arterial pulses that are hyperkinetic (bounding).

Figure 200-3 Phonocardiogram recorded at the left heart base from a dog with left-to-right patent ductus arteriosus. The lead II ECG is recorded simultaneously for timing purposes (ventricular mechanical systole is approximately the period from the middle of the QRS complex to the end of the T wave; the remainder of the time is diastole). The recorded murmur is continuous, increasing in intensity during systole, peaking near the end of systole, and decreasing in intensity during diastole.



Electrocardiography typically indicates left ventricular enlargement (increased R-wave voltages in leads II, III, and aVF and in the left chest leads, V_2 and V_4) and normal mean electrical axis (Figure 200-4). 981

Widened P waves may also be found, indicating left atrial enlargement. Chest radiographs indicate left atrial and left ventricular enlargement and pulmonary hypervascularity in proportion to the magnitude of the left-to-right shunt (Figure 200-5). On the dorsoventral (DV) projection, the aortic arch, left auricle, and main pulmonary artery may be abnormally prominent. The most specific radiographic finding is the appearance of an aortic bulge ("ductus bump") near the origin of the ductus, which is caused by abrupt narrowing of the descending aorta just caudal to the origin of the ductus (see Figure 200-5). Moderate to severe LV enlargement sometimes causes the cardiac apex to shift to the right (common in cats). 982

Figure 200-4 Electrocardiogram from a dog with left-to-right patent ductus arteriosus. The mean QRS axis is normal (+80%), but the QRS voltage (amplitude) is increased in several leads, including leads II, III, aVF, and V_4, consistent with left ventricular enlargement. (The square waves in each lead are 1 mV standardization impulses). Paper speed = 50 mm/s.

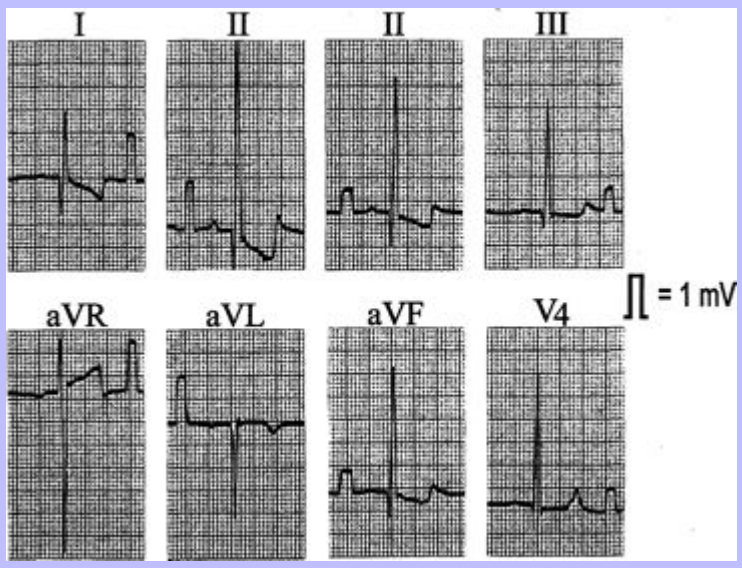


Figure 200-5 Thoracic radiographs from a dog with a left-to-right shunting PDA. **A,** Lateral projection shows left atrial enlargement and enlarged cranial pulmonary arteries and veins. **B,** Dorsoventral projection shows moderate cardiomegaly, a characteristic bulge in the descending aorta, dilatation of the main pulmonary artery, and left auricular enlargement. The pulmonary vasculature is prominent.

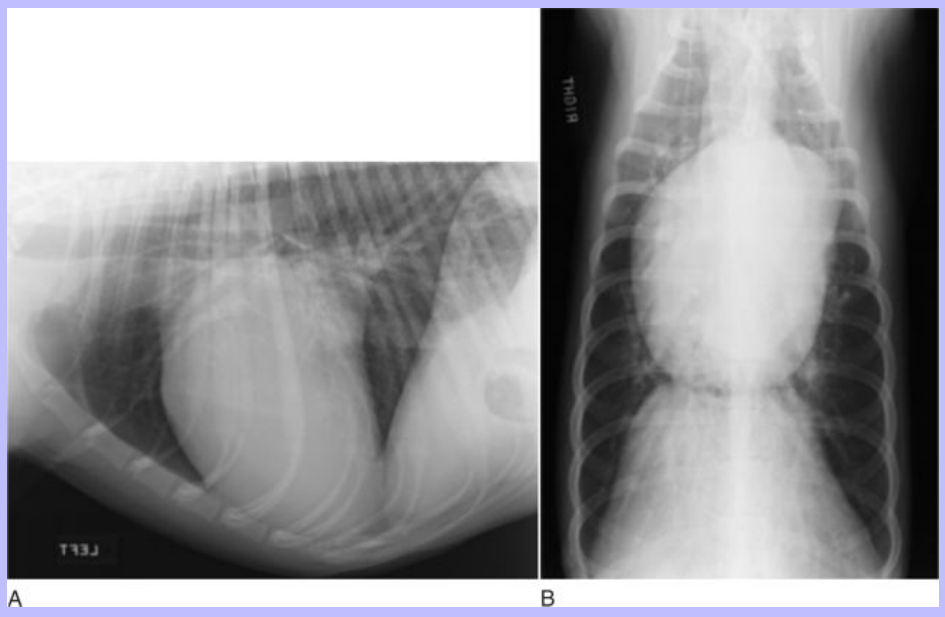

The diagnosis of a PDA can be confirmed by echocardiography in almost all cases. Two-dimensional and M-mode echocardiography demonstrate eccentric LV hypertrophy and dilatation of the left atrium, ascending aorta, and pulmonary artery (Figure 200-6).[11c] Reduced myocardial contractility is often observed and is reflected by reduced fractional shortening and/or increased LV end-systolic dimension and e-point to septal separation (EPSS) measurements. The ductus usually can be imaged from the left cranial parasternal window (see Figure 200-6). Doppler interrogation of the pulmonary artery consistently demonstrates high-velocity continuous ductal flow directed toward the pulmonic valve (see Figure 200-6). In the typical case, the peak velocity of this jet is about 4.5 to 5 m/s and occurs at end-systole. Other common echocardiographic findings include a mildly increased LV outflow velocity (1.8 to 2.3 m/s) and modest secondary mitral and pulmonary valve insufficiency. In dogs with PDA, associated cardiac defects are uncommon; nonetheless, a careful echocardiographic examination is worthwhile to exclude the concurrent presence of other common congenital defects, such as subaortic stenosis.[4a,44a] Cardiac catheterization and angiocardiography are usually not needed to confirm a diagnosis of PDA and are not advised unless the Doppler echocardiographic evaluation is ambiguous or additional congenital malformations are suspected.[12c,13c]

200.11.1.1.5 Patent ductus arteriosus with pulmonary hypertension (right-to-left shunting PDA)

High pulmonary vascular resistance that causes right-to-left shunting through a PDA defines the clinical syndrome commonly referred to as a reversed PDA.* Right-to-left shunting is observed in a very small minority of dogs with a PDA, but the prevalence of this phenomenon is probably underestimated and may be greater in dogs living at altitudes higher than 5000 feet above sea level.[16c] Obvious clinical signs are usually evident during the first year of life, but many owners do not recognize clinical signs in their pet during the first 6 to 12 months of life, and some animals are not diagnosed until 3 to 4 years of age or later. Reported signs include exertional fatigue, hindlimb weakness, shortness of breath, hyperpnea, differential cyanosis and, more rarely, seizures.

The clinical examination findings are very different from those in the more common left-to-right PDA. Right-to-left flow through a widely patent ductus arteriosus exhibits little turbulence, and the physical examination reveals either no murmur or only a soft, systolic murmur at the left base. The most common auscultatory finding is an accentuated and split second heart sound. Differential cyanosis (cyanosis of the caudal mucous membranes with pink cranial membranes) may be observed, but recognition may require examination after exercise. Differential cyanosis is caused by the location of the PDA, which shunts right to left from the pulmonary artery into the descending aorta (see Figure 200-2) but spares the proximal branches of the aorta, which provide normal oxygen delivery to the cranial portion of the body. Perfusion of the kidneys with hypoxemic blood triggers elaboration of erythropoietin and secondary polycythemia and hypervis-cosity as the packed cell volume (PCV) gradually increases to 65% or greater.[59a] Polycythemia may occur during the first year of life, but it often does not become severe until 18 to 24 months of age.

982

984

Figure 200-6 Echocardiography of left-to-right PDA. **A,** Right short axis view shows eccentric dilatation of the left ventricular cavity *(LV)* compared with the right ventricle *(RV)*. **B,** Right long axis view from the same dog reveals eccentric dilatation of the left ventricle *(LV)* and left atrium *(LA)*. The interventricular septum *(1)* and left ventricular posterior wall *(2)* appear relatively thin compared with the dilated left ventricle. The mitral valve *(3)* is in the closed position. The right ventricle *(RV)* and right atrium *(RA)* are normal. **C,** Continuous wave Doppler tracing of the PDA jet obtained from the left heart base, demonstrating continuous flow and a peak velocity of 5.2 m/s, which is converted to units of pressure (108 mm Hg) using the modified Bernoulli equation. **D,** View of the ductus *(D)* imaged from the left heart base. The typical left-to-right ductus is widest at the aortic *(Ao)* end *(1)* and tapers near the main pulmonary artery *(MPA) (2)*. **E,** Close-up view of the ductus *(D)*, pulmonary artery *(PA)*, and aorta *(Ao)*. **F,** Color flow Doppler imaging applied to the echocardiographic view in **E,** demonstrating turbulent left-to-right blood flow through the ductus.

The electrocardiogram of dogs with a reversed PDA almost always reveals evidence of right ventricular hypertrophy (i.e., right axis deviation and increased S-wave amplitude in leads I, II, and III and in the left precordial chest leads V_2, and V_4) (see Chapter 202). Thoracic radiographs indicate right heart enlargement, dilatation of the main pulmonary artery, a visible ductus bump, and variable appearance of the lobar and peripheral arteries. Echocardiography demonstrates right ventricular concentric hypertrophy and a dilated main pulmonary artery. In some cases a wide, cylindrical ductus may be imaged (Figure 200-7). Pulmonary hypertension can be verified in some cases by Doppler interrogation of tricuspid or pulmonic insufficiency jets. Contrast echocardiography, nuclear scintigraphy, oximetry, or angiography can be used to demonstrate the presence of right-to-left shunting should Doppler interrogation prove inadequate. Contrast echocardiography is performed by injecting air-agitated saline into a cephalic or saphenous vein, thereby opacifying the right heart, pulmonary artery, and descending aorta (best observed by imaging of the abdominal aorta dorsal to the bladder). Cardiac catheterization can demonstrate pulmonary artery hypertension with equilibration of right and left ventricular and aortic systolic pressures. Oximetry verifies decreased oxygen saturation distal to the entrance of the PDA in the descending aorta. Right ventricular angiography demonstrates right ventricular hypertrophy and usually outlines a wide PDA that appears to continue distally as the descending aorta (Figure 200-8). The lobar pulmonary arteries may appear normal, especially during the first year of life, or may show increased tortuosity. Aortic or left ventricular contrast injections permit visualization of an often extensive bronchoesophageal collateral circulation (see Figure 200-8).

200.11.1.1.6 Natural history of patent ductus arteriosus

Eyster[53a] reported that approximately 64% of dogs diagnosed with a left-to-right shunting PDA die of complications within 1 year of diagnosis if the condition is not surgically corrected. Complications include left heart failure with pulmonary edema, atrial fibrillation, pulmonary hypertension secondary to left heart failure, and mitral regurgitation secondary to left ventricular dilatation.[53a,58a] Dogs and cats with PDA and more modest shunts often survive to maturity, and some live beyond 10 years of age.[10c] In humans with an uncorrected PDA, the gradual development of pulmonary hypertension and shunt reversal is a significant risk, but this gradual transition to right-to-left shunting is uncommon in dogs. When persistent pulmonary hypertension in the neonate leads to reversed shunting, clinical signs result from hypoxemia, polycythemia, hyperviscosity, and cardiac arrhythmias. Congestive heart failure almost never develops, but sudden death and complications from hyperviscosity are common. Animals with reversed PDA often live 3 to 5 years, and some survive beyond 7 years if the PCV is kept below 65%.

200.11.1.1.7 Clinical management

Surgical correction is recommended in virtually all young dogs and cats with a left-to-right shunting PDA. Correction may not be warranted in older pets if the shunt volume is small and cardiomegaly is minimal or absent. Consultation with a specialist may be helpful in borderline circumstances. Recommended preoperative studies include ECG and chest radiographs to help assess the severity of the shunt and to determine whether congestive heart failure is present. An echocardiogram should always be performed to verify the diagnosis and to rule out additional defects. The timing of surgery is debatable, but PDA correction is typically recommended at an early age or as soon as the diagnosis is made, especially if congestive heart failure appears imminent. If pulmonary edema is found on the chest radiograph, the patient should be treated medically for heart failure (furosemide, angiotensin-converting

enzyme [ACE] inhibitors) prior to surgery. Positive inotropic support should also be considered. Treatment with prostaglandin inhibitors such as indomethacin (often used in premature human infants to assist closure of a structurally normal but functionally immature PDA) is not effective in dogs and cats, most likely because of the absence of smooth muscle in the ductal wall.

Two approaches to PDA correction are currently available. For many years, left thoracotomy and surgical closure, typically by ligation, was the only available treatment.[15c] Other surgical methods of repair include suture occlusion with metallic clips and surgical division. These techniques and their results have been described in detail in several reports, indicating high surgical success rates and an excellent prognosis after repair.[10b-12b,48a-54a] Complications of surgical PDA repair in dogs most often include hemorrhage, infection, pneumo-thorax, cardiac arrhythmias, cardiac arrest, and heart failure. Surgical mortality should be less than 3% in uncomplicated cases.[10b-12b,53a] Pre-existing congestive heart failure (CHF) dramatically increases the risk of anesthetic or operative death and the rate of serious complications, underscoring the necessity of resolving pulmonary congestion prior to surgery. Positive inotropic support provided through a dobutamine infusion should also be considered for patients in this circumstance. Most dogs experience an uneventful recovery after surgery, and overall cardiac size gradually decreases toward normal, although the heart and great vessels often retain an abnormal shape.[44a] Postoperative Doppler examination may indicate a small residual shunt, although the continuous murmur is usually absent and the clinical outcomes are good. A soft left apical systolic murmur, usually from residual secondary mitral regurgitation, is often heard for a variable period after ductus ligation.[47a] Echocardiographic LV fractional shortening declines sharply immediately after surgery as a result of diminished preload and increased afterload. Medical therapy is not usually needed if signs of heart failure were not evident preoperatively. Medical therapies required prior to surgery for CHF are often required for several months after repair. Postoperative ductal recanalization has been reported but is uncommon, occurring in less than 2% of cases, and it most commonly is associated with infection.[15c] Postoperative fever and pulmonary infiltrates may indicate infection at the surgical site and hematogenous pneumonia.[57a] The owner should be informed of the suspected heritable nature of the defect and should be advised not to use the animal for breeding.

Less invasive alternative techniques for PDA occlusion are gaining popularity.[17–20,17c-21c] Percutaneous embolization of the ductus using expandable metal devices imbedded with thrombogenic Dacron strands can be accomplished in most small animals with a PDA, avoiding the morbidity of surgical thoracotomy (see Fig. 200-9 *A* and *B*). The most commonly used embolization device is a helical metal coil that is delivered through a small catheter via the femoral artery or other peripheral vessel. After the device has been deployed in the ductus arteriosus, the attached Dacron feathers induce thrombus formation, thereby occluding the PDA. The purported advantages of PDA coil embolization over thoracotomy and surgical ligation include lower morbidity, shorter hospitalization, and faster recovery. To date the success rate of this technique has been promising and the major complication rate has been acceptably low, consisting mainly of residual shunting and pulmonary embolization of a coil.[17,19,17c-21c] Coils that embolize to the lungs can be ignored, pushed to a peripheral location, or removed. The authors prefer to remove dislodged coils, which can be quite easily accomplished using heartworm extraction forceps or other retrieval devices. Because device retention within the PDA is required for successful closure, the ideal candidates for coil occlusion should have a relatively small, funnel-shaped PDA that tapers to a diameter of 2 or 3 mm at the pulmonary artery end.[20]

Figure 200-7 Echocardiography in right-to-left PDA. **A,** Right long axis view from an American Eskimo dog shows enlargement of the right ventricle *(RV)* and atrium *(RA)*. **B**, Right short axis view shows enlargement of the right ventricle and flattening of the interventricular septum toward the left ventricle. This finding is highly suspicious for pressure overload of the right ventricle. **C,** Transesophageal echocardiogram of a dog with a right-to-left PDA. The ductus *(D)* connects the aorta *(Ao)* with the pulmonary artery *(PA)* and is wide and cylindrical in shape. Both the pulmonary artery and the left pulmonary artery *(LPA)* are enlarged. **D**, Continuous wave Doppler study of the dog in **A** showing bidirectional flow through the ductus. Right-to-left flow (below the baseline) occurs during systole, and left-to-right flow (above the baseline) occurs during diastole. **E**, Simultaneous two-dimensional and color flow Doppler study of the dog in **A**. Flow from the pulmonary artery *(PA)* can be seen moving right-to-left into the large ductus *(D)*. **F**, Continuous wave Doppler study of pulmonic insufficiency in the dog in **A.** The peak velocity of insufficiency is 4.5 m/s, indicating a pulmonary artery diastolic pressure of approximately 80 mm Hg. This finding is consistent with a diagnosis of pulmonary arterial hypertension and the presence of a right-to-left shunt.

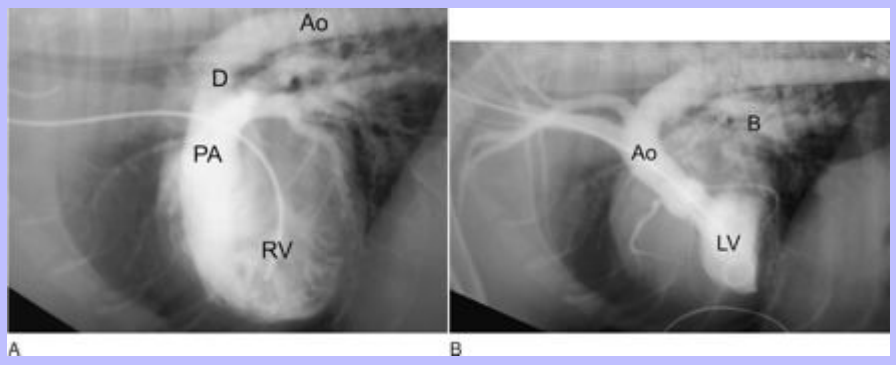
Note that the systemic arteries to the cranial portion of the dog are not opacified. **B,** Left ventricular injection of the same dog opacifies the left ventricle *(LV),* the aorta *(Ao),* and prominent collateral bronchoesophageal circulation *(B)*.



Occlusion of large-diameter PDAs (4 mm or greater) can be attempted by deploying multiple coils into the ductal ampulla, but coil dislodgment and residual shunting are more problematic in this circumstance (Figure 200-9).[19] Mushroom-shaped, self-expanding, occluding stents (Amplatzer) developed for human use have been successfully used to accomplish PDA closure in dogs (Figure 200-10).[18] Advantages of this technique include secure retention of the device in the ductus with a correspondingly low rate of dislodgment, ease of delivery through the femoral vein, and suitability for closing large-diameter PDAs with a single implant. The need for specialized equipment (i.e., coils, occluding stents, catheters, fluoroscopy) and an operator experienced in performing cardiac catheterization limits the application of transcatheter PDA closure techniques to university teaching hospitals and large specialty referral centers. The historical success of the traditional PDA surgery makes thoracotomy and ligation a perfectly acceptable and, in some circumstances, a preferable alternative to transcatheter closure.

Figure 200-9 Thoracic radiographs from a dog after coil embolization of a left-to-right PDA. **A,** Lateral view shows multiple coils in the ductus. **B,** Dorsoventral view shows multiple coils in the ductus near the bulge in the descending aorta.

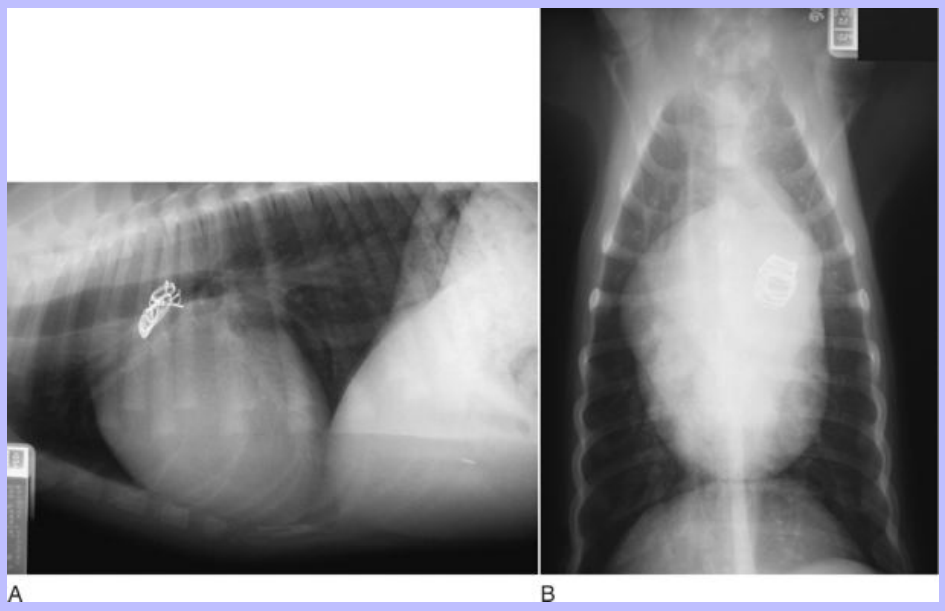

Figure 200-10 Aortic angiograms prior to and 15 minutes after deployment of an Amplatzer duct occluder into a patent ductus arteriosus (PDA). **A,** Contrast agent injected into the aorta before deployment of the duct occluder is seen flowing through the PDA into the pulmonary circulation. **B,** Contrast agent stops in the proximal PDA at the level of the Amplatzer occluder because of thrombus formation in the device.

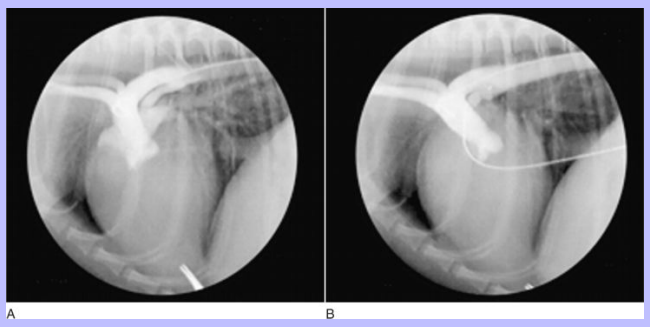


Animals with reversed PDA have irreversible obstructive pulmonary vascular disease. Morbidity and mortality is usually due to complications related to polycythemia and chronic hypoxemia rather than congestive heart failure. Treatment of these patients consists of exercise restriction, avoidance of stress, and maintenance of the PCV between 58% and 65% by periodic phlebotomy.[14] Long-term management by these techniques is possible.[21] Phlebotomy should be performed cautiously to avoid weakness or collapse, and intravascular volume may be supported during phlebotomy by administration of crystalloid solutions. Attempts to reduce the red cell volume of reversed PDA cases using drug therapy (e.g., hydroxyurea) have been reported and may be an alternative to repeated phlebotomy.[22] Activity restriction is usually advised, because exercise-induced systemic vasodilatation increases the degree of right-to-left shunting and predisposes to posterior paresis or collapse and cyanosis. Closure of reversed PDA is strongly contraindicated, because it invariably leads to late operative or early postoperative acute right heart failure and death.

200.11.1.2 Atrial and Ventricular Septal Defects

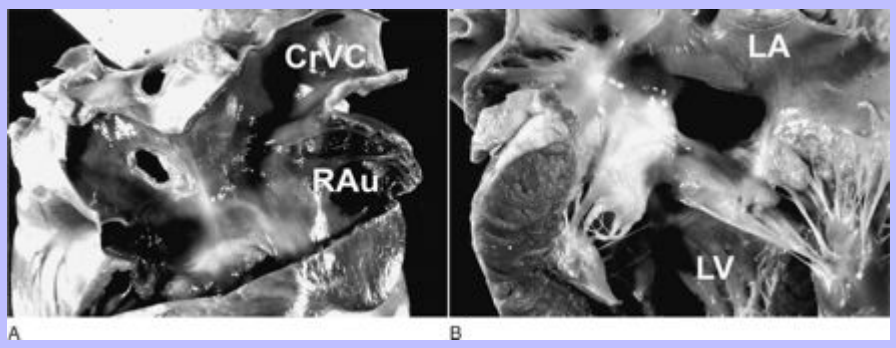
During cardiac embryonic development, the atria and ventricles begin as a common chamber. The heart is subsequently partitioned into the normal four-chambered heart by the growth of cardiac septa.[15a] The atria are partitioned by a wall formed mainly from two septa, the septum primum, which forms first, and the septum secundum, which develops to the right of the septum primum. The foramen ovale, a slitlike passageway that persists between these septa, permits right-to-left atrial shunting in the fetus, but functionally and anatomically closes in the neonate when left atrial pressure rises. The major portion of the ventricular septum forms by inward growth from the ventricular walls. The area of atrioventricular confluence, including the upper ventricular septum, lower atrial septum, and atrioventricular valves, is formed primarily by growth and differentiation of the endocardial cushions. Defects in the development of the embryonic ventricular septum, the primum or secundum atrial septa, or the endocardial cushions may result in atrial or ventricular septal defects, or both. Congenital septal defects are common in both dogs and cats as isolated lesions and as components of more complex lesions, such as tetralogy of Fallot.[4a,13a,62a-79a]

200.11.1.2.1 Pathogenesis

Except for the proven genetic basis of ventricular septal defect in keeshonden with conotruncal malformation,[124a] no data are available on the cause or causes of spontaneous septal defects in dogs or cats.[4a] Atrial septal defects (ASDs) are usually classified based on the anatomic region of the malformation.[15a,16a] Defects at or near the foramen ovale are referred to as *ostium* (or *septum*) *secundum defects*, and defects of the lower atrial septum are called *ostium primum defects* (Figure 200-11). Rarely observed sinus venosus atrial septal defects are found dorsocranial to the fossa ovalis near the entrance of the cranial vena cava.[65a] Because the endocardial cushions are responsible for partitioning the lowermost atrial septum, defects in the region immediately adjacent to the AV valves (septum primum) are often included in the term *endocardial cushion defects*. A defect in this area may also include anomalous development of the atrioventricular valves, such as a “cleft” in the septal leaflet of the mitral valve. A complete endocardial cushion defect is a large defect of the lower atrial septum and upper ventricular septum with fusion of the septal leaflets of both AV valves. This is also referred to as an *AV canal defect*, because the embryonic atrioventricular canal area never partitions, and communication exists between all four cardiac chambers. Patent foramen ovale is not a true ASD inasmuch as the atrial septum forms normally but the walls of the foramen are pushed apart, usually by conditions that increase

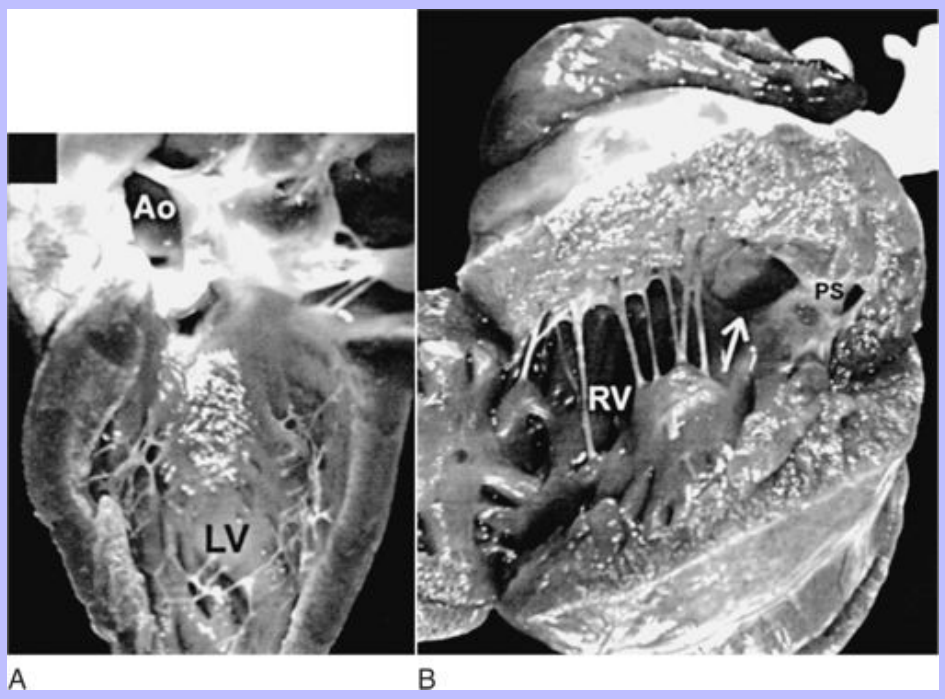
right atrial pressure.[62a] A patent foramen ovale achieves clinical significance when it allows right-to-left shunting, as may occur with severe pulmonic stenosis or tricuspid valve dysplasia.

Figure 200-11 Gross pathology of atrial septal defects (ASDs). **A,** Right atrial view in an 18-year-old dachshund with a secundum ASD. Location of the ASD at the site of the fetal foramen ovale and relative to the cranial vena cava *(CrVC)* and right auricle *(RAu)* is shown. **B,** Left-sided view in a 12-year-old Brittany spaniel with a primum ASD. Location of the ASD, low in the left atrium *(LA)* and near the mitral valve, can be appreciated. A prominent cleft in the mitral valve just below the ASD is also present. *LV,* Left ventricle.



Most ventricular septal defects (VSDs) are located in the upper ventricular septum (Figure 200-12).[68a] Muscular apical or midventricular septal defects are uncommon in small animals. On the left side, the typical location of a VSD is just below the aortic valve, most often centered between the right coronary and non-coronary cusps. On the right side, the opening is often described by its position relative to the crista supraventricularis muscular ridge.[15a] A subcristal (infracristal) VSD is located proximal to the crista supraventricularis near the cranial aspect of the septal leaflet of the tricuspid valve, which may partially cover it. A supracristal VSD is located distal to the crista supraventricularis just below the pulmonic valve. Large defects may obliterate the crista and are usually associated with additional defects, as in tetralogy of Fallot (see Figure 200-12).[2a,4a] The right side of the root of the aorta, including the right coronary and noncoronary cusps, may be displaced to the right so that the aorta straddles the defect. The altered geometry of the aortic root that accompanies many VSDs sometimes results in substantial aortic valve regurgitation.[17b]

Figure 200-12 Pathology of ventricular septal defect (VSD). **A,** Small, restrictive VSD in a young cat, viewed from the left ventricle *(LV)*. The defect is located in the upper septum, just beneath the aortic valve *(Ao)*. **B,** Large, unrestricted VSD in a young dog with tetralogy of Fallot, viewed from the right ventricle. The large defect is located just cranial to the tricuspid valve *(arrow)*. The right ventricle *(RV)* is markedly thickened, and a narrow, fibrous ring of subvalvular pulmonic stenosis *(PS)* is present where the pulmonic valve should be seen.



200.11.1.2.2 Pathophysiology

Shunting across small (resistive) defects depends primarily on the size of the communication and the pressure difference between the two chambers, whereas shunting across large (nonresistive) defects depends primarily on the relative resistances of the systemic and pulmonary circulations.[15a,62a,68a,72a,73a] In the absence of other abnormalities, left heart pressures exceed those on the right, and the direction of shunting is left to right. Cardiac chambers in the circuit of the shunt enlarge to accommodate the excess blood volume, and the pulmonary vasculature is overcirculated. Large-volume left-to-right shunts eventually result in myocardial failure, elevated filling pressures, and the development of overt congestive heart failure. Right-to-left shunting occurs via a septal defect when pulmonic stenosis,

988 989

tricuspid dysplasia, or pulmonary arterial hypertension raise pressures on the right side of the heart. The consequences of reversed shunting include cyanosis from arterial hypoxemia, polycythemia, hyperviscosity, and sudden death.

200.11.1.2.3

Atrial septal defect

Flow across an atrial septal defect occurs primarily during diastole. The pressure difference across the defect is low, and the direction and magnitude of the shunt are determined mainly by the relative diastolic resistance to inflow for each ventricle.[15a,65a] Normally, the right ventricle is more compliant than the left and offers little resistance to filling, causing blood preferentially to shunt from the left atrium into the right atrium and ventricle. The result is dilatation of the right atrium, eccentric hypertrophy of the right ventricle, and pulmonary overcirculation. Oxygen saturation in the right heart and pulmonary arteries is increased. The left atrium receives the shunted blood, but most of the increased pulmonary venous return is shunted immediately into the right atrium, resulting in minimal left atrial dilatation. If considerable left atrial enlargement is observed in an animal with an ASD, an additional defect, such as an endocardial cushion defect with mitral regurgitation, should be suspected. Endocardial cushion defects are more commonly detected in cats and may cause left-sided or bilateral congestive heart failure. Endocardial cushion defects are reported in dogs but are rare.[23]

The flow across an ASD does not usually generate an audible heart murmur because the pressure gradient and flow velocity across the defect are low. When the shunted blood joins blood entering from the vena cava, the volume and velocity of flow through the right heart are increased, resulting a murmur of relative pulmonic stenosis (common) or tricuspid stenosis (uncommon). Delayed closure of the pulmonic valve (and early closure of the aortic valve) causes splitting of the second heart sound.[62a,63a] Because the volume overload affects the right ventricle and not the left, large shunts culminate in the development of right heart failure.

200.11.1.2.4

Ventricular septal defect

Flow across ventricular septal defects occurs primarily during ventricular systole. In the absence of other cardiovascular defects, LV systolic pressure is four to five times that of the right ventricle, and flow proceeds from the left to the right ventricle. The magnitude of left-to-right shunting with small (resistive) defects is mainly determined by the diameter of the defect and the systolic pressure difference (gradient) between the ventricles. The peak pressure difference across the defect can be estimated noninvasively by Doppler echocardiography. Using the peak flow velocity (in meters per second) of the blood flow passing through the defect, the pressure gradient is calculated using the simplified Bernoulli equation ($\Delta P = 4V^2$). A resistive defect with normal right and left ventricular pressures (approximately 20 mm Hg and 100 mm Hg, respectively) would be expected to have a peak jet velocity equal to or greater than 4.5 m/s, corresponding with a peak pressure gradient across the defect equal to or greater than 80 mm Hg. If the peak velocity is lower than predicted, right ventricular systolic pressure is most likely increased, due either to the presence of pulmonic stenosis or to increased pulmonary vascular resistance (pulmonary arterial hypertension).

When a small VSD is located high in the membranous septum, blood is ejected by the left ventricle directly into the right ventricular (RV) outflow tract and out the main pulmonary artery; the right heart experiences only a very modest volume load, and right heart enlargement is minimal. Right heart enlargement is more prominent when the VSD is large or located in the muscular region of the

interventricular septum. With a typical, small, high VSD, oxygen saturation in the right ventricular outflow tract and pulmonary artery is higher than in the right atrium or apex of the right ventricle. Large shunts (those with a pulmonary to systemic flow ratio greater than 3:1) may overload the left and/or right heart enough to increase ventricular diastolic pressures and cause signs of left, right, or biventricular failure. Very large, non-resistive VSDs cause the pressures in both ventricles to equilibrate, and the two ventricles behave as a common pumping chamber. Unless the pulmonary circulation is protected by a stenotic pulmonic valve, the development of pulmonary hypertension is unavoidable.

200.11.1.2.5

Eisenmenger's syndrome

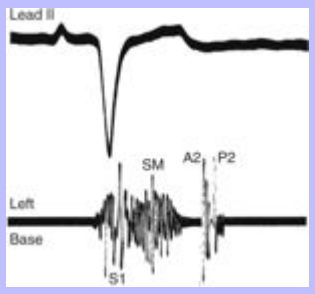
In newborn animals with a large VSD, pulmonary vascular resistance may not decline after birth, resulting in sustained pulmonary arterial hypertension.[13b,14b] If right ventricular systolic and diastolic pressures equilibrate at or above systemic (left ventricular) levels, bidirectional or right-to-left shunting may occur. The development of pulmonary hypertension associated with a shunting cardiac defect is known as *Eisenmenger's physiology* (or *syndrome*). When the defect is a VSD, the term *Eisenmenger's complex* often is used. Sustained pulmonary hypertension is characterized by progressive and irreversible changes in the pulmonary arteries similar to those mentioned in the section on reversed PDA. As in dogs with a PDA, reversed (right to left) shunting through a ventral septal defect is usually established prior to 6 months of age. In contrast to human patients, gradual development of pulmonary vascular disease and progressive pulmonary hypertension is relatively common in dogs and cats.

200.11.1.2.6

Clinical findings

Breed predispositions for atrial and ventricular septal defects are presented in Table 200-1. Clinical findings of the typical left-to-right ASD include a soft, grade II-III/VI, systolic ejection murmur over the left heart base and splitting of the second heart sound (Figure 200-13).[23c-25c,24] The murmur is often misinterpreted as mild pulmonic stenosis or as an innocent murmur. A low-pitched, right-sided diastolic murmur of relative tricuspid stenosis may occur, but it is usually not audible, especially in smaller patients. Cyanosis is absent unless an additional defect (e.g., pulmonic stenosis or tricuspid valve dysplasia)[15b] or the infrequent complication of pulmonary hypertension is present.[26c] Signs of right heart failure develop in dogs or cats with large defects. The differential diagnosis is anomalous pulmonary venous return, which is an extremely rare anomaly in dogs and cats.[80a]

Figure 200-13 Phonocardiogram recorded at the left heart base from a dog with a primum atrial septal defect. The lead II ECG has a negative, slightly prolonged QRS complex, which is indicative of a right ventricular conduction disorder (partial or incomplete right bundle branch block). The phonocardiogram shows a systolic ejection murmur *(SM)* that ends well before the second heart sound, which is widely split. S_1, First heart sound; A_2, aortic component of the second heart sound; P_2, pulmonic component of the second heart sound.



The main cardiac structural changes caused by an ASD include dilatation of the right atrium and eccentric hypertrophy of the right ventricle. The electrocardiogram may indicate right ventricular enlargement (i.e., right axis shift, increased S-wave depth in leads I, II, and III). Intraventricular conduction disturbances, especially partial or complete right bundle branch block (Figure 200-14), are also common, especially with atrial ostium primum or atrioventricular septal defects.[4a,64a,66a] Thoracic radiographs show enlargement of the right heart and main pulmonary artery, as well as pulmonary hypervascularity proportional to the magnitude of the shunt (Figure 200-15). The left atrium is only modestly enlarged unless concurrent mitral regurgitation from a cleft mitral valve or a more extensive endocardial cushion defect is present. Echocardiography permits direct imaging of atrial septal defects, but false-positive impressions of an ASD are common due to imaging artifacts caused by beam orientation and the thinness of some portions of the normal interatrial septum. Doppler evidence of transatrial shunting is more reliable and typically shows laminar or mildly turbulent diastolic flow through the ASD (Figure 200-16) and increased RV outflow and pulmonary artery velocities. Doppler studies are also helpful for demonstrating associated problems such as mitral regurgitation or other associated defects.[16b,24] Contrast echocardiography is helpful, particularly when the defect is large or when elevated right heart pressures cause reversed flow across the defect (see Figure 200-16).

Figure 200-14 Electrocardiogram from a dog with a primum atrial septal defect. The QRS axis is shifted to the right and cranially (+265 degrees), and the last two thirds of the complex is prolonged, as shown by widened and notched S waves in leads III and aVF. A prominent S wave is also present in lead V4. These changes are consistent with a right ventricular conduction disorder, often referred to as a partial or incomplete right bundle branch block. Paper speed = 50 mm/s, 10 mm = 1 mV.

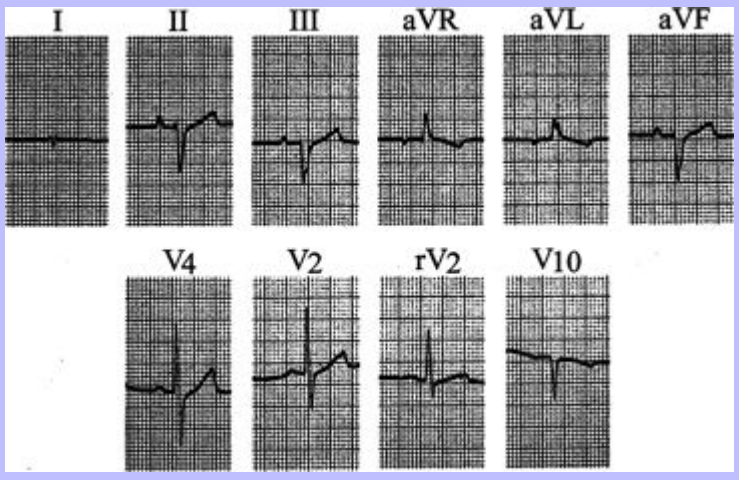


Figure 200-15 Lateral **(A)** and dorsoventral **(B)** radiographs from a standard poodle with an atrial septal defect. The cardiac silhouette is enlarged, with prominence of the right atrium, right ventricle, and pulmonary vessels.

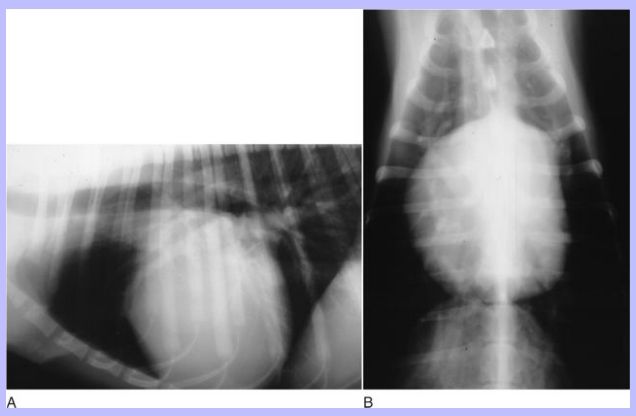


Cardiac catheterization of animals with an ASD is helpful in the evaluation of the magnitude and direction of shunting. In cases of left-to-right shunting, oximetry samples from the venae cavae, right atrium, and right ventricle indicate an increase in oxygen saturation between the venae cavae and the atrium and/or ventricle, and the magnitude of systemic to pulmonary shunting can be estimated.[25] Central venous and right ventricular diastolic pressures are elevated when congestive heart failure is present or imminent. Increased systolic flow across the pulmonic valve may result in "relative" pulmonic stenosis, identified by a mild systolic pressure gradient (5 to 15 mm Hg) between the right ventricle and pulmonary artery.[63a] Flow through the atrial septal defect can be demonstrated by angiocardiography. When introduced via a femoral vein, a catheter often can be easily passed from the right atrium through an ASD or patent foramen ovale into the left atrium, allowing injection of a contrast medium and visualization of the left-to-right shunting. Alternatively, injection of the contrast material into the pulmonary artery outlines left-to-right shunting defects during the left-sided phase of the study. After pulmonary venous return, the atrial septum usually can be seen between the left atrium and the aorta on the lateral projection. Passage of dye from the left atrium into the right atrium and vena cavae confirms the presence of the defect. With more extensive endocardial cushion defects, a left ventricular injection can be performed to demonstrate the VSD, mitral regurgitation, and occasionally left ventricular-to-right atrial shunting.

990 991

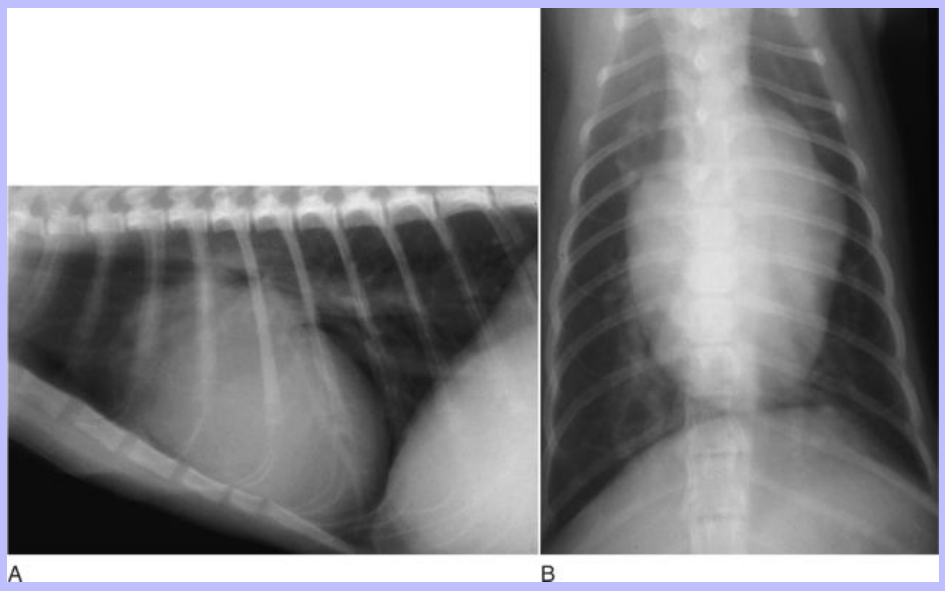
Figure 200-16 Echocardiography of atrial septal defect (ASD) and endocardial cushion defect. **A,** Right long axis view from a standard poodle with a secundum ASD. Color flow Doppler **(B)** and contrast echocardiography **(C)** studies indicate left-to-right flow through the ASD. **D,** Right long axis view from a dog with an endocardial cushion defect. A large ASD, a ventricular septal defect, and a single atrioventricular valve override the interventricular septum. Both the left and right atria are enlarged. *RA*, Right atrium; *RV*, right ventricle; *LA*, left atrium; *LV*, left ventricle.

The clinical features of a VSD depend on the magnitude of the shunt and whether complications or other defects are present. In animals with a typical small, subcristal VSD, a harsh, holosystolic murmur is heard best over the right midprecordium to cranial precordium.* In rare cases of supracristal VSD, the defect opens just under the pulmonic valve, and the systolic murmur may be heard best at the left base. Splitting of the second heart sound can occur, but it often is not recognized because of the imposition of the murmur on the second heart sound. If distortion of the aortic root causes significant aortic regurgitation, a blowing, decrescendo diastolic murmur is audible over the left ventricular outflow area. These combined systolic and diastolic murmurs are sometimes described as a *to-and-fro murmur*. Aortic regurgitation flow into the right ventricle can produce a diastolic murmur best heard on the right hemithorax.[17b] Systolic murmurs over the atrioventricular valves may also be detected if the defect is part of a more extensive endocardial cushion defect.

991

992

Figure 200-17 Lateral **(A)** and dorsoventral **(B)** thoracic radiographs of a cat with a ventricular septal defect and a large left-to-right shunt. Cardiac silhouette is enlarged, and rounding of the cranial border of the heart can be seen on the lateral view. The main pulmonary artery and left atrium are enlarged on the dorsoventral view. The pulmonary vasculature is prominent.



Electrocardiographic findings in animals with a VSD are variable. With moderate or large left-to-right shunts, there is often evidence of left atrial or ventricular enlargement, but right ventricular conduction defects also occur. Frontal plane leads may demonstrate a subtle abnormality in early ventricular septal activation, characterized by a Q wave that is wide or contains high-frequency notching.[69a] Right axis deviation and a narrow QRS complex in a dog with VSD usually indicates right ventricular hypertrophy

and a more complex lesion, such as VSD with pulmonic stenosis or pulmonary hypertension. Thoracic radiographs are very useful in assessing the magnitude of left-to-right shunting VSDs. Pulmonary hypervascularity and left atrial and ventricular enlargement are observed in proportion to the magnitude of the shunt (Figure 200-17).[22a,24a] The main, lobar, and peripheral pulmonary arteries are usually prominent. In animals with small defects, thoracic radiographs may appear entirely normal. With large defects, the right ventricle may also enlarge. A large pulmonary artery segment, underperfused lungs, and small peripheral pulmonary vasculature suggest the possibility of pulmonic stenosis or pulmonary hypertension and right-to-left shunting. Two-dimensional color flow Doppler echocardiography usually identifies all but the smallest VSDs (Figure 200-18). Spectral Doppler studies are useful for quantifying the high-velocity jet through small, resistive VSDs, as previously mentioned. Contrast echocardiography may also be used to identify flow through the defect, but it is usually not necessary if a careful echocardiographic examination is performed.

Cardiac catheterization in animals with a VSD allows identification of the anatomic defect and estimation of the degree of shunting.[27c] Oximetry samples demonstrate a “step-up” in oxygen content between the right ventricle and pulmonary artery. Intracardiac pressures are usually normal in dogs and cats with a small VSD. Right ventricular pressures are often elevated 5 to 15 mm Hg above the pressure in the pulmonary artery, a reflection of increased transvalvular flow and relative pulmonic stenosis. More dramatic increases in right ventricular systolic pressure indicate pulmonary hypertension or concurrent pulmonic stenosis, and the development of elevated end-diastolic ventricular pressures and central venous pressure herald the onset of heart failure. In uncomplicated cases, left ventricular angiocardiography can outline the VSD (Figure 200-19). Bidirectional or right-to-left shunting is observed when RV systolic pressure reaches and exceeds LV systolic pressure. Anatomic changes of the semilunar valves or great vessels, especially of the aortic root, are best visualized by injection of contrast in the proximal aorta, which is also the preferred location for determining the presence and severity of aortic regurgitation.[17b]

200.11.1.2.7

Natural history

The morbidity and mortality associated with atrioventricular septal defects depend on the size and location of the defect, the magnitude and direction of shunt flow, and whether additional lesions are present. Spontaneous closure of small VSDs often occurs in children, but this is an uncommon occurrence in cats and dogs.[71a] Animals with uncomplicated small defects (ASDs and VSDs) and modest shunts usually live a normal life span without ever developing recognizable clinical signs. Large shunts that cause moderate to severe cardiomegaly often lead to intractable congestive heart failure. 992

Moderate to severe aortic regurgitation, an uncommon complication of VSD, presents a very substantial 993 risk of left heart failure and shortened survival.[17b] It is often difficult to predict the outcome in very young animals with a VSD; this is more easily done when they grow closer to adult size at 6 to 12 months of age. Animals that develop pulmonary hypertension (Eisenmenger's syndrome) have a guarded short-term prognosis and a very guarded to poor long-term prognosis, although survival beyond 7 years is possible. Cats with severe endocardial cushion defects often develop marked cardiomegaly and biventricular congestive heart failure at an early age (less than 2 years), warranting a very guarded to poor prognosis.

Figure 200-18 Echocardiography of a Siamese cat with a ventricular septal defect (VSD). **A,** Right long axis view shows the VSD (*) between the left ventricular outflow tract *(LVOT)* and aorta *(Ao)* and opening into the right ventricle *(RV)*. Note the proximity of the VSD to the root of the aorta and the origin of the aortic valve *(arrowhead)*. **B,** Right long axis color flow Doppler study reveals systolic left-to-right shunting across the VSD into the right ventricle.

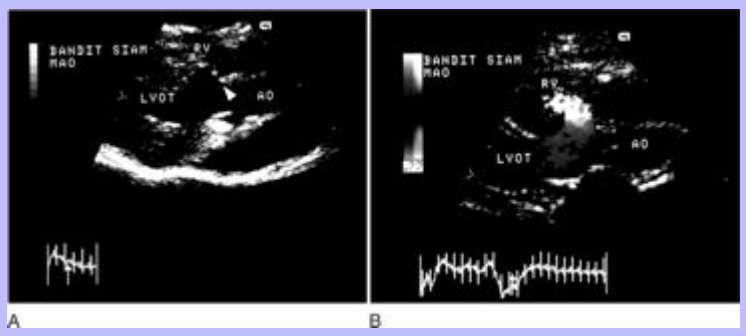

Figure 200-19 Angiogram of a 6-month-old Welsh corgi with a ventricular septal defect (VSD). An injection into the left ventricle *(LV)* outlines the aorta *(Ao)*. Contrast can be seen shunting across the VSD into the right ventricle *(RV)* and the pulmonary artery *(PA)*. The left ventricle is mildly enlarged. A portion of an aortic valve leaflet (*) appears to prolapse into the VSD.

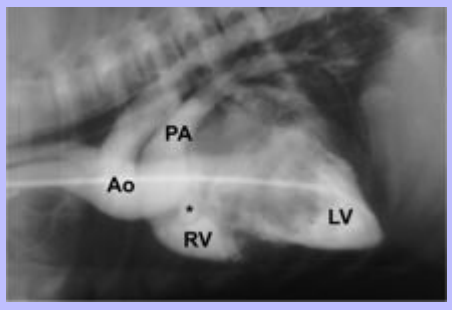


200.11.1.2.8 Clinical management

Surgical closure is the definitive treatment for all atrioventricular septal defects, but open-heart correction is uncommonly attempted in animals because of the usual requirement for cardiopulmonary

bypass or other techniques to arrest the heart.[29c-31c,76a,77a] Palliative treatment of a VSD may be accomplished without bypass by applying a constrictive band around the main pulmonary artery. This technique creates supravalvular pulmonic stenosis and increases the right ventricular systolic pressure, thereby reducing the magnitude of left-to-right shunting.[75a] This procedure is recommended for dogs and cats showing signs of rapidly progressive cardiomegaly and overt or impending congestive heart failure. Overaggressive banding should be avoided, because it can result in pressure overload, acute right heart failure or, in surviving animals, right-to-left shunting. Alternatively, systemic arterial vasodilators can be administered to reduce systemic vascular resistance and the magnitude of left-to-right shunting.[79a] As noted for reversed PDA, surgical correction should not be attempted in animals with Eisenmenger's syndrome. Restricted physical activity is probably the most prudent and effective strategy, and periodic phlebotomy may be useful in some patients that develop extreme polycythemia. The PCV should be maintained at 58% to 65%.

200.11.2 Valvular Regurgitation

200.11.2.1 Pulmonic and Aortic Valve Insufficiency

200.11.2.1.1 Pulmonic insufficiency

Primary congenital pulmonic insufficiency (PI) is an uncommon abnormality that results from abnormal development of valve leaflets or dilatation of the pulmonary artery annulus.[95a,96a] Pulmonic valve insufficiency causes volume overload and eccentric hypertrophy of the right ventricle. The main and proximal branches of the right and left pulmonary arteries enlarge to accommodate the concomitant increase in RV stroke volume. Isolated pulmonic valve insufficiency is often well tolerated, but heart failure can develop when severe PI is induced experimentally in dogs. Congenital pulmonic insufficiency is more likely to cause heart failure if pulmonary vascular resistance subsequently increases as a result of severe pulmonary parenchymal or vascular disease. Trivial pulmonic insufficiency is often observed in dogs with a PDA, presumably from dilatation of the main pulmonary artery. Most dogs with pulmonic valve stenosis have mild valvular insufficiency, but severe concurrent PI is sometimes seen. Pulmonic insufficiency of varying degrees of severity may also develop as a result of surgery or balloon dilatation to relieve PS. Pulmonic insufficiency is a potential consequence of any disorder that prompts the development of pulmonary hypertension.

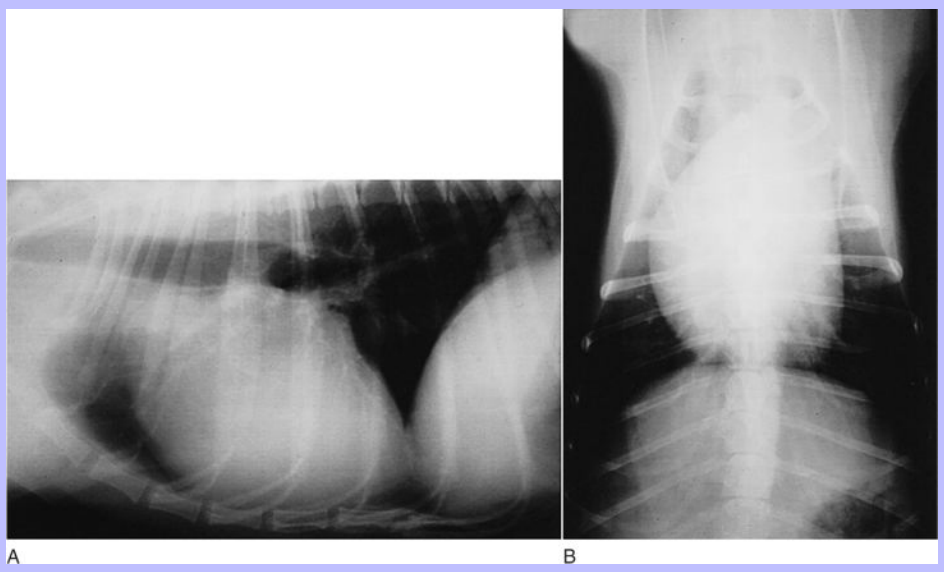
993

994

Clinical features of PI include variable systolic (due to increased flow) and diastolic murmurs best heard at the left heart base. This to-and-fro murmur should not be confused with the continuous murmur of PDA. Electrocardiograms from dogs with congenital PI may be normal or may reflect right ventricular enlargement. Thoracic radiographs show enlargement of the main pulmonary artery and right ventricle, giving the erroneous impression of PS to the unaware (Figure 200-20). Injection of a contrast medium into the main pulmonary artery using a small-diameter catheter documents valvular insufficiency (Figure 200-21). Slow clearance of contrast from the dilated and thin-walled right ventricle also supports a diagnosis of PI. Color flow Doppler echocardiography elegantly demonstrates these same features and permits visualization of the rudimentary or misshapen valve leaflets (see Figure 200-21). Doppler studies also aid the recognition of pulmonary arterial hypertension. When the velocity of the pulmonary regurgitant jet exceeds 3 m/s, pulmonary hypertension is the likely cause of the pulmonary artery dilatation and valvular insufficiency. Treatment for congenital PI has not been described in companion

animals. In dogs suffering from heart failure, conventional medical therapy with diuretics and ACE inhibitors is a reasonable palliative approach.

Figure 200-20 Radiographs from a Cavalier King Charles spaniel with congenital pulmonic valve insufficiency, showing convincing evidence of right ventricular enlargement in the lateral **(A)** and dorsoventral **(B)** projections. The pulmonary artery segment is markedly enlarged (see text for discussion).



200.11.2.1.2 Aortic insufficiency

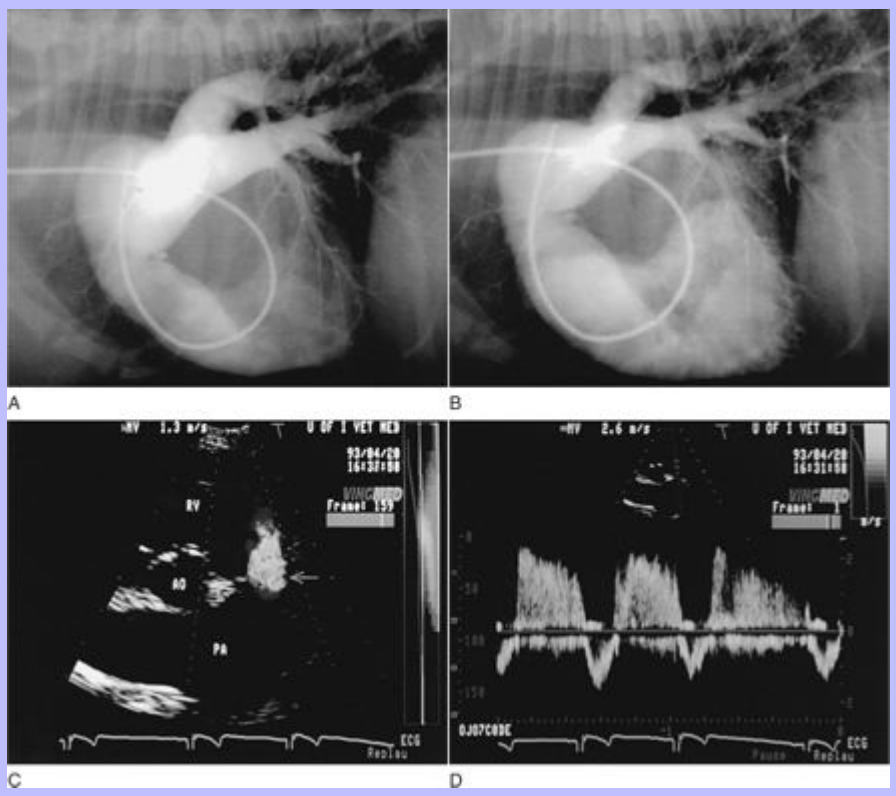
Isolated congenital aortic insufficiency (AI) is a rare disorder. It occasionally is detected in young or older dogs with idiopathic dilatation of the aorta *(annuloaortic ectasia)*. Mild to moderate aortic insufficiency has also been reported in a boxer and a hound with quadricuspid aortic valves.[26] With the increasing application of Doppler echocardiography, aortic regurgitation is recognized with increasing frequency as a complication of other cardiac malformations.[108a,109a] Aortic insufficiency often accompanies subvalvular aortic stenosis and has been observed with ventricular septal defects and tetralogy of Fallot and after balloon catheter dilatation for SAS. The potential mechanisms for aortic valvular insufficiency in these conditions have been reviewed.[108a] As in congenital pulmonic insufficiency, the murmur resulting from AI can be both systolic and diastolic (to-and-fro murmur) and is best heard over the left hemithorax. Many dogs with mild AI do not evidence an audible murmur. The diagnosis of AI is supported by palpation of a hyperkinetic arterial pulse resulting from the increased stroke volume and diastolic runoff of aortic blood back into the left ventricle. Left ventricular eccentric hypertrophy develops in proportion to the severity of the insufficiency. Severe AI commonly results in left-sided congestive heart failure. Documentation of AI and estimation of its severity requires angiocardiography or Doppler echocardiography. Definitive repair requires cardiac bypass surgery and valve replacement, an unlikely proposition. Use of arterial vasodilators can reduce the regurgitant

volume and may delay the onset of heart failure. Treatment with diuretics, ACE inhibitors, and positive inotropic drugs are indicated if heart failure is present.

994

995

Figure 200-21 Angiocardiogram recorded from the same dog as in Figure 200-20. **A,** Contrast material injected into the pulmonary artery leaks immediately back into the right ventricle through the incompetent pulmonic valve. **B,** Several frames later, the right ventricle has filled with contrast, establishing substantial pulmonic valve incompetence. A dysplastic valve remnant is also visible. **C,** A color flow Doppler study was performed several years later in the same dog. Disturbed flow entering the right ventricle *(RV)* from the pulmonary artery is shown on this black and white rendition of a color study. Note the very dilated main pulmonary artery. *Ao*, aorta. **D,** Pulsed wave Doppler study shows that the diastolic flow is moving at a relatively low velocity (just over 2 m/s), excluding the possibility of pulmonary hypertension.



200.11.2.2 Atrioventricular Valve Dysplasia

Congenital malformations of the mitral and tricuspid valves are reported in both cats and dogs.[1–5c,12a,58–62c,110a-121a] Consequences of these malformations include mitral and tricuspid regurgitation, inflow obstruction (i.e., mitral or tricuspid valve stenosis), and dynamic obstruction of the left ventricular outflow tract. The most common physiologic consequence of atrioventricular valve malformation is valvular insufficiency. The pathophysiology and clinical course of congenital mitral regurgitation are similar to acquired degenerative valvular disease in the dog. For this reason, only the salient features of these conditions are reviewed, and the reader is directed to Chapter 201 for greater detail. Congenital stenoses of the atrioventricular valves, as well as other interatrial obstructs, are recognized more frequently in dogs and cats, presumably because of the increased use of Doppler echocardiography. Systolic anterior motion (SAM) of the mitral valve apparatus and dynamic LV outflow obstruction in cats and dogs, long regarded solely as a manifestation of hypertrophic cardiomyopathy (see Chapter 203; 204), may be caused solely by architectural changes in the mitral valve apparatus in some animals. When the primary disorder is valve dysplasia, concentric left ventricular hypertrophy resolves if the obstruction is abolished by treatment (beta-receptor blocking drugs).

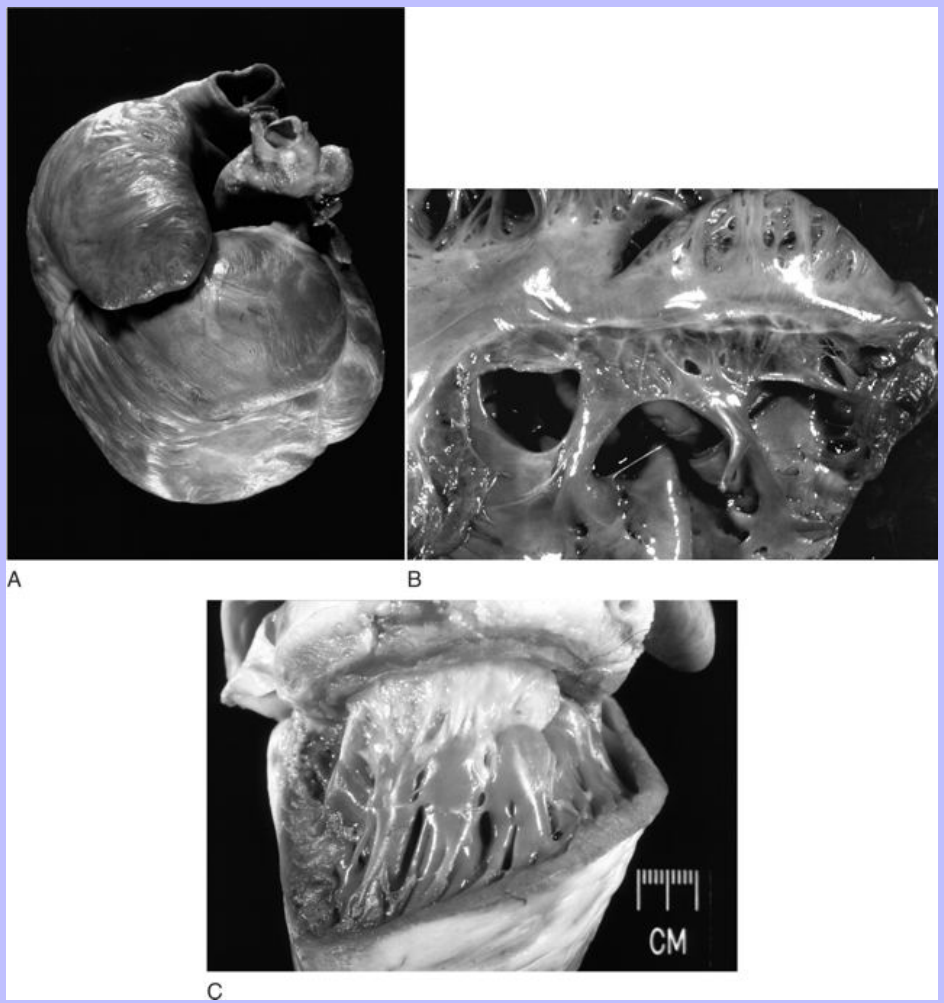
995

996

200.11.2.2.1 Pathology and pathogenesis

Tricuspid valve dysplasia has been shown to have a genetic basis in the most commonly afflicted breed, Labrador retrievers.[6,7] A heritable basis for mitral valve dysplasia in cats and some breeds of dogs is suspected, but convincing evidence has not yet been reported. A wide spectrum of morphologic abnormalities of the mitral and tricuspid valves have been described, including shortening, rolling, notching, and thickening of the valve leaflets; incomplete separation of valve components from the ventricular wall; elongation, shortening, fusion, and thickening of the chordae tendineae; direct insertion of the valve edge into a papillary muscle; and atrophy, hypertrophy, fusion, and malpositioning of the papillary muscles and chordae tendineae.[27,113a,120a] The usual consequence of these changes is valvular insufficiency. Examples of tricuspid and mitral valve dysplasia are shown in Figures 200-22 and 200-23. In dogs, mitral valve stenosis is common only in bull terriers, often occurring along with valvular aortic stenosis.[40b] Some dogs and cats with mitral or tricuspid dysplasia evidence a patent foramen ovale or a concurrent ASD, resulting in left-to-right or right-to-left shunting. Supravalvular mitral stenosis is discussed in a later section of this chapter, together with cor triatriatum.

Figure 200-22 Gross pathology of tricuspid dysplasia (TD). **A,** Cranial view of the heart from a patient with severe right atrial, auricular, and ventricular enlargement caused by TD. **B,** Tricuspid valve from a 2-year-old Labrador with severe TD. The edges of the valve leaflets insert directly into the papillary muscles, and conspicuous absence and shortening of the chordae tendineae are seen. The right atrium and ventricle are dilated. **C,** Curtainlike deformity of the tricuspid valve from a 2-year-old Samoyed with TD and tricuspid stenosis. The tricuspid valve is thickened and opaque. Multiple large, fused papillary muscles with short chordae tendineae are present.



200.11.2.2.2 Pathophysiology

The fundamental pathophysiologic abnormalities of atrioventricular valve malformations are briefly presented. Valvular insufficiency produces volume overloading, manifested as atrial dilatation and eccentric hypertrophy of the affected ventricle. Congestive heart failure often develops at a young age but occasionally does not develop until adulthood. In some dogs and cats with tricuspid dysplasia, cyanosis can be observed as a consequence of right-to-left shunting across a patent foramen ovale or ASD. Malformations that cause valve stenosis obstruct ventricular filling, resulting in increased atrial pressures and signs of congestive heart failure. Severe stenosis limits cardiac output such that hypotension, syncope, or collapse with exertion may be observed. Pulmonary hypertension and right heart failure frequently develop secondary to severe mitral stenosis as a consequence of chronically elevated left atrial pressure. As a result, some dogs that initially present with signs of pulmonary congestion from mitral stenosis can present again months later with signs of right heart failure. Dogs and cats with severe congenital valvular stenosis or regurgitation are predisposed to atrial fibrillation and paroxysmal or sustained supraventricular tachycardia; these conditions typically result in sudden clinical deterioration.

Figure 200-23 Gross pathology of mitral valve dysplasia. **A,** Marked left atrial dilatation in a cat with mitral valve dysplasia. **B,** Mitral valve in this cat shows a bizarre malformation of the anterior (cranioventral) leaflet. Also, the posterior (caudodorsal) papillary muscle is abnormally located, and it attaches directly to the leaflet with no intervening chordae. **C,** Marked dilatation of the left atrium is seen as a result of obstructed flow into the left ventricle. **D,** Grossly distorted mitral valve from a bull terrier with concurrent stenosis and insufficiency of the mitral valve. A thickened aortic valve, which caused mild aortic stenosis, is just visible on the left side of the picture. *LA*, left atrium.

200.11.2.2.3 Clinical findings

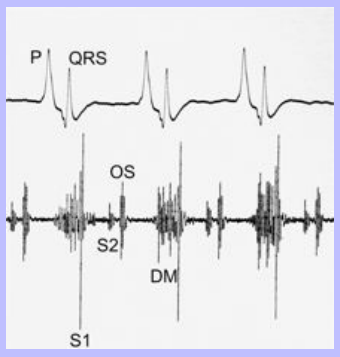
Cats of all breeds, Great Danes, German shepherds, bull terriers, golden retrievers, Newfoundland retrievers, Dalmatians, and mastiffs are predisposed to mitral dysplasia.[30b,111a,114a] Tricuspid dysplasia occurs in cats but seems to be most common in large male dogs, particularly Labrador retrievers.[9a,28] Clinical signs are referable to exertional fatigue or to right ventricular, left ventricular, or biventricular congestive heart failure. The hallmark of valvular insufficiency is a holosystolic murmur heard best over the affected valve area. A loud gallop may also be detected.[111a] A soft, late diastolic murmur and opening snap are sometimes auscultated in dogs or cats with valvular stenosis, but these findings are often absent or missed (Figure 200-24). In severe cases of tricuspid dysplasia, a murmur may not be present because the valve offers no resistance to regurgitant blood flow (Figure 200-25). Jugular venous distension and pulses are common findings in cases of tricuspid dysplasia.

Splintered QRS complexes (Rr′, RR′, rR′, rr′) are a distinctive and common ECG finding in dogs and cats with tricuspid dysplasia.[64c] Right heart enlargement patterns are also manifest. Tall or wide P waves are observed with all types of valvular dysplasia, but ventricular enlargement patterns are mainly limited to animals with regurgitant physiology and are not observed with isolated valve stenosis except when pulmonary hypertension develops secondary to mitral stenosis. Atrial arrhythmias, especially atrial fibrillation, are often recorded. The pattern of chamber enlargement on the thoracic radiographs generally reflects the involvement of the affected valve and resulting physiologic consequences (Figure 200-26). In cases of tricuspid dysplasia the degree of cardiomegaly is often impressive, and the heart may have a globoid appearance resembling that produced by pericardial effusion. The possibility of valvular stenosis should be considered whenever the atrium is markedly dilated without enlargement of the ipsilateral ventricle.

997

998

Figure 200-24 Phonocardiogram from the right apex in a 2-year-old Samoyed with tricuspid dysplasia and tricuspid stenosis. The ECG shows markedly elevated P waves consistent with right atrial enlargement. An early diastolic opening snap (OS) is present, followed by a late diastolic (presystolic) murmur (DM) that coincides with the P wave and atrial systole. S_1, First heart sound; S_2, second heart sound.



Definitive diagnosis of atrioventricular valve malformation requires echocardiography or cardiac catheterization and angiocardiography. Abnormal location, shape, motion, or attachment of the valve apparatus is easily observed by echocardiography (see Figure 200-25). With valve stenosis, color flow Doppler studies show a prolonged high-velocity jet (often greater than 2 m/s) entering the left or right ventricle during diastole, indicating the presence of a diastolic pressure gradient. With valve insufficiency, Doppler studies demonstrate regurgitant jets streaming from the ventricle into the atrium through the incompetent valve. Diastolic pressure gradients (valve stenosis) and varying degrees of ventricularization of atrial wave forms (valve insufficiency) can be recorded during cardiac catheterization. Angiographic visualization of valvular insufficiency is best appreciated by ventricular injections of contrast material, whereas valve stenosis is best demonstrated after an atrial injection (transseptal catheterization is required to accomplish left atrial injection).

200.11.2.2.4 Clinical management

Repair of the affected valve can be attempted, and surgical replacement of dysplastic atrioventricular valves has been successfully accomplished in a small number of animals.[65c-67c] Cardiac bypass is required for these infrequently performed procedures. Balloon valvuloplasty, with limited success, has been described in dogs with tricuspid stenosis.[68c,29] In most affected animals, medical treatment is instituted only if heart failure develops. Treatment of valvular insufficiency largely consists of diuretics, ACE inhibitors, and digoxin.[28] In dogs with tricuspid dysplasia and refractory heart failure, periodic thoracocentesis or abdominocentesis is often needed. In patients with valve stenosis, diuretics are used to control congestion. Inasmuch as tachycardia is poorly tolerated in patients with stenosis, every effort should be made to prevent stress and to restrict exercise. Administration of beta blockers, calcium channel blockers, and/or digoxin is helpful in some cases for the management of atrial fibrillation or other supraventricular tachyarrhythmias. Some patients tolerate serious defects surprisingly well for many years. In other cases, rapid progression to heart failure and death occur.

200.12 DEFECTS THAT CAUSE PRIMARILY PRESSURE OVERLOAD

200.12.1 Ventricular Outflow Obstructions

200.12.1.1 Pulmonic Stenosis

Pulmonic stenosis (PS) is the third most common congenital heart defect in dogs,[5c,30] and it is occasionally recognized in cats.[2c,32c,89a] In most cases pulmonic stenosis occurs as an isolated heart defect, but it frequently is accompanied by other cardiac anomalies, such as tricuspid dysplasia. Congenital outflow tract obstructions of the right heart can develop in the subvalvular and supravalvular regions, but primary malformation of the pulmonary valve (dysplasia) is the most frequently observed defect in dogs. Patterson et al.,[86a] who studied the heritability and pathology of pulmonic valve dysplasia in the beagle, initially suggested a polygenic mode of transmission for this defect. However, these breeding studies did not exclude the possibility of a single-gene mechanism with variable penetrance. The pattern of inheritance of PS has not been studied in other predisposed dog breeds or in cats.

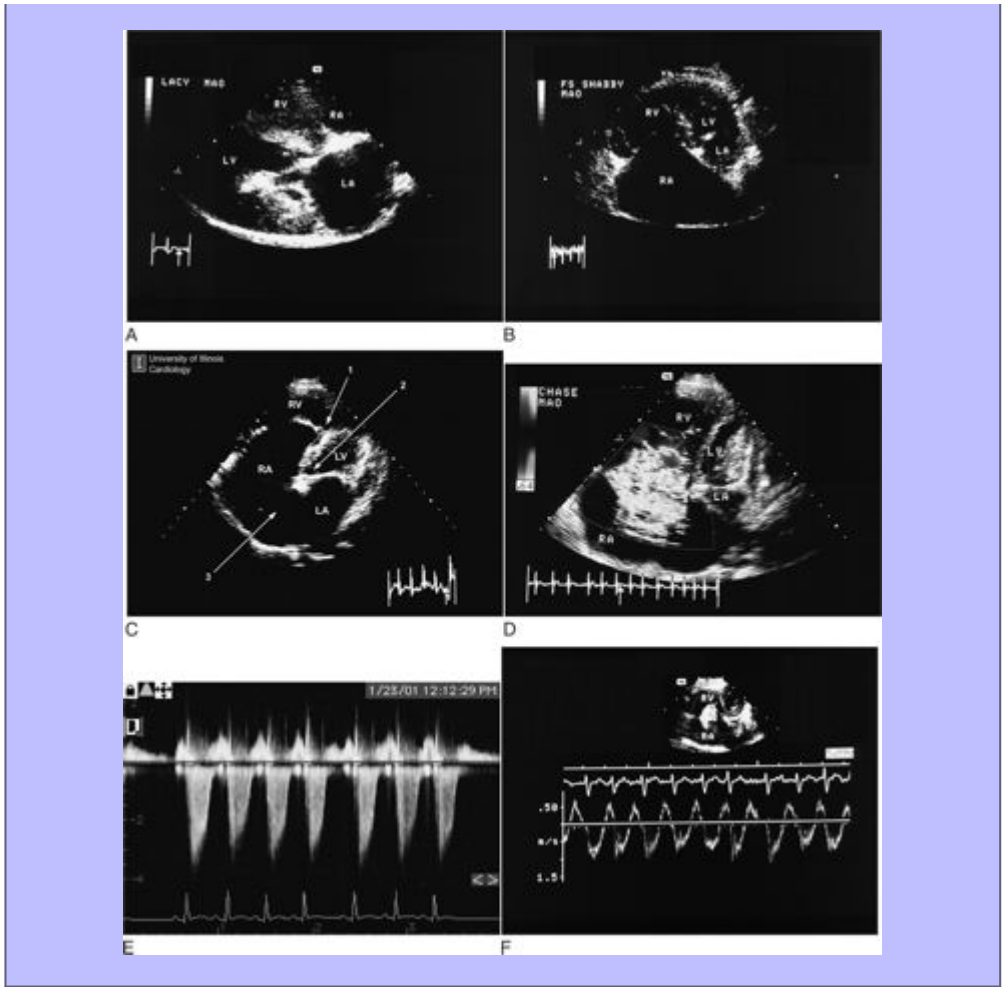
200.12.1.1.1 Pathology

Valvular lesions consist of varying degrees of valve thickening, leaflet fusion, and/or hypoplasia of the valve annulus. Although some dogs manifest a thin, dome-shaped valve with a central orifice (Figure 200-27), many dogs have more complicated lesions that resemble atypical PS in children.[15a,86a,88a] The valve leaflets are often thickened, misshapen, and/or fused (see Figure 200-27). The annulus of the pulmonic valve is hypoplastic in some dogs, which further narrows the area available for right ventricular ejection. Histologic abnormalities include thickening of the valve spongiosa and the presence of bands of fusiform cells in a dense collagen network. These changes are thought to represent overproduction of normal valve elements or failure of conversion of the cushionlike embryonic valve primordia. Some dogs with valve dysplasia have a fibrous ring just below the valve leaflets in addition to the valvular changes. In other dogs, the obstructive lesion occurs in the infundibular region of the right ventricular outflow tract (RVOT). On occasion the RVOT is partitioned from the body (inflow region) of the right ventricle by a well-developed, fibromuscular ridge, resulting in an anomaly referred to as double-or dual-chambered right ventricle.[31] Supravalvular PS is uncommon and in the authors' experience has been most often observed in giant schnauzers. A unique form of subvalvular PS caused by anomalous development of the coronary arteries has been described in English bulldogs and in boxers.[32,33] In this condition, the left and right coronary arteries branch from a single large coronary artery, which originates from the right aortic sinus of Valsalva (Figure 200-28). From this location the anomalous left coronary artery encircles the RVOT just below the pulmonary valve, contributing to the subvalvular component of this complex malformation (see Figure 200-28).

998

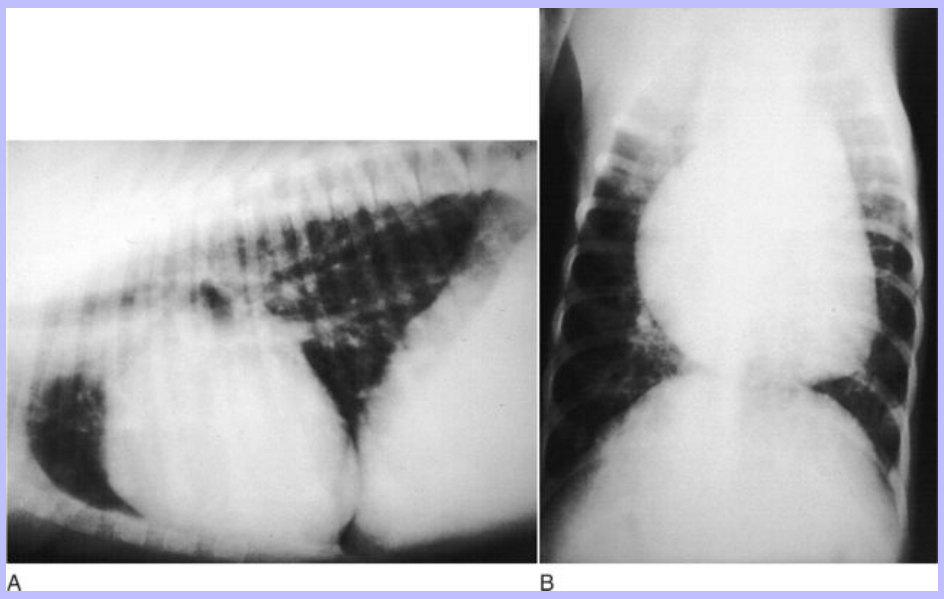
1000

Figure 200-25 Echocardiography of mitral dysplasia (MD) and tricuspid dysplasia (TD). **A,** Right axis view from a 4-month-old pit bull with MD and aortic stenosis. The mitral valve leaflets are markedly thickened, and the chordae tendineae are shortened. The left atrium *(LA)* is enlarged, and the left ventricle *(LV)* is hypertrophied. **B,** Left apical view from a cat with TD, showing severe right atrial (*RA*) and right ventricular *(RV)* enlargement. **C,** Left apical view from a dog with an Ebstein-like abnormality. The origin of the tricuspid valve is displaced apically, and the septal leaflet is fused to the interventricular septum *(1)*. The origin of the mitral valve leaflet *(2)* is shown for comparison. The near-parallel orientation of the ultrasound beam gives the false impression of a large atrial septal defect *(3)*. **D,** Left apical color flow Doppler study from a 2-year-old Labrador retriever with severe tricuspid regurgitation caused by TD. **E,** Continuous wave Doppler tracing of tricuspid regurgitation from a dog with TD. The maximal velocity of the regurgitant jet is 3.5 m/s, suggesting a moderate increase in right ventricular systolic pressure. **F,** Pulsed wave Doppler study from a 7-year-old cat with severe TD demonstrates low velocity and laminar tricuspid regurgitation, indicating that the defect is very large and offers little resistance to regurgitant flow. No murmur was ausculted in this patient.



A
B
C
D
E
F

Figure 200-26 Lateral **(A)** and dorsoventral **(B)** thoracic radiographs from a dog with tricuspid dysplasia (TD). Right atrial and ventricular enlargement is seen in both views. The lateral film demonstrates a bulge in the cranial waist, most likely due to right auricular enlargement.



Increased resistance to systolic ejection results in concentric right ventricular hypertrophy, which generally develops in proportion to the severity of the obstructing defect. Although this compensatory response serves to normalize wall stress, it can have deleterious effects. In some dogs with PS, secondary hypertrophy of the infundibular region of the RVOT contributes to outflow tract obstruction, particularly during exercise or stress. The existence of this additional mechanism of obstruction can complicate the clinical outcome of surgical valvotomy or interventional balloon valvuloplasty. Other cardiac defects can complicate the physiology and alter the clinical presentation and prognosis of patients with PS. Pulmonic stenosis and tricuspid valve dysplasia can be a particularly injurious combination. Insofar as the volume of tricuspid regurgitation is a function of the size of the regurgitant orifice (the severity of dysplasia) and the systolic pressure gradient (the severity of PS), severe tricuspid regurgitation tends to develop in affected dogs, leading to intractable right-sided heart failure.

Meticulous ultrasonic examination, often using contrast echocardiography, reveals that patent connections between the right and left heart occur in a substantial percentage of dogs with PS, and some dogs with severe PS become cyanotic as a result of right-to-left shunting through an ASD, patent foramen ovale, or VSD. Many of these abnormalities have a common origin in the maldevelopment of the embryonic conotruncal septum. These types of defects are discussed more thoroughly in the section on tetralogy of Fallot.

200.12.1.1.2 Pathophysiology

Obstruction to right ventricular outflow increases resistance to ejection, causing a proportional increase in ventricular systolic pressure. Concentric hypertrophy of the right ventricle develops in an attempt to normalize wall stress. During systole, blood ejected from the right ventricle accelerates as it traverses the obstructive orifice. Blood flow velocity increases and becomes turbulent distal to the obstruction. A poststenotic dilatation develops in the main pulmonary artery as the turbulent jet of blood decelerates and expends some of its kinetic energy against the vessel wall.

Concentric hypertrophy reduces right ventricular diastolic compliance, impairs ventricular filling, and often results in elevated right atrial pressure. Tricuspid regurgitation from progressive ventricular dilatation, valvular dysplasia, or a combination of these factors can contribute to further increases in atrial pressure. As right atrial pressure approaches 15 mm Hg, jugular distension, ascites, pleural effusion, and other signs of right-sided congestive heart failure develop. Syncope and sudden death are uncommon in dogs with PS. The physiologic mechanisms responsible have not been elucidated. Hypotension is presumed to develop as a consequence of reduced cardiac output (secondary to bradycardia or worsening of a dynamic infundibular obstruction) and in combination with peripheral arteriolar vasodilatation (with or in anticipation of exercise). Stimulation of mechanoreceptors in the pressure overloaded right ventricle may trigger the reflex bradycardia and vaso-dilatation. Reduced right coronary blood flow has been documented in some dogs with pulmonic stenosis and may contribute to the development of syncope, exercise intolerance, and myocardial failure. On rare occasion, severe septal hypertrophy due to PS results in dynamic left ventricular outflow tract (LVOT) obstruction.

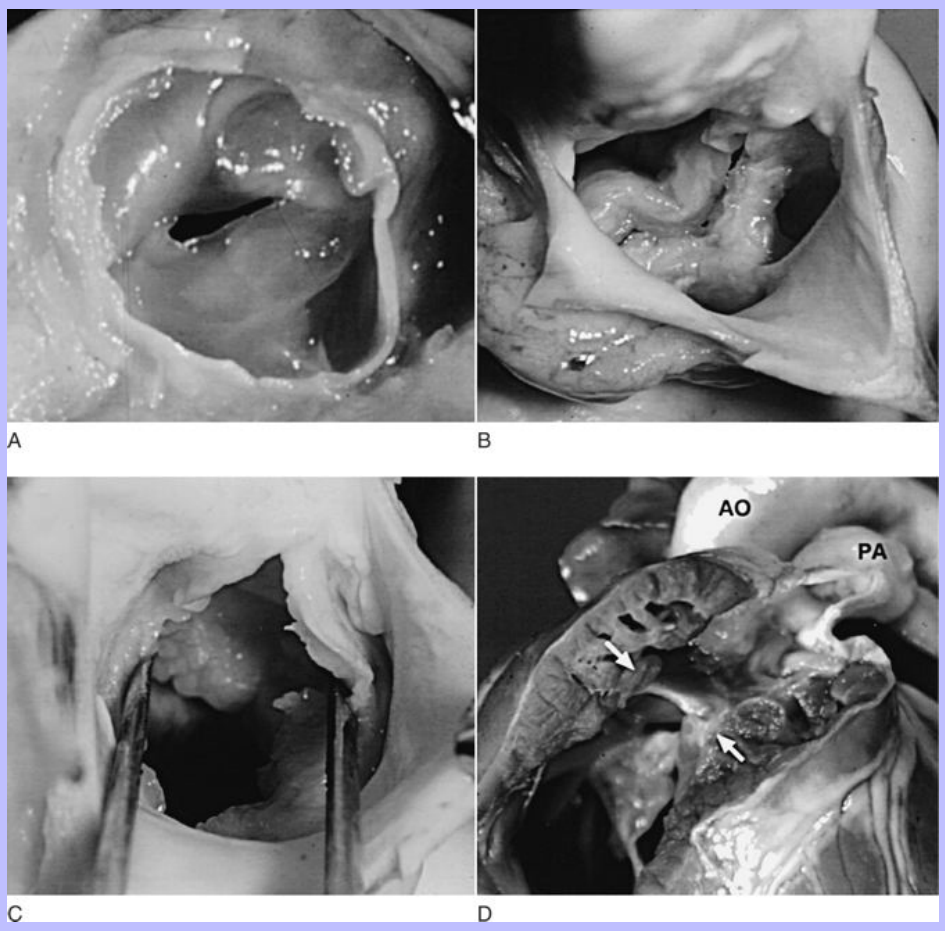
200.12.1.1.3 Clinical findings

Pulmonic stenosis is common in certain breeds, including beagles, Samoyeds, Chihuahuas, English bulldogs, miniature schnauzers, cocker spaniels, Boykin spaniels, Labrador retrievers, mastiffs, chow chows, Newfoundland retrievers, basset hounds, and other terrier and spaniel breeds.[8a,9a,9b,19b] Miniature Doberman pinschers also seem predisposed. Most dogs with PS are asymptomatic in the first year of life, during which the condition usually is discovered through detection of a heart murmur. Approximately 35% of dogs with severe disease demonstrate clinical signs, which can include exertional fatigue, syncope, or ascites.[34] Signs of congestive right heart failure (e.g., ascites) are most often reported in older dogs.[88a] Cyanosis may be noted when PS is complicated by right-to-left shunting across a patent foramen ovale or coexisting atrial or ventricular septal defect.

1000

1001

Figure 200-27 Pathology specimens from dogs with pulmonic stenosis (PS). **A,** Pulmonic valve leaflets are thin but fused with a central orifice in this 1-year-old Labrador retriever; they are similar to the domed valves of children with PS. **B,** Very thick (dysplastic) and bicuspid pulmonic valve from a Staffordshire terrier. **C,** Same dog as in **B;** the leaflets have been distracted to show a small subvalvular ridge. **D,** Fibromuscular ring *(arrows)* in the right ventricular infundibulum several centimeters below the pulmonic valve.



The most prominent physical examination finding is a systolic ejection murmur that is best heard over the left heart base and that often radiates dorsally. In some cases the murmur is heard equally well on the right cranial thorax. In dogs with concurrent severe pulmonic valvular insufficiency, the systolic ejection murmur is accompanied by a soft decrescendo diastolic murmur, which is heard best just ventral to the pulmonic valve region. A holosystolic murmur of tricuspid regurgitation may be noted over the right

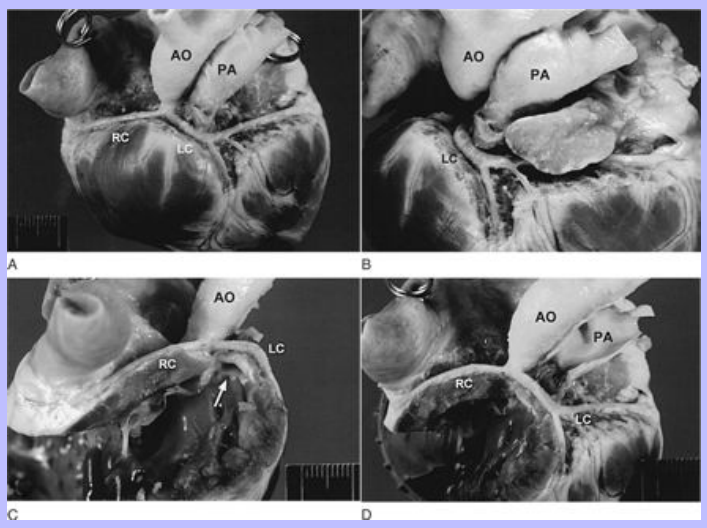
hemithorax as well. Large-amplitude jugular pulses may result either from a giant *a wave* caused by atrial contraction into the stiff right ventricle or from *cv waves*, which indicate significant tricuspid regurgitation. Jugular venous distension and prominent jugular pulses are evident in most dogs with right heart failure and ascites. Peripheral arterial pulses are usually normal.

Right ventricular enlargement is usually present on the electrocardiogram unless the lesion is very mild.[31a,32a,90a] Right axis deviation and deep S waves in leads I, II, and III and in the left precordial chest leads (V_2 and V_4) are common indicators of right heart enlargement (Figure 200-29). Thoracic radiographs typically show a prominent right heart and poststenotic dilatation of the main pulmonary artery (Figure 200-30).[8a,22a,24a,88a] These changes are usually most evident on the dorsoventral view. Additional and more variable findings include dilatation of the proximal left pulmonary artery, diminished size of the pulmonary vasculature, and enlargement of the caudal vena cava.

1001

1002

Figure 200-28 Coronary artery anomaly seen in some English bulldogs with pulmonic stenosis. **A,** Left and right coronary arteries are seen to branch from a single large coronary artery that originates from the right aortic sinus of Valsalva. From this location, the left coronary artery encircles the right ventricular outflow tract just below the pulmonary valve **(B),** thereby contributing to the subvalvular component of this complex malformation **(C** and **D). C,** Left coronary artery courses over the right ventricular outflow tract just below the annulus of the pulmonic valve *(arrow)*. **D,** Anterior wall of the pulmonary artery *(PA)* has been removed to show the hypoplastic pulmonic annulus, the diminutive proximal PA, and the crowded and thickened valve leaflets.



Echocardiography is the technique most commonly used to confirm a diagnosis of PS. M-mode and two-dimensional imaging typically show concentric hypertrophy of the right ventricle, increased prominence of the papillary muscles, deformity in the region of the obstruction or obstructions, narrowing of the RVOT, varying degrees of right atrial enlargement, and poststenotic dilatation of the main pulmonary artery (Figure 200-31).[3,35] Of the four cardiac valves, the pulmonic valve is often the most difficult to visualize clearly by transthoracic echocardiography. Thus it is impossible to visualize the exact location and nature of the obstruction in some dogs. It is often particularly difficult to identify a discrete subvalvular obstruction close to the pulmonary valve. The pulmonic valve leaflets are typically thickened and often fused, and they appear to dome upwards into the pulmonary artery during systole (see Figure 200-31). Hypoplasia of the pulmonic valve annulus further obscures the valve anatomy and confounds consideration of treatment. Color flow Doppler echocardiography is useful for establishing the anatomic location of the obstruction, because the turbulent, high-velocity jet can usually be seen emerging just distal to the obstructive orifice (see Figure 200-31). Mild to moderate pulmonic valve insufficiency is also apparent in many dogs with valvular PS.

For accurate quantification of the severity of the obstruction, the peak velocity of the blood flow jet must be recorded on a spectral Doppler tracing acquired with the continuous wave Doppler beam in parallel alignment with the direction of flow (see Figure 200-31). This usually is accomplished from either the right or left cranial parasternal windows. The modified Bernoulli equation ($\Delta P = 4V^2$) is applied to relate the instantaneous pressure gradient across an obstruction (ΔP, in mm Hg) to the peak velocity of the jet distal to the obstruction (V, in m/s). As a general rule, Doppler-derived gradients are 40% to 50% higher than the gradient measured during cardiac catheterization in an individual dog.[20b] Such discrepancies are attributed in part to the fact that Doppler studies are performed in awake animals, and transvalvular flow is considerably higher under these circumstances than in dogs that have been anesthetized for cardiac catheterization. In addition, hemodynamic studies typically indicate the severity of obstruction as a peak-to-peak pressure gradient, and such measures are almost always lower than the instantaneous peak pressure gradient calculated from Doppler measures of peak flow velocity.[36] Doppler interrogation of the right heart is also particularly helpful for identifying and assessing the severity of coexisting tricuspid valve insufficiency. Measurement of the velocity of this regurgitant jet is particularly helpful for assessing the severity of the PS obstruction when proper alignment with flow through the outflow tract cannot be obtained. In dogs with both dynamic (infundibular) and fixed (valvular) stenosis, Doppler interrogation of the outflow tract and pulmonary artery can produce a tracing that displays the temporal and velocity relationship between the two components of the stenosis.

1003
1005

Figure 200-29 Electrocardiogram from a dog with pulmonic stenosis, showing a typical right ventricular enlargement pattern. The mean electrical axis is shifted to the right (–100 degrees), and prominent S waves are seen in leads II, III, aVF, V_2, and V_4.

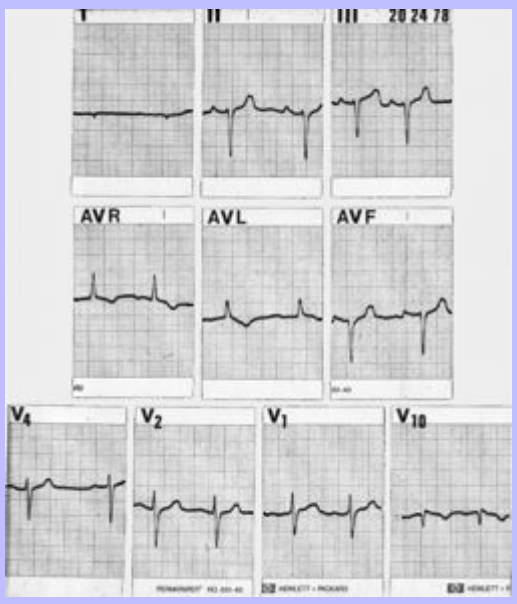

Figure 200-30 Lateral **(A)** and dorsoventral **(B)** thoracic radiographs from a dog with pulmonic stenosis. Rounding of the sternal border and a bulge in the cranial waist of the heart can be seen in the lateral view. Right heart enlargement and a bulge in the main pulmonary artery segment are seen in the dorsoventral view. Pulmonary vessels are diminished even in the absence of a right-to-left shunt.

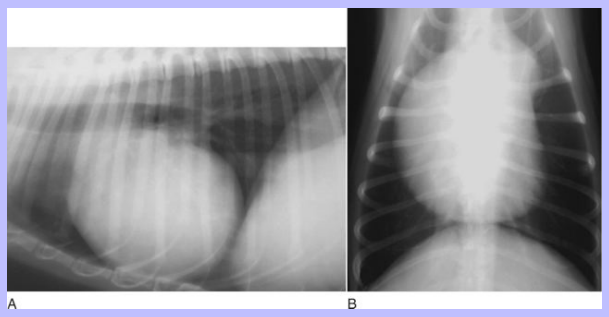

Figure 200-31 Echocardiography of pulmonic stenosis (PS). **A,** Right long axis view from a dog reveals severe concentric hypertrophy of the right ventricle *(RV)*. Right atrium *(RA)* is dilated. **B,** Right short axis view from a dog shows flattening of the interventricular septum and right ventricular concentric hypertrophy caused by pressure overload. **C,** Right short axis view of the heart base from a dog with valvular PS shows thickened pulmonic valves. Poststenotic dilatation of the PA can be seen (PA, pulmonary artery). **D,** Transesophageal ultrasound study of a young rottweiler with valvular PS. The pulmonic valve leaflets can be seen doming into the pulmonary artery *(PA)* during systole. **E,** Color flow Doppler study in a dog shows high velocity and turbulent blood flow moving from the right ventricle *(RV)* through the stenosis *(arrow)* and into the main pulmonary artery *(MPA)*. **F,** Continuous wave Doppler tracing obtained from a view similar to **E** shows high-velocity systolic flow (5 m/s) through the obstruction. Pulmonic insufficiency is also noted during diastole. *LA,* Left atrium; *LV,* left ventricle; *RVOT,* right ventricular outflow tract.

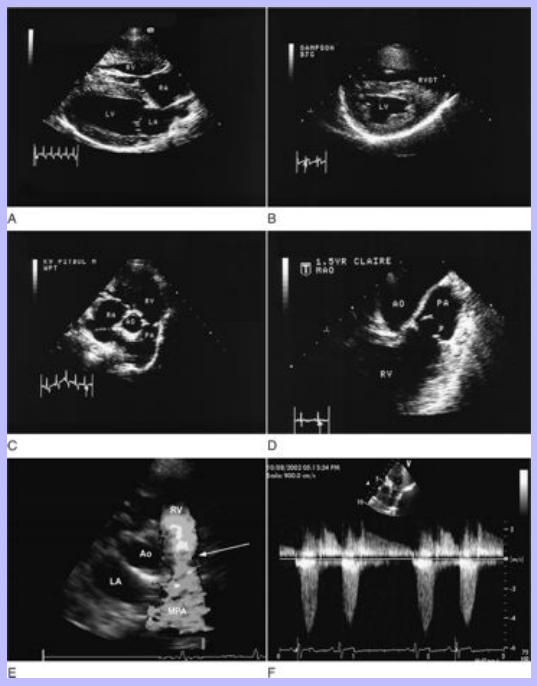

Figure 200-32 Diastolic **(A)** and systolic **(B)** frames of a right ventricular angiogram in a dog with pulmonic stenosis. Note the narrow jet of contrast as it passes through the pulmonic orifice. Poststenotic dilatation of the pulmonary artery is visible in both frames, as is hypertrophy of the RV wall and papillary muscles.

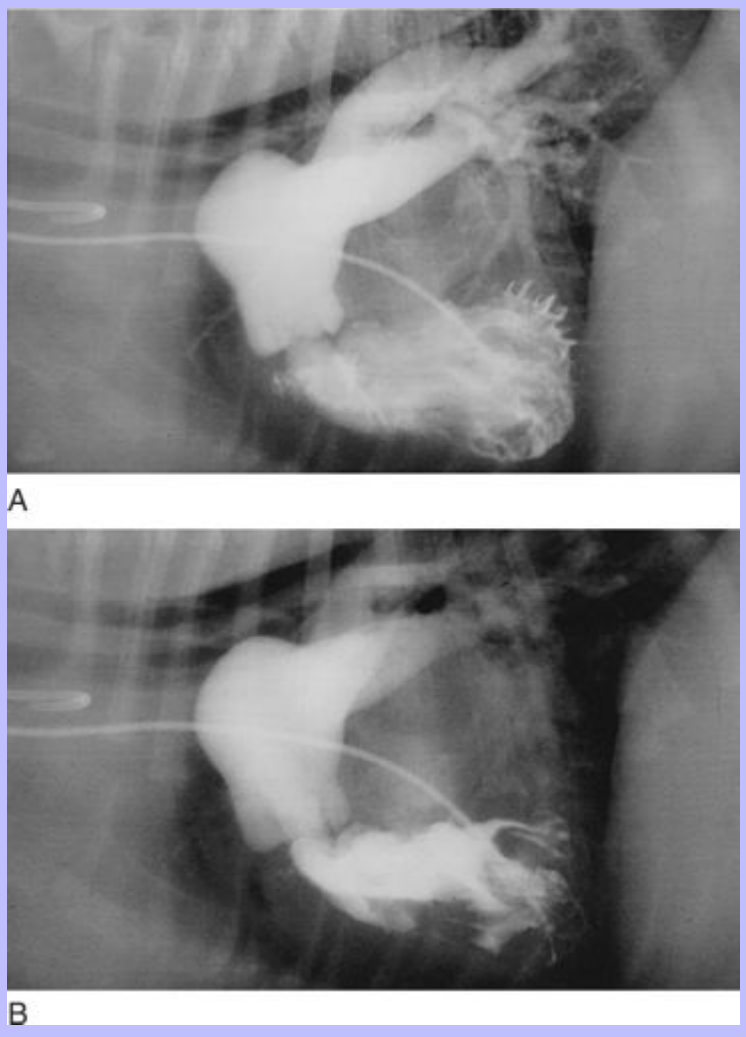
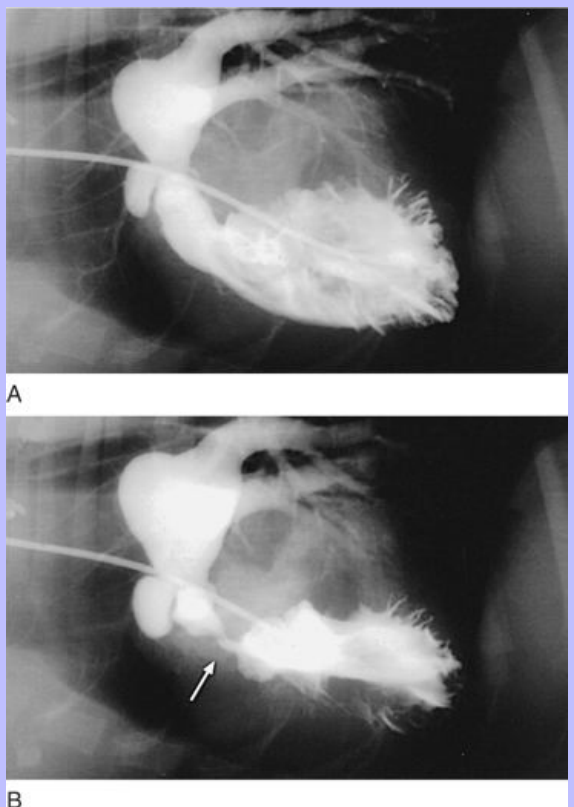


Angiocardiography is often performed just prior to balloon valvuloplasty or to clarify right heart anatomy in anticipation of surgery. Such studies clearly demonstrate the anatomic location of the obstruction or obstructions, the degree of right ventricular hypertrophy, whether tricuspid regurgitation is present, and poststenotic dilatation of the pulmonary artery. The angiographic features of valvular stenosis consist of any combination of the following: narrowing at the immediate base of the valve

sinuses; asymmetric valve sinuses; hypoplasia of the annulus or of a valve sinus; thickening of individual valve leaflets, producing a lucent filling defect; narrowing of the dye column, with a central or asymmetric jet of contrast medium observed within a narrowed valve orifice; or systolic doming of the valve (indicating fusion of the commissures) (Figure 200-32).[86a,88a] Dynamic muscular obstruction of the right ventricular infundibulum is often visible in dogs with PS (Figure 200-33). The term *double-chambered right ventricle* is used when the right ventricle is divided into a low-pressure region (the infundibulum) and a high-pressure region (the apex and inlet portion of the RV) by a muscular or fibromuscular ridge deep in the infundibulum (Figure 200-34). Left ventricular angiography or coronary arteriography should be performed when abnormalities of the left heart or coronary circulation are suspected. Such studies must be performed whenever surgery or balloon valvuloplasty is contemplated in an English bulldog or a boxer. Enlargement of the right coronary artery is an expected finding in all dogs with PS, as is well-developed right ventricular hypertrophy.

Figure 200-33 Right ventricular angiocardiogram from a dog with severe pulmonic stenosis. Comparison of the diastolic **(A)** and systolic **(B)** frames shows complete obliteration of the outflow tract due to vigorous contraction of the hypertrophied infundibulum. Compare with Figure 200-32. Also note the distortion of the pulmonic valve sinuses *(arrow)*.

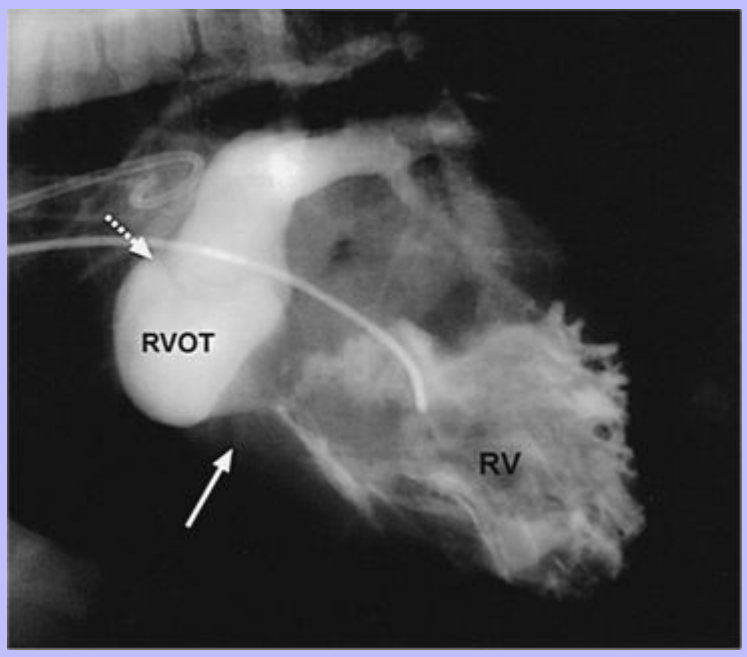


Hemodynamic confirmation of outflow tract obstruction is accomplished by measurement of a systolic pressure gradient across the lesion (see Figure 200-1). The severity of the obstruction usually is defined as the difference in peak systolic pressures measured above and below the obstruction (peak-to-peak pressure gradient). Inasmuch as the recorded gradient varies with the rate of flow across the obstruction, this measurement is greatly affected by myocardial contractility and the anesthetic regimen selected. Despite these limitations, the systolic pressure gradient has been used to categorize patients with pulmonic stenosis as having mild (less than 50 mm Hg), moderate (50 to 80 mm Hg), or severe (greater than 80 mm Hg) disease.[87a,88a,93a] A more accurate approach requires the measurement of cardiac output and calculation of the functional area of the constricted orifice.

200.12.1.1.4 Natural history

Precise criteria for establishing an accurate prognosis have not been developed for dogs and cats with PS. 1005
Clinical experience indicates that most dogs with mild and even moderate PS (Doppler-derived gradient 1006
less than 80 mm Hg) usually live normal or nearly normal lives. This generalization does not include dogs with other complicating defects. The problem of concurrent tricuspid valve dysplasia and its relation to developing heart failure has already been discussed. Although systolic pressure gradients are not always predictive of clinical outcome, a general correlation between pressure gradient and survival appears to exist. Dogs with Doppler-derived gradients greater than 125 mm Hg frequently develop secondary tricuspid regurgitation, heart failure, exertional syncope, or a serious cardiac arrhythmia (e.g., atrial fibrillation). When an ASD, patent foramen ovale, or VSD coexists with PS, the potential for right-to-left shunting exists. If the right-to-left shunting is pronounced, the consequences include arterial hypoxemia, polycythemia, and serious debilitation. Sudden death occurs in some dogs with severe PS, but this is uncommon.

Figure 200-34 Right ventricular angiocardiogram recorded from a rottweiler with an unusual form of subvalvular muscular pulmonic stenosis. Some refer to this lesion as a "double-chambered right ventricle" to distinguish it from dynamic collapse of the hypertrophied infundibulum (see Figure 200-32). Others use the term only when the lesion is deeper within the right ventricle, and some avoid the term altogether. Solid arrow indicates the muscular obstructing lesion in the right ventricular outflow tract. Dashed arrow indicates the location of the pulmonic valve.



200.12.1.1.5 Clinical management

Patients with uncomplicated PS of mild or moderate severity usually do not require treatment. Serial echocardiographic examinations can be performed to monitor the degree of ventricular hypertrophy and to determine whether secondary infundibular stenosis or tricuspid regurgitation has developed. Exercise restriction is usually unnecessary. Some dogs develop more severe obstruction over time. Dogs with severe or symptomatic disease are candidates for surgery or balloon valvuloplasty. The exact pressure gradient warranting intervention cannot be stated with certainty. Dogs with a Doppler gradient exceeding 100 to 125 mm Hg should be considered candidates for balloon valvuloplasty or surgery. Dogs with lesser gradients are also candidates for these procedures if they are symptomatic or have a large amount of tricuspid regurgitation. Intervention at a young age should be encouraged, because the development of

overt congestive heart failure substantially lessens the chance for a successful outcome, regardless of the method of repair. Due to a high likelihood of heritability, even mildly affected dogs should not be bred.

The goals of intervention in dogs with severe PS are to abolish or reduce the systolic pressure gradient to the mild range and to provide symptomatic relief in dogs experiencing clinical signs. The effect of intervention on survival time in dogs or cats is not known. For many years surgery was the only available option for treating PS, and a number of surgical techniques have been advocated, including valve dilatation, patch grafting, or the placement of a conduit from the right ventricle to the pulmonary artery.[*] The open patch-graft technique is a particularly versatile and cost-effective method of treating dogs with PS, particularly cases involving a substantial subvalvular obstruction.[22b,34c,35c] The technique is well-suited to the treatment of some defects not amenable to balloon valvuloplasty (e.g., muscular RVOT obstruction, double-chambered right ventricle, or severe hypoplasia of the pulmonic annulus). The patch-graft technique should not be performed in dogs with subvalvular PS caused by anomalous coronary artery development, because severing of the artery and death will result.

Catheter-based percutaneous balloon valvuloplasty is a preferred alternative to surgery in many dogs with valvular PS.[*,†] A dilatation catheter tipped with an inflatable balloon is placed across the obstructing orifice and repeatedly inflated (Figure 200-35). Successful reduction of the obstructive gradient by 50% or more has been reported in 75% to 80% of dogs treated with this technique.[34,38–40] Improvements in the design of the balloon catheter and refinements in the technique have expanded the application of this procedure to dogs weighing as little as 2 kg.[40c] Balloon valvuloplasty is most successful when the pulmonary annulus is normally developed and the valves are relatively thin and fused. More variable results are obtained in dogs with complex lesions and hypoplasia of the pulmonary annulus.[38c,41c] In the authors' experience, balloon dilatation has been of dubious value in dogs with severe muscular RVOT obstruction or double-chamber-type defects. Although balloon valvuloplasty is generally regarded as a safe procedure with a low complication rate, life-threatening problems such as hemorrhage, cardiac puncture, and arrhythmias do occur. Dogs with hypoplasia of the pulmonary annulus or anomalous development of the coronary arteries are at particular risk for serious complications, including avulsion of the coronary artery or rupture of the pulmonary annulus.[36c] Delayed restenosis can occur, but this is not thought to be an important problem.[39] When CHF or atrial fibrillation develops secondary to PS, the prognosis is poor. If medical stabilization can be achieved, balloon valvuloplasty or surgery can be attempted.

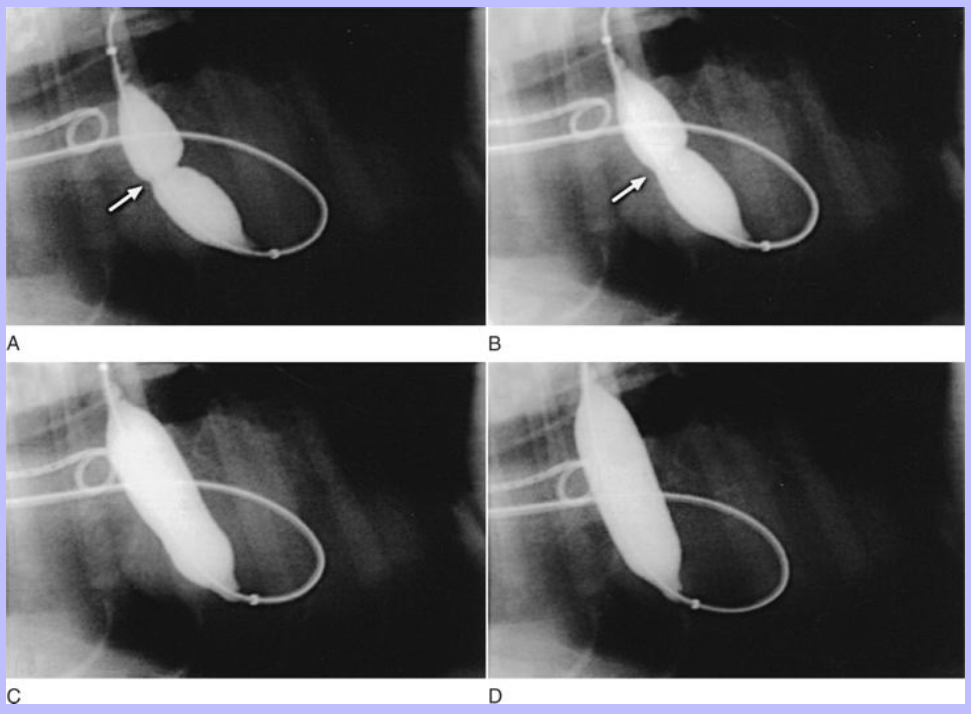
† References 20b, 23b, 24b, 35c-39c, 38, and 94a.

200.12.1.2 Aortic Stenosis

Subvalvular aortic stenosis is the most common congenital cardiac malformation in large-breed dogs.[1c-5c,42c,97a,109a] Most cases of SAS result from a fixed ridge or ring of fibrous tissue located in the left ventricular outflow tract just below the aortic valve. Subvalvular aortic stenosis is a problematic disorder for several reasons. It is very difficult to diagnose in mildly affected dogs, and when the condition is severe, it is difficult to treat. The phenomenon of dynamic SAS is also being recognized with increasing frequency in dogs and cats with a variety of cardiac disorders, including fixed SAS, mitral valve dysplasia, hypertrophic cardiomyopathy, and other conditions that cause hypertrophy of the interventricular septum (i.e., PS, tetralogy of Fallot).[26b] Bull terriers are predisposed to valvular aortic stenosis in which the leaflets

are thickened and the aortic valve annulus is mildly hypoplastic. Mild aortic stenosis (AS) caused by a bicuspid valve occurs on rare occasion. Fixed aortic stenosis has been described in a small number of cats,[12a,13a,25b,36a] including one case of supravalvular stenosis.[101a]

Figure 200-35 Sequence of radiographs taken during balloon dilatation in a dog with valvular pulmonic stenosis. The balloon catheter is seen to traverse the cranial vena cava, right atrium and ventricle, and pulmonary artery. Radiopaque markers on the catheter are used to help position the balloon across the valve. Prominent stenotic lesion *(arrow)* is seen on inflation of the balloon **(A)**; it becomes less obvious as the lesion is stretched or torn open **(B)** and **(C)**; and it is no longer evident when the balloon is fully inflated **(D)**.



200.12.1.2.1 Pathology and pathogenesis

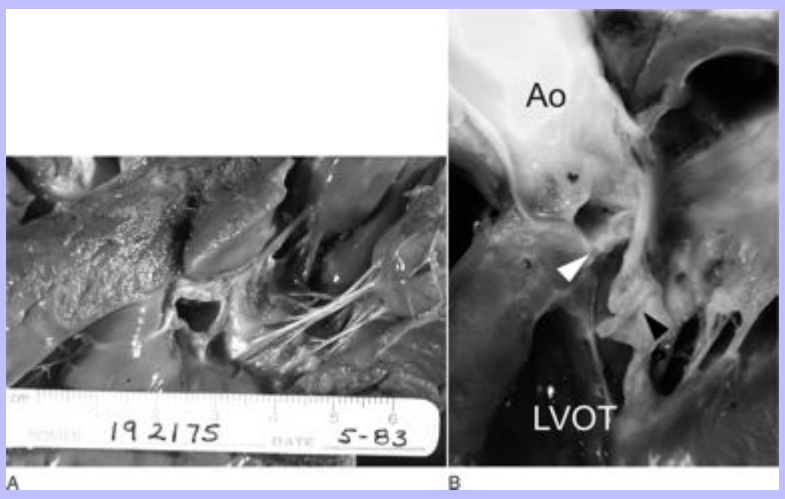
Subvalvular aortic stenosis has been extensively studied in Newfoundlands, for which breeding studies have established a genetic basis for the perpetuation of SAS.[4a,100a] The pattern of inheritance is most compatible with an autosomal dominant mode of transmission with modifying genes; however, a polygenic mechanism cannot be excluded. The breeding colony studies of Pyle and Patterson further indicate that the obstruction may not be present at birth but rather may develop during the first 4 to 8

weeks of life.[4a,99a,100a,103a,104a] This progression is particularly significant with regard to identification of cardiac murmurs in pups of breeds known to be at risk for SAS.

The lesions of SAS in Newfoundlands have been described in postmortem studies as mild (grade 1), consisting of "small, whitish, slightly raised nodules on the endocardial surface of the ventricular septum immediately below the aortic valve"; moderate (grade 2), consisting of a "narrow ridge of whitish, thickened endocardium" extending partly about the LVOT; and severe (grade 3), consisting of "a fibrous band, ridge, or collar completely encircling the left ventricular outflow tract just below the aortic valve".[4a,100a] This ring is raised above the endocardium, extends to, and may involve the cranioventral leaflet of the mitral valve and the base of the aortic valves (Figure 200-36). The stenotic ring consists of loosely arranged reticular fibers, mucopolysaccharide ground substance, and elastic fibers. Discrete bundles of collagen and even cartilage are found in advanced lesions.[100a] Cardiac catheterization of dogs with grade 1 lesions failed to reliably detect the postmortem lesion, whereas grade 2 lesions often were associated with soft cardiac murmurs and minimal systolic pressure gradients. As evidenced by these studies, clinical detection of mild SAS can be quite difficult and genetic counseling can be fraught with error. A variety of cardiac abnormalities can accompany SAS, most notably mitral valve dysplasia, PDA, and a host of aortic arch abnormalities. The valvular lesions seen in bull terriers, including myxomatous degeneration and cartilaginous metaplasia of the valve leaflets, resemble those in humans with calcific valvular stenosis.[41]

In some affected dogs, the pathologic findings diverge from the classical description. The anterior mitral valve leaflet is thickened in apposition to a septal plaque of endocardial fibrosis where the mitral leaflets impact the interventricular septum as a consequence of dynamic obstruction. Instead of a fibrous collar, the septum is uniformly hypertrophied, or a broad, fibromuscular ridge that arises from the base of the interventricular septum protrudes into the LVOT. Malformed, malpositioned, or malaligned papillary muscles, thickened chordae tendineae, and elongated or distorted mitral leaflets contribute to the development of obstruction.[42,43]

Figure 200-36 Gross pathology of subaortic stenosis (SAS). **A,** Left ventricular outflow tract in a dog, as viewed from the apex of the left ventricle, shows a circumferential ring of fibrous tissue. The anterior mitral valve leaflet and associated chordae tendineae are seen to the right of the lesion. **B,** Cutaway view of the left ventricular outflow tract *(LVOT)* and aorta *(Ao)* in a dog with fixed, dynamic SAS. A ridge of thick, fibrous tissue *(white arrowhead)* is seen just below the aortic valve. The anterior leaflet of the mitral valve *(black arrowhead)* is thickened and elongated.



Concentric hypertrophy of the left ventricle develops in dogs with valvular, fixed, or dynamic SAS more or less in proportion to the severity of the outflow obstruction, although the correlation between wall thickness and the magnitude of the measured gradient is often poor.[44] Structural and functional abnormalities of the left ventricle[45] and coronary circulation are well documented in dogs with SAS.[103a,104a] Abnormal coronary flow has also been measured in the larger, extramural arteries, with diminished baseline diastolic flow and reversal of coronary flow during systole.[8a,104a] Focal areas of myocardial infarction and fibrosis are commonly observed in the papillary muscles and subendocardium of dogs with severe SAS, often in association with abnormal intramural coronary arteries. Histologic changes of the intramural coronary arteries in these locations include intimal proliferation of connective tissue and smooth muscle, and medial degeneration. These changes are presumably related to the high wall tension found in this condition, and their genesis may be related to the elaboration of angiotensin II or other biochemical mediators of hypertrophy and remodeling.[46–48] Moreover, these arterial lesions may be important in the genesis of malignant ventricular arrhythmias and sudden death.

200.12.1.2.2

Pathophysiology

Obstruction to left ventricular outflow causes an increase in left ventricular systolic pressure and concentric hypertrophy. Consequent to fixed obstruction, left ventricular ejection is delayed, causing a diminished and late rising arterial pulse (*parvus et tardus*). High-velocity and turbulent flow across the stenotic area produces the systolic ejection murmur and results in poststenotic dilatation of the ascending aorta, aortic arch, and brachiocephalic trunk. Left atrial hypertrophy develops as a consequence of the reduced compliance of the hypertrophied left ventricle. Mild aortic regurgitation is commonly present, presumably due to thickening of the valve leaflets or dilatation of the ascending aorta. Damage to the aortic valvular endothelium (jet lesions) predisposes dogs with SAS to bacterial endocarditis. Dogs with severe SAS can develop left-sided congestive heart failure from myocardial failure, diastolic pump failure due to increased ventricular stiffness, mitral regurgitation, atrial fibrillation, or a combination of these factors. More often, exertional syncope or sudden death is reported, presumably as a result of myocardial ischemia and the development of malignant ventricular arrhythmias. In some dogs, exertional collapse may be due to hypotension precipitated by exercise-induced increases in left ventricular pressure, activation of ventricular mechanoreceptors, and inappropriate bradycardia or vasodilatation.[49]

200.12.1.2.3

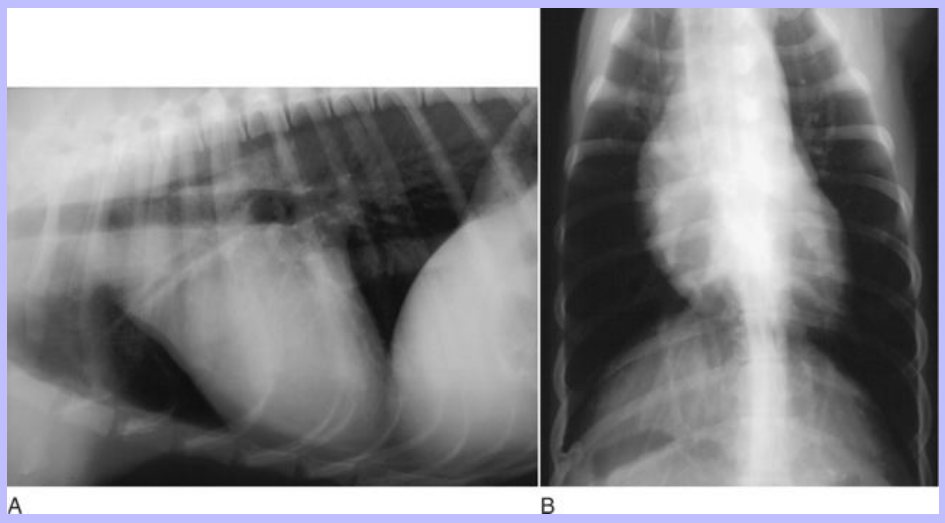
Clinical findings

Congenital SAS is most common in Newfoundland retrievers, boxers, rottweilers, golden retrievers, and German shepherds.[30,50] Valvular AS is common only in bull terriers. The clinical findings of SAS vary with the severity of the obstruction and the presence of concurrent cardiac defects. Clinical findings in pups with mild SAS are often subtle and easily overlooked.[5a,9a,98a,100a] Asymptomatic dogs have a soft to moderately intense ejection murmur that can easily be confused with an innocent or functional heart murmur.[51] Insofar as the lesions of SAS can develop during the postnatal period, the murmur may become increasingly prominent during the first 6 months of life. Severely affected dogs may present with exertional fatigue, syncope, or left-sided congestive heart failure, but the vast majority of dogs are asymptomatic. In dogs with severe disease, a common client observation is that the affected dog is smaller than healthy littermates. Sudden death, without premonitory signs, is common in dogs 1 to 3 years of age.[50c]

Figure 200-37 Electrocardiograms demonstrating ST segment depression **(A** and **B)** and elevation **(C)** in three dogs with severe SAS. These results are suggestive of myocardial ischemia. (Sensitivity =10 mm/mV.) **A,** Tracing from a 1-year-old golden retriever (25 mm/s). **B,** Tracing from a 6-month-old Newfoundland retriever that collapsed and died suddenly 1 hour after the ECG was performed (25 mm/s). **C,** Tracing from a 1-year-old golden retriever (50 mm/s).

Recognition of severe SAS is not difficult, because the murmur generally becomes louder and longer when the obstruction is more severe.[46c] The murmur of severe SAS is usually best heard at the left heart base, recognizing that in some dogs, the systolic murmur is equally loud or louder at the right cardiac base, presumably from radiation into the ascending aorta. The murmur of aortic stenosis often radiates up the carotid arteries and can be ausculted over the ventral cervical region. In some affected dogs, a soft diastolic murmur secondary to aortic valve insufficiency is also detected. A substantial percentage of dogs with SAS have mitral regurgitation, but these murmurs are usually difficult to separate, given their similar timing and overlapping areas of maximal intensity. Other physical abnormalities detected in moderate to severely affected dogs include a diminished and late-rising arterial pulse and a prominent left ventricular heave arising from the hypertrophied left ventricle.

Figure 200-38 Lateral **(A)** and dorsoventral **(B)** radiographs from a young dog with subaortic stenosis. Prominent bulge in the cranial waist on the lateral view and widening of the cranial mediastinum on the dorsoventral view are consistent with poststenotic dilatation of the ascending aorta.



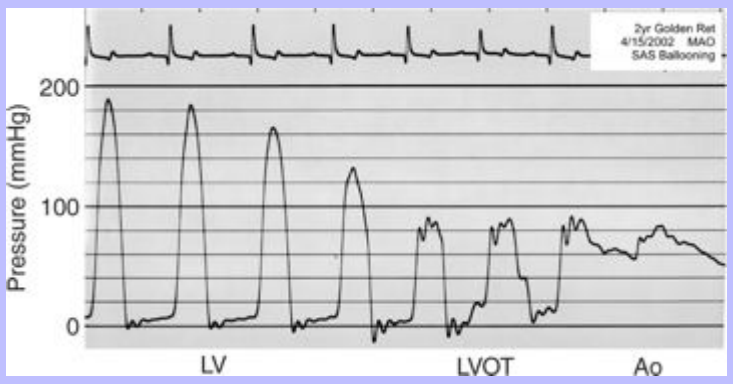
The electrocardiogram is often normal but in severe cases may indicate left ventricular hypertrophy (increased R wave amplitude in leads II, III, aVF, V_2, and V_4). Depression of the ST segment and T-wave changes suggest myocardial ischemia, particularly when these alterations are precipitated by exercise or occur in the company of ventricular ectopia (Figure 200-37). Compared with the resting electrocardiogram, 24-hour ambulatory (Holter) ECG recordings offer a more sensitive method of detecting ventricular arrhythmia and ST-segment changes, particularly when such changes are precipitated only by exercise. The severity of arrhythmias detected in this fashion often corresponds to the severity of disease.[52]

Thoracic radiographs may be normal or may indicate left ventricular hypertrophy.[8a,22a-24a] Poststenotic dilatation of the horizontally inclined ascending aorta causes loss of the cranial waist on the lateral radiograph and widening of the mediastinum on the dorsoventral radiograph (Figure 200-38). Mild left atrial enlargement is common in dogs with moderate or severe SAS, but marked left atrial enlargement suggests concurrent mitral regurgitation. Angiocardiography is useful for delineating the site and geometry of obstruction, which is usually most evident in the ventral aspect of the outflow tract when viewed on the lateral projection (Figure 200-39). Other angiographic findings include poststenotic dilatation of the ascending aorta, enlargement of the left coronary artery and its extramural branches, a small left ventricular cavity, and hypertrophy of the papillary muscles and left ventricular wall. Supravalvular aortic injections can be performed to identify insufficiency of the aortic valve, but Doppler echocardiography is a more sensitive technique. Hemodynamic recordings are made to document the presence and severity of a systolic pressure gradient across the obstruction (Figure 200-40). Such recordings are also useful for detecting elevated left ventricular end-diastolic pressure and

impending congestive heart failure.[8a,105a] As a result of diminished flow (cardiac output), pressure gradients recorded from dogs with SAS are depressed by general anesthesia to approximately 40% to 50% of those measured in the unanesthetized state.[47c]

Figure 200-39 Angiogram from a dog with subaortic stenosis. Left ventricular injection opacifies the left ventricle and aorta. Tunnel-like narrowing of the contrast column is seen in the left ventricular outflow tract; a prominent left circumflex coronary artery is also seen.

Figure 200-40 Intracardiac and aortic pressures from a 2-year-old golden retriever with subaortic stenosis obtained through cardiac catheterization. The catheter is withdrawn from the left ventricle (LV) into the left ventricular outflow tract (LVOT) and the ascending aorta (Ao). A 100 mm Hg systolic pressure gradient is demonstrated between the LV and LVOT, indicating the subvalvular location of the obstruction.



Moderate to severe SAS is easily confirmed by two-dimensional and Doppler echocardiography. Typical findings include concentric left ventricular hypertrophy, a subvalvular obstructing lesion, and poststenotic dilatation of the aorta (Figure 200-41).[3,27a,35,106a] The papillary muscles and endocardial surface of the ventricular myocardium often appear hyperechoic, presumably as a result of myocardial ischemia and replacement fibrosis or calcification. Structural changes in the mitral valve can often be appreciated and abnormal motion of the mitral valve (systolic anterior motion) can be detected in dogs with coexisting mitral valve dysplasia and dynamic obstruction.[43] Spectral Doppler interrogation of the left ventricular outflow tract is used to assess the severity of disease through measurement of the peak velocity of flow in the LVOT.[48c] Such measurements show excellent correlation with invasive measurements (see Figure 200-41).[49c] Doppler measurements can be made from a variety of parasternal or subcostal imaging windows, although velocities obtained from the subcostal position generally display the highest values.[27b] Doppler-estimated pressure gradients between 80 and 100 mm Hg (peak flow velocities ranging from 4.5 to 5 m/s) are used to indicate moderate LVOT obstruction, and higher velocities are used to indicate severe obstruction, but these designations are somewhat arbitrary. Doppler-derived pressure gradients are affected by the amount of flow (cardiac output) through the obstructive orifice and may either overestimate the severity of obstruction if cardiac output is high (e.g., in dogs that are stressed or excited) or underestimate severity if flow is subnormal (e.g., in dogs with concurrent myocardial failure). In these cases, indexing the gradient to stroke volume or some related measure or simple estimation of the two-dimensional orifice area may provide a better estimate of disease severity.[44,53] Color flow Doppler recordings are valuable for detecting and estimating the severity of coexisting aortic or mitral valve insufficiency.

Antemortem detection of the mildest forms of SAS by echocardiography is often not possible. Dogs with subtle abnormalities (i.e., grade 1 lesions as described previously) escape detection by even the most accomplished examiners. Even with dogs that have grade 2 lesions, segregation from normal dogs on the basis of left ventricular velocities is problematic. An upper limit for aortic velocity in normal dogs has been reported but is not well established for differing breeds and examination conditions.[54] The maximum normal aortic velocity in the authors' laboratory is 1.7 m/s (upper limit of the 95% confidence interval); however, velocities in excess of this value are sometimes recorded in completely normal dogs or in dogs with no evidence of a discrete outflow obstruction but that have slightly diminished outflow tract dimensions (boxers, bull terriers, golden retrievers). A diagnosis of mild SAS is more secure when mildly elevated velocity measurements are accompanied by disturbed flow, when an anatomic lesion is visible, and when velocity flow suddenly accelerates over a discrete region in the LVOT. Inability to reliably detect mild SAS is a great source of frustration with regard to efforts to provide genetic counseling to breeders, who are interested in reducing the incidence of disease.

200.12.1.2.4

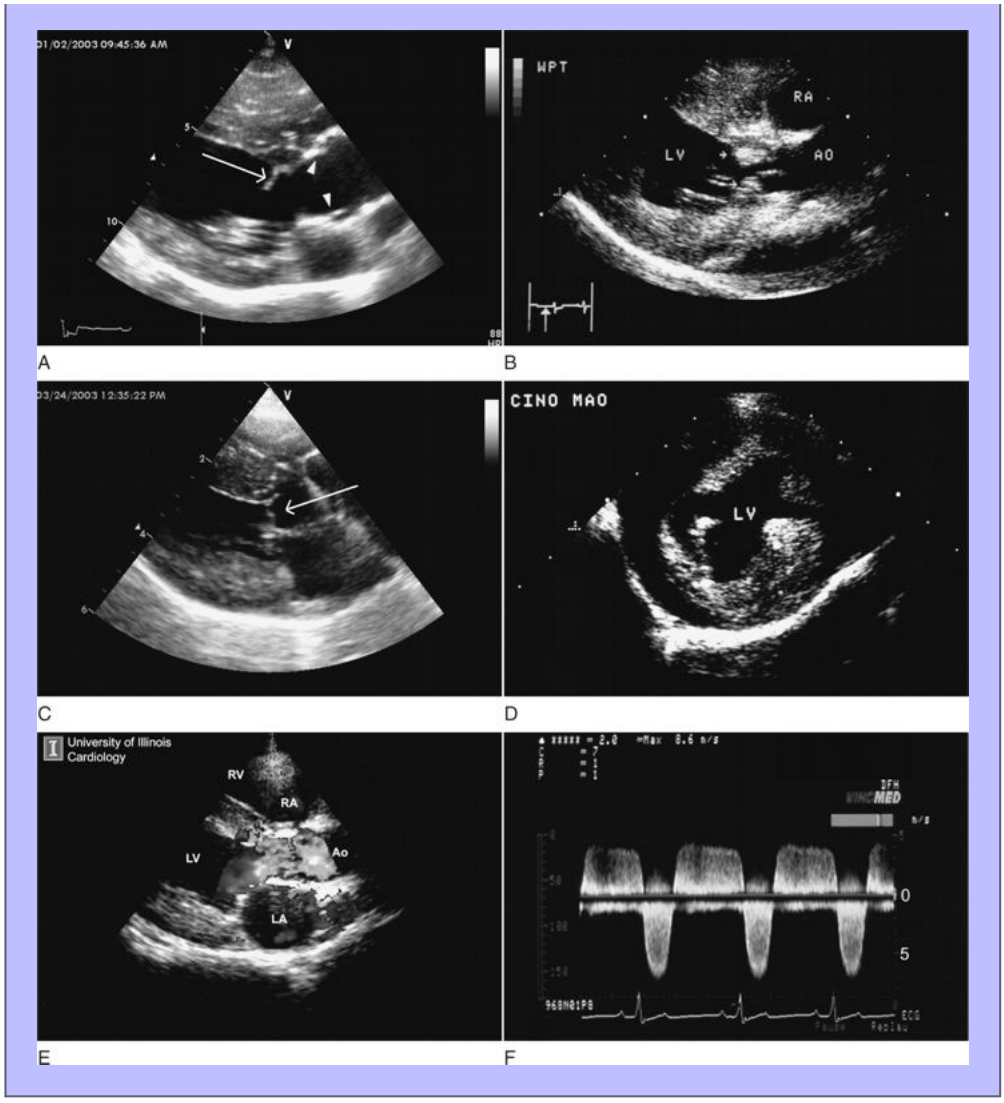
Natural history

Severe SAS is a discouraging condition, because many affected dogs die prematurely. In a retrospective survey of 96 dogs with SAS, 21 died suddenly, most often during the first 3 years of life.[50c] Eleven dogs developed endocarditis or left heart failure and 32 dogs showed evidence of exercise intolerance or syncope. Dogs with minimal ventricular hypertrophy, mild ventricular outflow obstruction, and a maximal Doppler pressure gradient of less than 50 mm Hg are more likely to live normal lives, whereas dogs with pressure gradients in excess of 125 mm Hg are very likely to develop serious complications or to experience sudden death. Complicating factors that contribute to an adverse outcome include: mitral regurgitation, aortic regurgitation, aortic valve endocarditis, and atrial fibrillation.[51c-53c] Sudden death is most likely to occur during or shortly after vigorous activity.

1010

1012

Figure 200-41 Echocardiography of subaortic stenosis (SAS). **A, B,** and **C** are right long axis views showing the various morphologic forms of obstruction in the left ventricular outflow tract in dogs with SAS. **A,** Mild membranous SAS in a 5-year-old rottweiler. A thin, membranous flap of tissue extends from the interventricular septum. No appreciable left ventricular concentric hypertrophy is noted. The open aortic valve leaflets are indicated by the arrowheads. **B,** Severe, tunnel-like SAS in a 4-year-old golden retriever. Two ridges of hyperechoic tissue are present at the base of the aortic valve *(arrows)*. The left ventricle is hypertrophied and has a hyperechoic endocardial surface. **C,** Dynamic SAS in a poodle. Systolic anterior motion of the mitral valve is seen projecting into the left ventricular outflow tract *(arrow)*. The left ventricle shows concentric hypertrophy. The blood flow velocity across the obstruction exceeded 5.5 m/s, indicating a severe degree of pressure overload to the left ventricle. **D,** Right short axis view from a 3-month-old mixed breed dog shows left ventricular concentric hypertrophy and marked hyperechogenicity of the subendocardial tissue and papillary muscles. This finding is thought to represent areas of myocardial ischemia and replacement fibrosis. **E,** Right long axis color flow Doppler study from a dog with SAS shows high-velocity, turbulent blood flow in the left ventricular outflow tract and aorta. **F,** Continuous wave Doppler tracing from the left apical view in a dog with severe SAS shows a peak systolic velocity of 6.5 m/s, indicating a pressure gradient of 169 mm Hg across the obstruction. Aortic insufficiency is also detected.



200.12.1.2.5 Clinical management

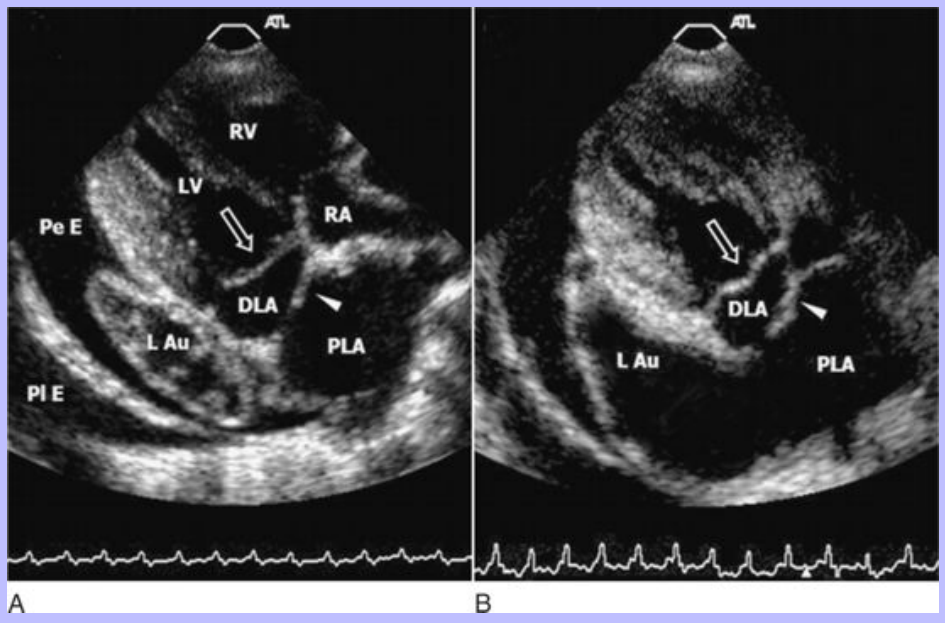
Dogs with mild SAS are not treated other than with administration of prophylactic antibiotics during periods of anticipated bacteremia, such as during dental procedures, surgery, or whenever a concurrent infectious disease is suspected. This practice remains common despite the fact that the efficacy of prophylactic antibiotics for reducing the risk of bacterial endocarditis in dogs with SAS has not been definitively established.[53c] A number of treatment options can be considered for dogs with moderate to severe SAS, but most are of uncertain value. Open resection of the obstructing lesion during cardiopulmonary bypass clearly offers the best opportunity to reduce the systolic pressure gradient substantially and permanently[54c,55c]; however, an otherwise successful procedure does appear to alter the prevalence of sudden death significantly.[55c] Other surgical procedures for dilating or bypassing the obstruction have either failed to achieve sustained reduction of the systolic pressure gradient or have

entailed an unacceptable risk of complications.[56c,57c] Moreover, these remedies are usually limited in their availability and are prohibitively expensive.

Balloon dilatation of SAS has been attempted in dogs as an alternative to surgery. On average, catheter-based balloon dilatation can reduce the severity of SAS obstruction in dogs by 50%.[29b] This benefit is attenuated in some (and perhaps a majority) of dogs over time.[48c] Balloon dilatation of SAS is more challenging than balloon valvuloplasty of pulmonic stenosis. Life-threatening complications of SAS include fatal arrhythmia, the development of aortic valve endocarditis, rupture of the aortic annulus, and avulsion of the brachiocephalic artery during balloon withdrawal. Moreover, the inability of surgical resection to prevent sudden death suggests that effective treatment requires more than reduction of the pressure gradient.

The authors typically recommend avoidance of prolonged, vigorous exercise, recognizing that in young and otherwise healthy dogs, even this conservative recommendation is not always practical. Based on clinical and pathologic evidence of myocardial ischemia, the authors also advise administration of beta-adrenergic receptor blockers to dogs with high gradients or a history of syncope. Beta blockers (e.g., atenolol) reduce the maximal heart rate, decrease myocardial oxygen consumption, and improve diastolic coronary artery flow, thereby exerting a protective effect on the myocardium against ischemia and the development of arrhythmias. Moreover, dogs on high doses of beta blockers seem less willing (or are less able) to indulge in prolonged, vigorous exercise. In theory, treatment with calcium channel blockers or ACE inhibitors may also be of value in dogs with SAS; however, none of the medical strategies have been evaluated in placebo-controlled clinical trials.

Figure 200-42 Long-axis, four-chamber, two-dimensional echocardiograms of a cat with supravalvular mitral stenosis. **A,** Clearly visible membrane *(solid arrow)* is located above the mitral valve *(open arrow)* that partitions the left atrium into proximal (PLA) and distal (DLA) compartments. **B,** Left auricle (LAu) communicates with the proximal left atrial compartment, and the membrane is located distally. This feature distinguishes supraventricular mitral stenosis from cor triatriatum (sinister), in which the partitioning membrane is proximal to the auricle. *RV,* Right ventricle; *RA,* right atrium; *Pe E,* pericardial effusion; *Pl E,* pleural effusion. (Fine DM, Tobias AH, Jacob KA: Supravalvular mitral stenosis in a cat. *J Am Anim Hosp Assoc* 38:403–406, 2002.)



200.12.2 Anomalous Development of the Atria and Cor Triatriatum

Cor triatriatum (sinister and/or dexter) has been reported in both cats and dogs.[33b,69c-72c,156a,158a] With these defects, the atrium is partitioned into an accessory atrial chamber, which receives venous return, and is separated from the true atrium by a perforate membrane. The suffix, *sinister* or *dexter*, is used to indicate whether the left or right atrium is abnormally partitioned; the term *cor triatriatum* alone usually refers to a left-sided lesion. If the partitioning membrane causes obstruction, dilatation of the venous chamber and the entering veins is evident and congestion develops. In contrast to mitral or tricuspid valve stenosis, blood flows through the stenotic orifice during both systole and diastole; however, the functional consequences of these

defects are very similar. From a clinical perspective, supravalvular mitral stenosis (SMS) often closely resembles cor triatriatum (sinister); however, SMS is frequently accompanied by additional mitral valve abnormalities. The primary distinction between SMS and cor triatriatum (sinister) relates to the location of the obstructing membrane. In animals with SMS, the obstructing membrane is located ventral (distal) to the foramen ovale, and the left auricle is functionally part of the proximal chamber and dilates as pressure in this chamber rises (Figure 200-42).[55] In animals with true cor triatriatum (sinister), the obstructing membrane is located dorsal (proximal) to the foramen ovale; the left auricle lies downstream from the obstruction and is not enlarged. If the foramen ovale is closed, there is little difference between these defects. Affected cats typically present with signs of pulmonary congestion, but pulmonary hypertension and right heart failure are also seen.

1012

1013

Cor triatriatum dexter results from persistence of the embryologic right sinus venosus valve.[71c] In dogs with this malformation, the right atrium is partitioned by a diaphragm located caudal to the tricuspid valve and foramen ovale. Affected dogs usually evidence congestion in the caudal half of the body (ascites) but fail to demonstrate jugular distension or an audible murmur. Other clinical findings include prominence of the cutaneous abdominal veins, hepatomegaly, and diarrhea from malabsorption. Dogs with congenital or acquired obstruction of the caudal vena cava (Budd-Chiari syndrome) present with similar clinical findings. In most affected dogs, the electrocardiogram and thoracic radiographs, with the notable exception of caudal vena cava enlargement, are unremarkable. Diagnosis can be accomplished by echocardiography or angiography.[56] Treatment for cor triatriatum generally requires surgical resection or bypass of the obstruction,[57,73c,74c] Balloon dilatation of the obstructing membrane can also be attempted.[58,59]

200.12 LESIONS THAT CAUSE RIGHT-TO-LEFT SHUNTING: CYANOTIC HEART DISEASE

The term *cyanotic congenital heart disease* is used to categorize congenital defects that cause admixture of venous and arterial blood, such as tetralogy of Fallot. Because the pathophysiology and clinical signs of these conditions are similar, they are considered as a group. Only the most important defects are discussed to illustrate the clinical syndrome common to these conditions. The reader is also directed to the previous sections on PDA and VSD, which comment on the complicating conditions promoting right-to-left shunting.

200.13.1 Pathophysiology

200.13.1.1 Mechanisms of Right-to-Left Shunting

For desaturated blood to shunt into the systemic arteries, a defect must exist that allows admixture of unsaturated and saturated blood, as occurs with transposition of the great vessels, or a communicating defect that connects the two sides of the circulation and some mechanism elevating pressures on the right. Reversed shunting has been observed with PDA, aorticopulmonary window, ventricular septal defect, and atrial septal defect. The term *Eisenmenger's syndrome* is invoked to describe circumstances in which increased pulmonary vascular resistance causes reversal of a left-to-right shunt and cyanotic heart disease.[148a-150a] The factors underlying the development Eisenmenger's syndrome are incompletely understood but are most likely related to shear stresses caused by the high flow rates in the pulmonary vasculature and proliferative changes in the vessel wall.[15a,49a,60a,148a,150a] Eisenmenger's syndrome usually develops rapidly in small animals and almost always before 6 months of age.

Intimal thickening, medial hypertrophy, and plexiform lesions of dogs and cats with Eisenmenger's physiology are similar to those of humans as described by Edwards and Heath and amended by Roberts.[15]

These plexiform lesions are considered irreversible; consequently, neither medical therapy nor closure of the shunt effectively improves the condition once these changes have developed. In fact, surgical closure of the shunt pathway forces the right ventricle to work solely against a tremendous resistance, resulting in right ventricular failure, circulatory collapse, and death.

200.13.1.2 Effects of Hypoxemia

Systemic response to arterial hypoxemia includes an increase in red blood cell mass in an attempt to improve systemic oxygen transport. Hypoxia of the renal tissue incites erythropoietin release and induces secondary polycythemia. When the PCV exceeds 65% to 68%, the high viscosity of the blood predisposes the patient to thrombosis and microvascular complications.[15a,148a] This hyperviscosity syndrome is the primary cause of morbidity and mortality in affected animals. Clinical manifestations include weakness, hemostatic deficiencies, renal dysfunction, metabolic acidosis, iron deficiency, cerebrovascular events, syncope, and seizures.[59a,60,137a,139a]

200.13.1.3 Ratio of Systemic to Pulmonary Resistance

The magnitude of right-to-left shunting fluctuates with the relative resistances of the systemic and pulmonary circulations. Exercise promotes systemic arteriolar vasodilatation and decreases systemic resistance, thereby increasing the magnitude of right-to-left shunting. In cases of right ventricular hypertrophy and VSD, tachycardia or elevated sympathetic tone can increase the magnitude of right-to-left shunting by exacerbating dynamic infundibular obstruction and increasing resistance to right ventricular ejection.[60] Beta-adrenergic blocking drugs are sometimes used to blunt or prevent this phenomenon, particularly in patients with tetralogy of Fallot.[139a,140a] Beta blockers also tend to limit exercise, offering another explanation for their efficacy in some patients. Anemia, absolute or relative, reduces the ratio of systemic to pulmonary resistance when pulmonary resistance is fixed.[138a] By this mechanism, overzealous phlebotomy can increase the severity of arterial hypoxemia as it decreases the oxygen-carrying capacity of blood.

200.13.1.4 Additional Circulatory Factors

Right-to-left shunting leads to compensatory increases in nutritive blood flow to the lung via the bronchial arteries. These systemic collateral vessels are easily recognized at angiography. Although the phenomenon is uncommon, these vessels can rupture, leading to hemoptysis. Paradoxical embolization is another potential complication of right-to-left shunting defects. Normally, the pulmonary vasculature filters systemic venous emboli before they can reach the left side of the circulation. With reversed shunting, the possibility of a venous embolus reaching the coronary, cerebral, or other systemic arteries must be considered, particularly when intravenous catheters are used. By this mechanism, a thrombus, infectious agents, or air may gain access to vital systemic organs. Animals with cyanotic heart disease sometimes experience adverse reactions (particularly bradycardia) to sedatives and tranquilizers.

200.13.2 Clinical Evaluation of the Patient with Cyanotic Heart Disease

Common causes of cyanotic heart disease in companion animals include septal defects in association with tricuspid valve disease (ASD + TVD) or pulmonic stenosis (ASD or VSD + PS); and patent ductus arteriosus or septal defects complicated by pulmonary hypertension (PHT + ASD or VSD or PDA). Presenting signs

include failure to grow, shortness of breath, exertional fatigue, weakness, syncope, and seizures. Affected animals evidence dyspnea when stressed. Systemic hypoxemia is best confirmed by measurement of the oxygen content of an arterial blood sample obtained while the animal breathes room air. It is important to realize that providing 100% oxygen does not significantly improve the hypoxemia caused by right-to-left shunting.[61] Administration of 100% oxygen raises the concentration of dissolved oxygen but does not substantially raise the amount of oxygen bound to hemoglobin, which represents the primary reservoir of oxygen in the blood. Animals with cyanotic heart disease are usually polycythemic. This phenomenon is most obvious when the hemoglobin concentration of young animals with cyanotic heart disease is compared to age-matched normal animals.[128a]

1013

1014

Clinically detectable peripheral cyanosis of the mucous membranes or skin occurs when the amount of reduced (unoxygenated) hemoglobin is greater than 3 g/dL. If this condition is suspected, the mucous membranes of both the cranial and caudal portions of the patient should be examined and compared, preferably both before and after exercise. A finding of cyanosis limited to the caudal tissues is known as *differential cyanosis* and suggests the presence of a right-to-left shunting PDA.

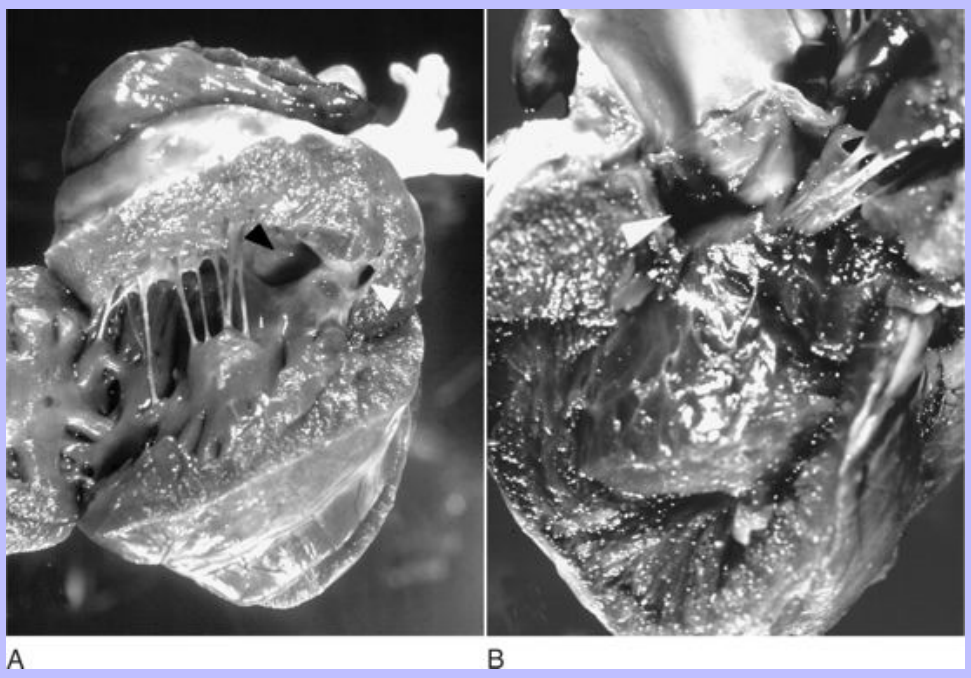
Cardiac auscultation of cyanotic patients varies in accordance with the underlying defects. Dogs and cats with tetralogy of Fallot usually evidence the typical systolic murmur of pulmonic stenosis. In contrast, most animals with Eisenmenger's physiology lack a prominent murmur but often display a loud or split second heart sound due to pulmonary hypertension and asynchronous semilunar valve closure.[8a,9a,128a] On occasion, an ejection sound with a soft, short, systolic murmur may be evident at the left heart base.

Cyanotic heart disease, with rare exceptions (i.e., tricuspid atresia and anomalous systemic venous return), is characterized by right ventricular hypertrophy, which is usually evident on ECG recordings, thoracic radiographs, and echocardiograms. As a general rule, the pulmonary arteries and veins are diminished in size and the lungs appear underperfused (hyperlucent) on survey chest films.[24a] The main pulmonary artery and proximal lobar arteries are usually visibly dilated when Eisenmenger's syndrome is the basis for reversed shunting, but these structures are not enlarged with pulmonary or tricuspid atresia. In dogs with classic tetralogy of Fallot with a muscular infundibular obstruction, the pulmonary artery is hypoplastic, and poststenotic dilatation of the main pulmonary artery is not prominent on the dorsoventral radiograph. Dogs and cats with valvular pulmonic stenosis and a restrictive VSD demonstrate more prominent enlargement of the pulmonary artery segment and proximal lobar arteries. These seemingly trivial distinctions often become important when surgical repair is contemplated.

200.13.2.1 Echocardiography

The echocardiogram is particularly helpful in the assessment of the cyanotic patient, because most defects can be easily visualized. Careful evaluation of the right ventricular inflow and outflow tracts usually reveals the site of shunting, and the direction of blood flow can be easily ascertained by Doppler or contrast imaging.[3] Detailed ultrasound studies often render cardiac catheterization unnecessary unless surgery is contemplated and pulmonary hypertension (as opposed to pulmonic stenosis) cannot be otherwise ruled out. The pulmonary vascular and right ventricular pressures can often be estimated noninvasively by measuring the peak velocity of even a small jet of pulmonic or tricuspid valve insufficiency and applying the Bernoulli equation (see Cardiac Imaging). Echocardiographic contrast agents can be used to amplify weak signals from small jets, permitting more accurate assessment of jet peak velocity and cardiac pressures.

Figure 200-43 Gross pathology of tetralogy of Fallot. **A,** Right-sided view of a dog with tetralogy of Fallot shows concentric hypertrophy of the right ventricular wall, a markedly narrowed and hypoplastic right ventricular outflow tract *(white arrowhead),* and a large ventricular septal defect (VSD) *(black arrowhead)*. **B,** Left-sided view of a large, nonresistive VSD *(white arrowhead)* in a patient with tetralogy of Fallot. Note the proximity to the root of the aorta and the possibility for prolapse of an aortic valve leaflet into the VSD.



200.13.2.2 Cardiac Catheterization

Cardiac catheterization and angiocardiography are advisable whenever uncommon or complex defects are suspected or when surgical repair is contemplated. In addition to showing the location and severity of the shunt, angiography outlines the anatomy of the defect (e.g., pulmonic, tricuspid dysplasia) and permits visualization of the pulmonary vasculature. Direct measurements of intravascular pressure are useful for assessing the severity of pulmonary hypertension and for confirming the presence of unusual or easily overlooked defects, such as tricuspid valve stenosis. The measurement of pulmonary artery pressure is essential when cardiac or vascular surgery is contemplated for a patient with cyanotic heart disease. If pulmonary vascular resistance is normal, pulmonary flow can be augmented and systemic hypoxemia improved by the creation of an artificial left-to-right shunt between a systemic and a pulmonary artery distal to the site of the cyanotic defect (e.g., Blalock-Taussig shunt).[61,128a,136a,141a]

200.13.3 Tetralogy of Fallot

The defining anatomic features of tetralogy of Fallot include right ventricular outflow obstruction (pulmonic stenosis), secondary right ventricular hypertrophy, a subaortic ventricular septal defect, and a rightward-positioned aorta (Figure 200-43). Pulmonic stenosis that occurs in combination with an isolated VSD produces similar findings, but the infundibular septum is not malaligned, the aorta is normal in size, and the infundibulum of the right ventricle is not narrowed.[75c] These distinctions are commonly ignored in veterinary patients because corrective surgery is rarely performed.

1014 1015

200.13.3.1 Pathogenesis

Tetralogy of Fallot has been extensively studied in keeshond breeding colonies, and a spectrum of lesions ranging from the subclinical to the clinically complicated has been identified.[31b,124a,127a] Patterson et al.[124a] graded the conotruncal defects as follows:

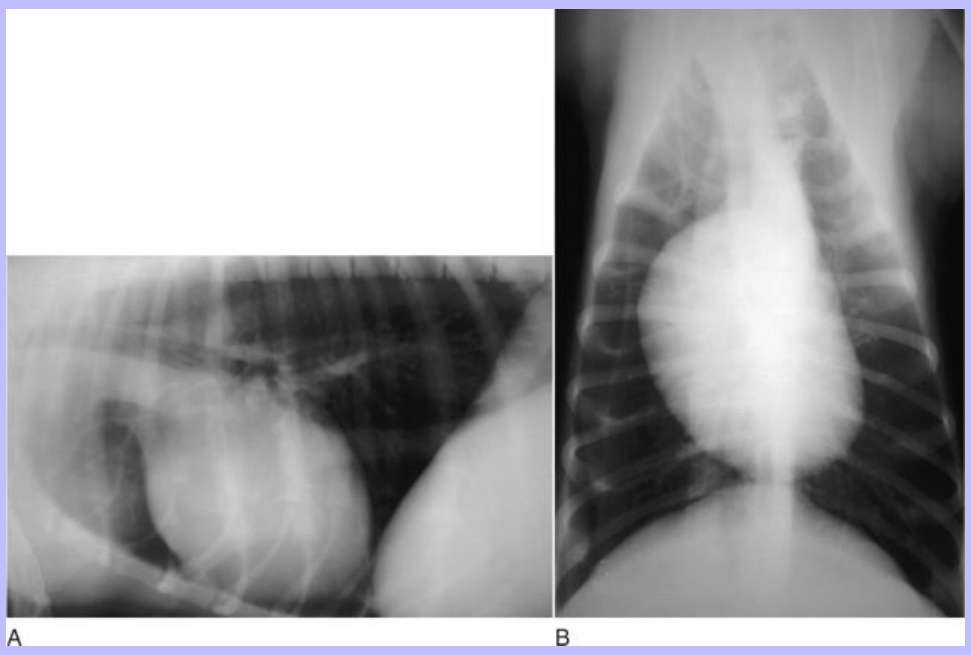
- *Grade 1:* Subclinical malformations involving persistence of the conus septum fusion line, aneurysm of the ventricular septum, and absence of the papillary muscle of the conus.
- *Grade 2:* Pulmonic stenosis or ventricular septal defect in addition to the grade 1 lesions.
- *Grade 3:* Tetralogy of Fallot—pulmonic stenosis, ventricular septal defect, and dextropositioned aorta (with secondary right ventricular hypertrophy.

Additional abnormalities found in some dogs included a dilated and tortuous ascending aorta, pulmonary atresia, hypoplasia of the supraventricular crest, and anomalies of the aortic arch system. Based on extensive breeding studies and sophisticated genetic analysis, conotruncal defects have been shown to be an inherited autosomal recessive trait with variable expression.[76c]

200.13.3.2 Pathophysiology

The essential components of tetralogy of Fallot are severe right ventricular outflow tract obstruction and a ventricular septal defect. As a result of the outflow obstruction and elevated right ventricular pressure, desaturated blood shunts from the right heart through the septal defect to mix with oxygenated blood coming from the left ventricle.[122a-123a] Pulmonary arterial blood flow and pulmonary venous return are scant, and the left atrium and left ventricle are small (underdeveloped). The addition of unoxygenated blood from the right ventricle to the systemic side of the circulation causes arterial hypoxemia, decreased hemoglobin oxygen saturation, cyanosis, and secondary polycythemia. Systemic collateral circulation to the lung increases via the bronchial arterial system. These vessels supply blood to the capillaries of the pulmonary parenchyma either directly or via anastomosing connections with a larger pulmonary artery. A substantial portion of this blood can participate in pulmonary gas exchange. Other aspects of clinical pathophysiology have been previously described (see Clinical Evaluation of the Patient with Cyanotic Heart Disease, above).

Figure 200-44 Lateral **(A)** and dorsoventral **(B)** radiographs of a dog with tetralogy of Fallot. Right heart enlargement is suggested by the rounding of the sternal border on the lateral view and the reverse D appearance on the dorsoventral view. The main pulmonary artery and peripheral pulmonary vessels are diminished. The appearance of the heart on the dorsoventral view is classically described as "boot shaped" *(coeur en sabot)* but is often difficult to reconcile.



200.13.3.3 Clinical Findings

Tetralogy of Fallot is common in the keeshond and English bulldog and in some families of other breeds.[30] It has also been recognized in the cat.[9a] Presenting complaints and clinical signs are as previously described for cyanotic heart disease. In most cases, the murmur of tetralogy of Fallot is produced by blood flowing through the stenotic pulmonic valve.[75c] A right-sided murmur, resulting from blood flow through the VSD, may predominate when PS is mild and left-to-right shunting occurs across a restrictive VSD (i.e., an acyanotic defect). The absence of an obvious murmur suggests pulmonary atresia and/or polycythemia with hyperviscosity (which reduces blood flow turbulence) and ejection across a large, nonrestrictive VSD. Exercise or excitement may induce or enhance detection of peripheral cyanosis by accentuating right-to-left shunting by mechanisms previously described.

Radiography usually reveals a small or normal-sized heart with rounding of the right ventricular border (Figure 200-44). The main pulmonary artery is not always visibly enlarged, in contrast to the usual case of

pulmonic stenosis with intact ventricular septum. The pulmonary vasculature is diminished, and the left auricle may be inconspicuous as a consequence of decreased venous return. The ECG typically exhibits criteria for right heart enlargement, including right axis deviation, although left or cranially directed vectors may be found in some cats.[129a] Echocardiographic findings include right ventricular hypertrophy, increased right ventricular chamber dimensions, reduced left atrial (LA) and LV dimensions, a large subaortic VSD, and right ventricular outflow obstruction (Figure 200-45). Doppler or contrast studies can be used to document right-to-left shunting at the ventricular outflow level (Figure 200-46).[3,130a]

Figure 200-45 Echocardiography of tetralogy of Fallot in a keeshond puppy. **A,** Right long axis view shows severe right ventricular (RV) concentric hypertrophy and right atrial enlargement. **B,** Right short axis view shows severe RV concentric hypertrophy, flattening of the interventricular septum, a small, underloaded left ventricle (LV), and hyperechogenicity of the RV subendocardium. **C,** M-mode study shows enlargement of the RV compared with the LV. The tricuspid and mitral valves are seen moving in the center of their respective ventricles. Paradoxical septal motion toward the RV during systole appears to occur. **D,** Right long axis view shows the ventricular septal defect (VSD) and rightward (dextropositioned) displacement of the aortic root and aorta (Ao). **E,** Color flow Doppler study of an image similar to that in **D** shows right-to-left shunting of blood from the right ventricle, across the VSD, and into the aorta. **F,** Continuous wave Doppler study from the left heart base across the pulmonic valve indicates the presence of high-velocity blood flow and pulmonic stenosis.

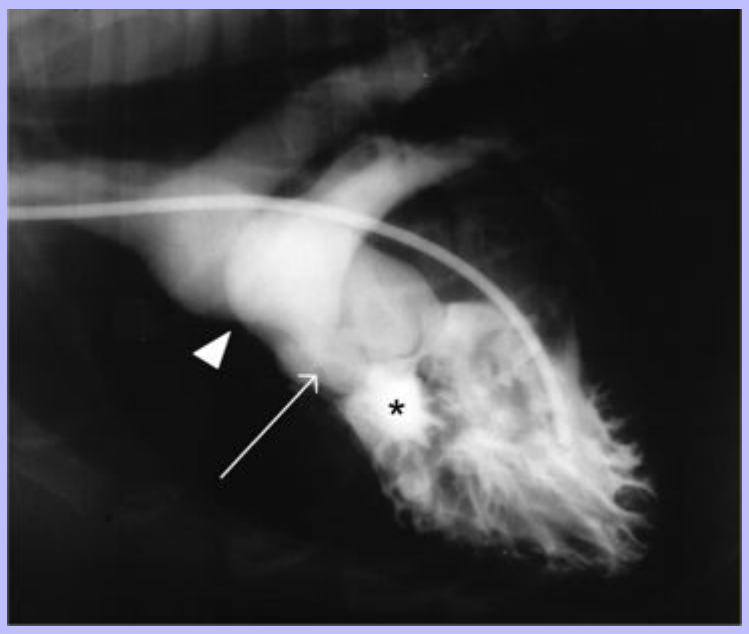
Figure 200-46 Angiogram from a keeshond with tetralogy of Fallot. The right ventricular injection opacifies the right ventricle, pulmonary artery, and aorta. Contrast can be seen in the region of the suspected ventral septal defect (*). The contrast column narrows in the right ventricular outflow tract and the region of the pulmonic valve (*arrow*). A large, poststenotic dilatation of the main pulmonary artery (*arrowhead*) is present. A wide, rightward-positioned aorta can be appreciated.



Cardiac catheterization demonstrates equilibration of left and right ventricular systolic pressures, compatible with a large, nonrestrictive VSD.[128a] Oximetry samples reveal a step-down at the left ventricular outflow level, and the aortic blood is relatively desaturated. Angiocardiography reveals right ventricular hypertrophy, narrowing of the right ventricular infundibulum, pulmonic stenosis with minimal poststenotic dilatation, varying degrees of pulmonary artery hypoplasia, a large subaortic VSD, a small, dorsally displaced left ventricle, an enlarged and rightward-positioned aorta, and prominent bronchial circulation (Figure 200-46).[124a,128a] Bidirectional shunting across the VSD is common in anesthetized animals. Anticoagulation therapy (e.g., heparin) should be considered to prevent cerebral embolization during and immediately after cardiac catheterization.

200.13.3.4 Clinical Management

The natural history and survival times of dogs and cats with tetralogy of Fallot are not well characterized. Like other cyanotic heart diseases, tetralogy of Fallot can be tolerated for years if pulmonary blood flow is

maintained and hyperviscosity is controlled.[21] Most affected animals have severely limited exercise capacity. In cases of pulmonary atresia, pulmonary blood flow must be derived from a patent ductus arteriosus, the bronchial artery, or an elaborate network of systemic collaterals. Sudden death is common due to the combined consequences of hypoxia, hyperviscosity, or cardiac arrhythmia. Unlike with pulmonic stenosis with intact ventricular septum, congestive heart failure is an unusual outcome.

Options for treating animals with tetralogy of Fallot include medical and surgical approaches. Definitive correction of the defect (i.e., closure of the VSD and removal or bypass of the stenosis) can be done under cardiopulmonary bypass, but such surgery is rarely performed in animals.[62,77c] As a general rule, the stenosis should not be relieved if the VSD cannot be closed because the loss of right ventricular pressure results in marked left-to-right shunting with subsequent left-sided congestive heart failure.[63,128a] As an alternative to definitive correction, surgical palliation through the creation of a systemic to pulmonary shunt can be quite rewarding.[64,78c,128a,141a] Subclavian to pulmonary artery (Blalock-Taussig), ascending aorta to pulmonary artery (Potts), and aorta to right pulmonary artery (Waterston-Cooley) connections have been made in dogs and cats. Creation of a left-to-right shunt distal to the cyanotic defect increases pulmonary perfusion and allows a greater contribution of oxygenated blood to the systemic circulation. The size of the accessory shunt must be controlled to prevent overloading of the diminutive left ventricle and subsequent pulmonary edema. The extent to which these shunts remain patent over long periods in veterinary patients has not been reported.

Periodic phlebotomy, performed to maintain the PCV between 62% and 68%, produces a satisfactory result in many cases.[21] Excessive bleeding should be avoided, and the blood that is withdrawn is replaced with crystalloid fluids to maintain cardiac output and tissue oxygen delivery.[138a] Some children with tetralogy of Fallot benefit from beta blockade with propranolol; however, controlled studies of the clinical efficacy of this treatment in animals are lacking.[139a,140a] Severe hypoxic spells should be treated with cage rest, oxygen, and sodium bicarbonate (if metabolic acidosis is evident). Treatment with vasoconstrictive agents such as phenylephrine can also help reduce the amount of right-to-left shunting. Drugs with marked systemic vasodilating properties should be avoided.

200.13.4 Other Causes of Cyanotic Congenital Heart Disease

200.13.4.1 Valvular Atresia

Pulmonary atresia with a ventricular septal defect is essentially an exaggerated form of tetralogy of Fallot (Figure 200-47). All the blood ejected from the right heart is shunted right-to-left across a large VSD and into an enlarged aorta. The tricuspid valve is usually normal. The term *pseudotruncus arteriosus* has been used to describe this defect, which differs from a true truncus arteriosus because careful dissection reveals an imperforate pulmonic valve and a vestigial cord representing the main pulmonary trunk. On occasion, both the pulmonic and tricuspid valves are atretic (see Figure 200-47). The right ventricle is small or hypoplastic, and blood returning to the right atrium shunts through a patent foramen ovale or ASD to produce cyanosis. The lungs are supplied via a PDA or an extensive bronchoesophageal collateral circulation.

Aortic atresia with a hypoplastic left heart is a rare form of cyanotic heart disease in dogs. The aortic orifice is often imperforate, the ascending aorta is hypoplastic, and the mitral valve is usually atretic or hypoplastic. In the absence of a VSD, the left ventricle is very small; when a VSD is present, the left

ventricle is better developed. The right heart supplies the entire pulmonary and systemic circulations, resulting in profound cyanosis and, in most cases, early death.

200.13.4.1.1 Double outlet right ventricle

Double outlet right ventricle (DORV), in which both great vessels exit from the right ventricle, has been reported in dogs and cats (Figure 200-48).[146a,147a] A VSD provides the left ventricle with an avenue for outflow into the great vessels. Depending on the location of the VSD in relation to the origin of the great vessels, DORV can manifest as either pulmonary overcirculation or cyanosis. Concurrent abnormalities such as pulmonic stenosis, pulmonary hypertension, and coarctation of the aorta can also affect the development of clinical signs. Cyanosis is likely if the VSD lies under the pulmonary artery. Surgical correction of this condition in dogs has been reported.[31]

1017

1018

Figure 200-47 **A,** Specimen from a cat with tetralogy of Fallot and pulmonary artery atresia (pseudotruncus arteriosus). The left ventricle has been opened to expose the large ventricular septal defect *(white arrow)*, the hypoplastic pulmonary artery *(small arrow)*, and the dilated aorta *(Ao)*. Pulmonary flow was through the ductus arteriosus, the origin and termination of which are shown by arrowheads. Although the lobar pulmonary arteries were patent, almost no blood was found in the main pulmonary artery. **B,** Specimen from a dog that exhibited severe cyanosis from birth. The proximal aorta is hypoplastic, and an aortic opening (valve) could not be identified. A huge pulmonary artery gives origin to the right and left pulmonary branches, and a large patent ductal segment connects to the aortic arch, supplying the brachiocephalic vessels, the descending aorta, and the hypoplastic aorta. **C,** Same dog as in **B**. Note the marked hypertrophy of the opened right ventricle, as well as the ventricular septal defect, which received blood from the underdeveloped left heart.

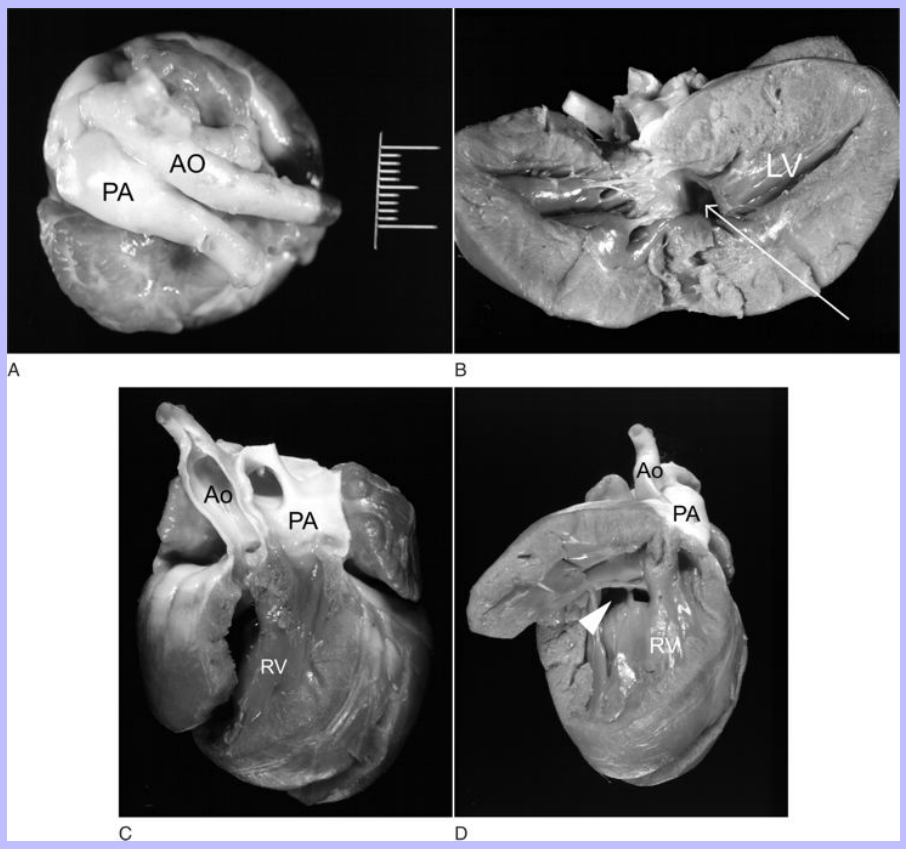
200.13.4.1.2 Transposition of the great arteries

In D-transposition of the great arteries, the aorta originates from the right ventricle and the pulmonary trunk from the left ventricle.[15a,145a] In the pure and fatal case, two independent circulations exist, and the systemic arteries never receive oxygenated blood. Survival of an animal with D-transposition depends on the presence (or production) of shunts between the two circulations to allow for mixing of blood to prevent fatal hypoxemia. These defects are complex, generally lethal, and most likely underdiagnosed in animals, relative to children, because most animals probably die at a very young age undiagnosed.

200.13.4.2 Miscellaneous Cardiac Defects

The potential for anatomic and physiologic variants of congenital heart disease is tremendous, and it is beyond the scope of this chapter to discuss the entire spectrum of malformations. The following descriptions summarize clinically relevant aspects of rarely encountered cardiac and pericardial defects.

Figure 200-48 Pathology of a double outlet right ventricle (DORV) in a 6-month-old domestic shorthair cat. **A,** Dorsal view of the heart showing the side-by-side positioning of the aorta *(Ao)* and pulmonary artery *(PA)* at the cranial right edge of the heart. **B,** View of the ventricular septal defect *(arrow)* from the left ventricular *(LV)* side. Note the absence of a left ventricular outflow tract and aorta originating from the LV and the discontinuity between the mitral valve apparatus and the missing aorta. **C,** View from the right cranial aspect showing the origin of the aorta and pulmonary artery from the right ventricle. The opening of the VSD into the right ventricle is below the crista supraventricularis and is not easily seen in this view. **D,** View of the right side of the interventricular septum reveals the location of the VSD *(arrowhead)* near the origin of the aorta (aortic-committed DORV) (Courtesy Dr. Richard Kienle, Gilroy, CA.)



Endocardial fibroelastosis has been reported in dogs[65,151a,154a,155a] and cats and is probably familial in some lines of Burmese and Siamese cats.[12a,79c,151a-153a] The gross anatomic findings include left ventricular and left atrial dilatation with severe endocardial thickening, characterized grossly by diffuse, white, opaque thickening of the luminal surface (Figure 200-49). Histologic lesions in the cat include diffuse hypocellular, fibroelastic thickening of the endocardium with layering of thin, randomly organized collagen and elastic fibers.[151a,153a] Edema of the endocardium with dilatation of lymphatics is prominent, and there is no evidence of myocardial inflammation or necrosis. The clinical features of endocardial fibroelastosis include early development of left or biventricular failure, generally before 6 months of age. Mitral regurgitation may be detected. Left ventricular and atrial dilatation are evident on radiographs and on the ECG. The limited echocardiographic studies performed to date suggest reduction of left ventricular myocardial function as opposed to pure valvular disease in which shortening fraction tends to be normal or increased.[155a] The diagnosis of primary endocardial fibroelastosis is at times tenuous, inasmuch as chronic left ventricular dilatation may lead to similar changes, particularly in the setting of mitral dysplasia, aortic stenosis, restrictive and dilated cardiomyopathy, or myocarditis. Dogs with endocardial fibroelastosis often have thickening of the mitral valve leaflets and mitral regurgitation.[154a,155a] Affected animals fail to thrive. Medical treatment of congestive heart failure may be effective in prolonging life, but recovery is unlikely.

1019

1020

Figure 200-49 Gross pathology of a cat with endomyocardial fibrosis. Cutaway views of the left ventricular inflow tract **(A)** and the left ventricular outflow tract **(B)** show diffuse fibrosis of the endomyocardial surface of both the atrium and ventricle.

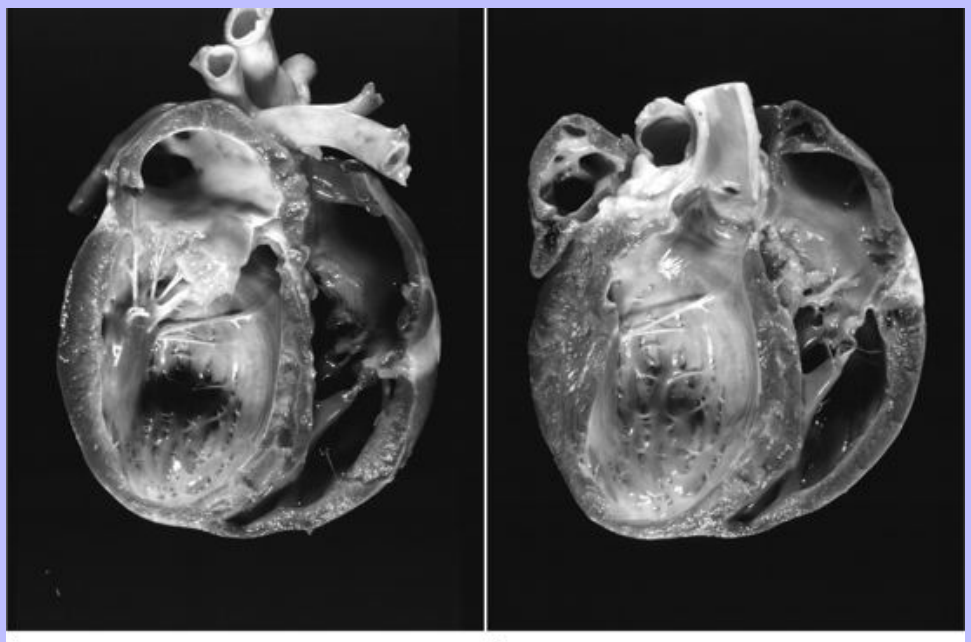


Figure 200-50 Gross pathology from a dog with persistent right aortic arch, patent ductus arteriosus *(D),* anomalous origin of the left subclavian artery *(LSC),* and persistent left cranial vena cava *(PLCVC)*. The left-sided view of the heart, great vessels, and esophagus *(Eso)* shows the entrapment and cranial dilatation of the esophagus by the patent ductus arteriosus. The origin of the left subclavian artery is moved distal from its usual location and is behind the esophagus. The persistent left cranial vena cava can be seen extending laterally alongside the esophagus and left heart base and coursing around the caudal waist of the heart.

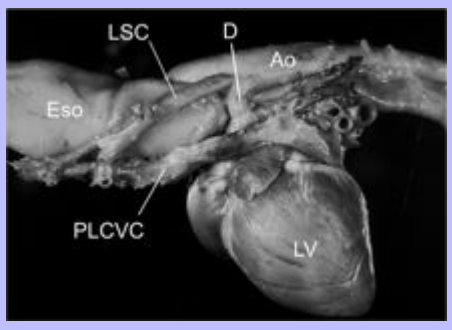

Peritoneal-pericardial diaphragmatic hernia (*PPDH*) is a relatively common developmental anomaly of dogs and cats.[163a,170a] This condition is not a true cardiac anomaly, but it can be confused with other congenital and acquired conditions. For further information, the reader is referred to Chapter 205.

200.13.4.3 Vascular Anomalies

Vascular anomalies can be classified based on their location in the vascular system. A number of vascular malformations have been reported.[49a,50a,66–68,171a-196a] Patent ductus arteriosus, discussed previously, is the most important of the vascular malformations. Peripheral vascular disorders, including abnormal abdominal and hepatic venous drainage and arteriovenous fistulas,[37b] are detailed in their respective chapters. Unilateral atresia of a pulmonary artery has been described in a cat with respiratory difficulty.[185a] Coronary arteries can develop anomalously but rarely cause documented clinical disease except when associated with pulmonic stenosis.[33] Other major vascular defects center about the aorta and the systemic venous drainage, and the salient features of these disorders are briefly addressed.

200.13.4.4 Aortic Anomalies

Persistence of the right aortic arch, as opposed to the left fourth aortic arch, causes regurgitation in weanlings due to constriction of the esophagus.[49a,50a,171a-183a] Vascular ring anomalies include this

common malformation and other total or partial ring anomalies, such as those formed by retroesophageal subclavian arteries, double aortic arch, or left aortic arch with right-sided ligamentum arteriosum.[177a,179a,180a,184a] The condition is quite common in German shepherds and has been recognized in many other canine breeds, including Irish setters and Great Danes. The condition is uncommon in cats. Occasionally, other cardiac defects are present, including PDA (Figure 200-50 and Figure 200-51). This condition is described more fully in Chapter 208.

Aorticopulmonary septal defect (window) is caused by failure of the truncus arteriosus to differentiate; this results in a common opening between the aorta and the pulmonary artery, and shunting develops between the left and right sides of the circulation. Although a clinical condition similar to PDA can develop, some reports suggest that in most cases, pulmonary hypertension develops during the first year of life and that clinical signs are similar to those in dogs that develop Eisenmenger's syndrome due to other defects.[68,188a,191a] Management is similar to that for a reversed PDA. Surgery is difficult without cardiopulmonary bypass and should not be attempted if pulmonary vascular resistance is markedly elevated.

1020

1021

Figure 200-51 Surgeon's view of a persistent left cranial vena cava. This venous anomaly is often encountered during the approach to a patent ductus arteriosus. No hemodynamic consequences result from this anomaly.

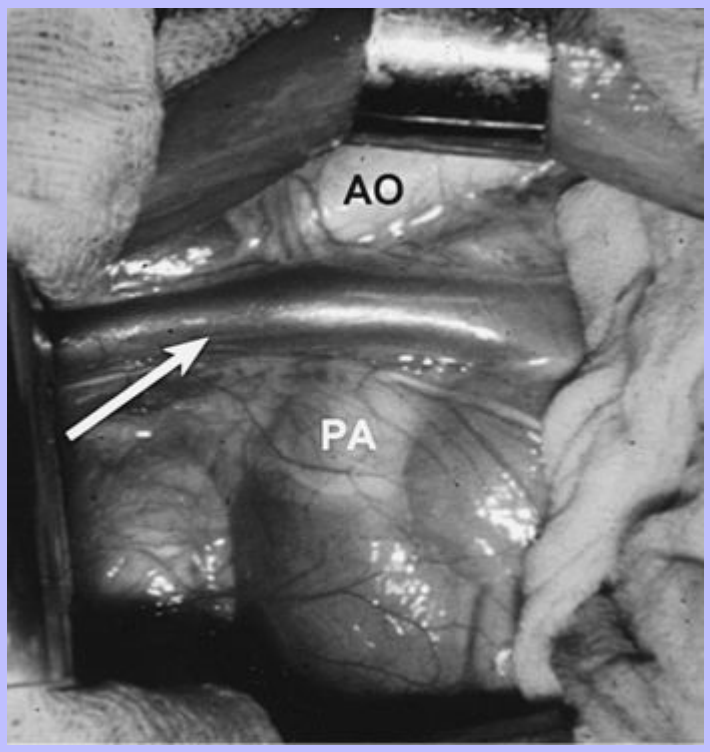

Figure 200-52 Persistent left cranial vena cava in a dog. Contrast was injected simultaneously into the right and left jugular veins. The normal right cranial vena cava is evident (*R*), as is the persistent left vena cava (*L*). Note that the left vena cava enters the caudal portion of the right atrium and empties into the coronary sinus.

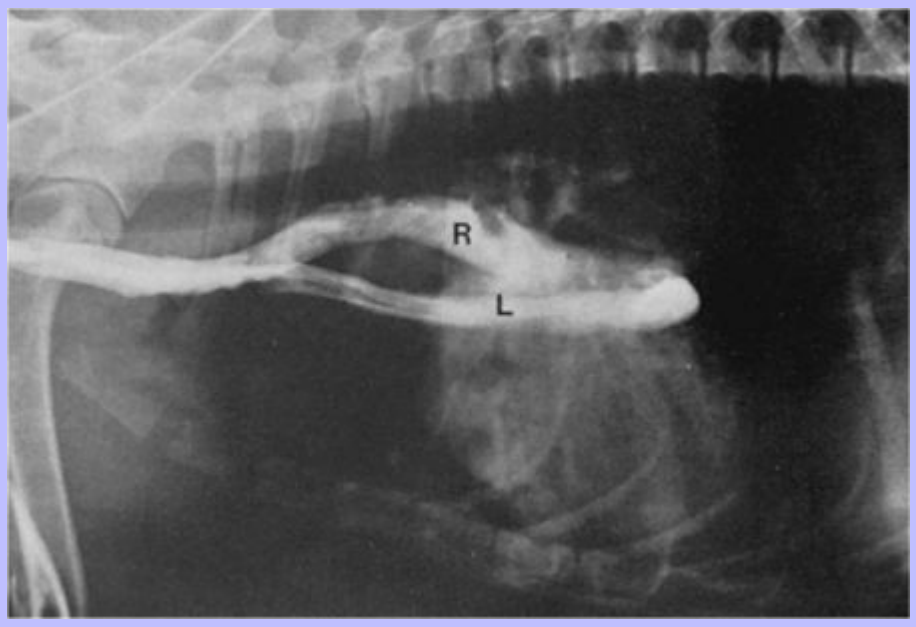

Coarctation and interruption of the aorta is a rare defect in dogs that is characterized by narrowing of the aorta distal to the subclavian artery, adjacent to the ductus arteriosus. A case reported by Eyster[193a] demonstrated systolic and diastolic murmurs and left ventricular failure. The clinical features of coarctation in children are well described and in many ways are similar to this case.[15a] Aortic interruption has been reported in two dogs,[80c,193a] and a case of tubular hypoplasia of the ascending aorta in a dog has also been described.[194a] Although these lesions differ from coarctation, they are additional examples of malformation of the aorta in small animals. Definitive diagnosis usually requires angiography, although MRI and CT are effective methods of evaluating lesions of the aortic arch. Surgical correction has been successful in affected dogs.

200.13.4.5 Venous Anomalies

Thoracic venous anomalies rarely cause cardiac problems in small animals. Total or partial anomalous pulmonary venous return, which has been reported in a dog, behaves functionally as a left-to-right shunt at the atrial level.[80a] Abnormalities of abdominal venous drainage, such as patent ductus venosus, can induce hepatic encephalopathy. A relatively common venous abnormality of clinical significance during thoracic

surgery or cardiac catheterization is the persistent left cranial vena cava.[69,81c,195a] This structure, normally present in the fetus as part of the left cardinal venous system, may persist and drain into the embryologically related coronary sinus in the caudal aspect of the right atrium. Persistent left cranial vena cava may interfere with surgical exposure, particularly during surgical treatment of persistent right fourth aortic arch, or may confound cardiac catheterization, but otherwise it is of no known functional significance. As with persistence of the right fourth aortic arch, this vascular anomaly is common in German shepherds and has been reported in other canine breeds and in cats.[133a,195a] Division of this vessel generally poses no clinical problem provided the normal right cranial vena cava is also present. Venous aneurysms or related anomalies are extremely rare.[38b]

201 CHAPTER • 201 Acquired Valvular Heart Disease

Jens Häggström

Clarence Kvart

Henrik D. Pedersen

201.1 CHRONIC MITRAL VALVE INSUFFICIENCY

Chronic mitral valve insufficiency (CMVI) in dogs is usually caused by a progressive myxomatous degeneration of the atrio-ventricular valves. The disease has been given many names in the veterinary literature, including endocardiosis and chronic valvular disease. Similar changes of the mitral valve are also seen in humans, horses, and pigs.[1–3]

201.1.1 Occurrence

CMVI is common in the dog and has been estimated to account for 75% to 80% of canine cardiac diseases.[4–7] The prevalence of CMVI is strongly age dependent: from only a few percent in young dogs to approximately 75% in dogs older than 16 years.[4,5,7,8] CMVI is encountered in all breeds, but the prevalence of the disease varies greatly: dogs of small-to medium-size breeds, such as the Papillon, Poodle, Chihuahua, Dachshund, and Cavalier King Charles spaniel, are most commonly affected.[9–12] The prevalence of CMVI in cats without primary myocardial disease is unknown but seems to be low.

201.1.2 Significance and Progression

CMVI is characterized by slow progression. Risk factors for progression of CMVI from mild to severe in small dogs include severity of valve lesion, age, and gender.[13–17] The disease progresses into moderate and severe CMVI at a lower age in males than in females.[13,14,18,19] Whether or not these risk factors apply in large dogs is unknown. Typically, it takes several years for the disease to evolve from mild, clinically silent CMVI to severe disease with signs of heart failure.[14,15,19] Many affected dogs will therefore not develop clinical signs from the disease during their lifetime. The most severely affected dogs, however, will end up needing therapy for heart failure, and, in the end, die or be euthanized due to refractory cardiac failure (Figure 201-1). CMVI has been reported to account for 75% of the cases of congestive heart failure in dogs[7,20], a proportion which is considerably higher in affected breeds.[10,13,21] Furthermore, the presence of CMVI and ongoing medical treatment for heart failure may complicate medical treatment for other conditons and decisions for surgical procedures or anesthesia.

201.1.3 Pathology

Macroscopic appearance of myxomatous degeneration depends on at which stage of disease the valve is examined. Macroscopic findings in cases of mild myxomatous degeneration may not be apparent and may be overlooked, especially in dogs without evidence of valvular insufficiency. Common findings at early stages include elongated chordae tendineae and enlarged, thickened leaflets with areas showing

bulging/ballooning/prolapse towards the atrial side (Figure 201-2, *A*).[6,22,23] The changes begin in the area of apposition of the leaflets and are usually most pronounced in sections where chordae tendineae inserts. The bulging of such areas towards the atrial side of the leaflets has been described as rolling of the edges. With progression, the bulging becomes worse and the free edge becomes thickened and irregular and the lesions spread into other parts of the leaflets. Within the same valve leaflet one section may look relatively normal while another, neighboring section is moderately or severely diseased. In late stages, secondary fibrosis can cause marked thickening and contraction of leaflets and chordae tendineae. The chordae tendineae may rupture[23], which leads to an unattached free edge, that is, a flail leaflet.[24] Ultrastructurally, there is myxomatous proliferation of the valve, in which the spongiosa component of the valve is unusually prominent and the quantity of acid-staining glucosamino-glycans (GAGs) is increased (Figure 201-2, *B*).[6,22,23] The valvular interstitial cells in affected areas often have morphologic changes of the nucleus, a localized concentration of abnormally shaped mitochondria and rough endoplasmic reticulum, disorganized cytoskeleton, and lack of secretory vesicles.[25] There is haphazard arrangement, disruption and fragmentation of the collagen fibrils surrounding the interstitial cells (see Figure 201-2, *B*). The endothelial cells covering affected areas become polymorphic and some areas completely loose the endothelium, exposing the underlying extracellular matrix (Figure 201-2, *C*, and 201-2, *D*).[25] Exposure of collagen and other matrix components to the blood is expected to promote thrombosis. Although thrombosis may develop as a complication in CMVI dogs, thrombus formation on the mitral valve is uncommon. Why it is absent in the presence of endothelial damage is currently not known. Inflammation is not an apparent part of the degenerative changes.

Figure 201-1 Proposed model for progression of CMVI in the Cavalier King Charles Spaniel population. The effect of age on the annual percentage of new cases of heart murmurs attributable to CMVI out of the total population in male (thin black line) and female dogs (thin gray line), and on the annual percentage deaths/euthanasias caused by heart failure (thick black or gray lines). Note that both curves resemble a distribution of a random variable with a means of approximately 6 to 7 years (heart murmurs) and 9 to 10 years (deaths/euthanasias), respectively. The male and female populations differ in their epidemiology concerning age of onset of MR and mortality attributable to CMVI. Initiated breeding programs aim at pushing the curve of new cases of CMVI to higher age to reduce the number of cases of congestive heart failure. (From Häggström J: Chronic valvular disease in Cavalier King Charles Spaniels—epidemiology, inheritance and pathophysiology. Thesis, Swedish University of Agricultural Sciences, Uppsala, 1996.)

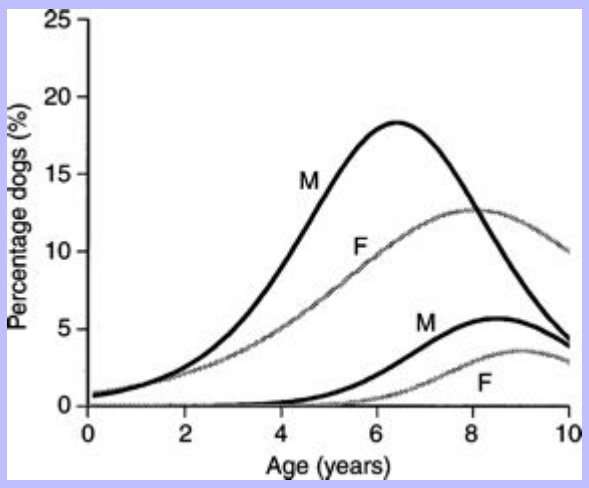

Figure 201-2 **A,** Postmortem specimen of an opened left ventricle (LV) and left atrium (LA) from a dog that suffered from CMVI. The left ventricle and atrium are dilated, and the mitral valve leaflets are thickened and contracted, with nodules rolling in the free edges *(arrowheads)*. Evidence of chordal involvement present in the form of ruptured chordae tendinae *(arrow)*. Jet lesion is present on the atrial wall *(between white arrowheads)* result when the regurgitant streams of blood from the left ventricle strike the atrial wall. **B,** Transmission electron micrograph demonstrating loss of collagen in the subendothelial layer of the mitral valve of a dog with CMVI due to myxomatous degeneration. Fragments of valvular interstitial cells *(white arrow)* are visible interspersed between disrupted bundles of collagen (C). There is obvious variation in the appearance of the endothelial cells (E). **C**, Scanning electron micrograph of the surface of the distal zone of a diseased mitral valve. The triangular area of endothelium in the middle of the picture (E) is the only endothelium left in this area; the remaining area is completely denuded. Underlying collagen has been revealed, which indicates the absence of basement membrane remnants. **D,** Higher magnification of the triangular "endothelial island *(E)*" in Figure **C,** shows that these cells are somewhat clumped, with a very dense microappendage population, considerably more dense than is seen in the normal state with the entire cell surface covered. (**A,** From Pedersen HD, Häggström J: Mitral valve prolapse in the dog: a model of mitral valve prolapse in man, *J Cardiovasc Res* 47:234, 2000. **B, C,** and **D,** Courtesy Brendan Corcoran, Alexander Black, Joanna Dukes-McEwan, Anne French, University of Edinburgh, Scotland and University College Galway, Ireland.)

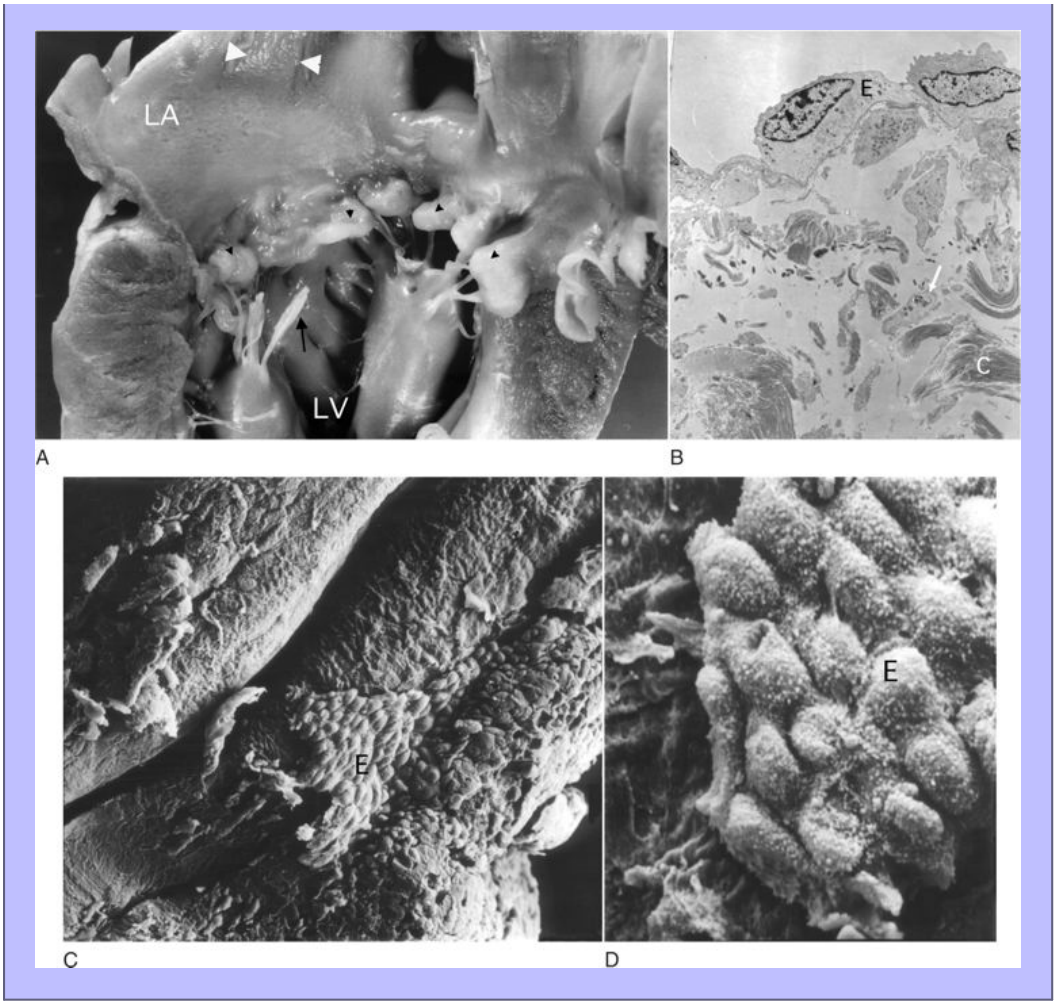


The valvular regurgitation leads to secondary changes including dilation of the left atrium, mitral annulus, and left ventricle (eccentric hypertrophy), atrial endocardial lesions (fibrosis) opposite the mitral orifice (i.e., “jet lesions”), and, in severe cases, varying degrees of atrial rupture, such as endomyocardial splits, ruptured pectinate muscles in the atrial appendage, acquired atrial septal defect, and hemopericardium.[6] Myxomatous degeneration is not restricted to the mitral valve and it may be detected in any of the four intra-cardiac valves. The incidence of valve involvement in dogs was reported as follows: mitral valve alone 62%; mitral and tricuspid valve 32.5%; tricuspid valve alone 1.3%.[6] The pulmonary and aortic valves are less commonly affected. Interstingly, lesions similar to myxomatous degeneration of the atrioventricular valves have been described in the main pulmonary artery in Cavalier King Charles spaniels.[26] Other findings in dogs with advanced stages of CMVI include intramural arteriosclerosis and multiple small myocardial infarcts.[27–29] In contrast to humans with mitral valve prolapse, infectious endocarditis affecting the damaged leaflet is a rare complication in dogs.[1]

201.1.4 Inheritance and Breeding

The etiology of CMVI has not been ascertained but heredity has long been suspected to play a major role, owing to the strong association of this disease with certain small to medium-sized breeds. Two recent studies of families of Cavalier King Charles spaniels and families of Dachshunds provide evidence that genetic factors play a large role in the etiology.[17,18] The disease seems to have a polygenic inheritance; that is, multiple genes influence the trait and a certain threshold has to be reached before CMVI develops.[17,18] Males have a lower threshold than females, which means that males will develop the disease at younger age than females within a family of dogs in which the offspring on average have the same genotype. The polygenic mode of inheritance means that a combination of a sire and a dam that both have an early onset of CMVI will give offspring that have, on average, an early onset of CMVI (and heart failure). A combination of dogs with late onset will give offspring that manifest the disease at old age or never. The major role played by genetic factors implies that other factors, such as level of exercise, degree of obesity, and diet, play a relatively minor role in the etiology. Likely because of this, very little is known about the influence of such factors on the disease. Breeding programs aimed at reducing the prevalence of CMVI have been launched in Europe and North America and elsewhere for Cavalier King Charles spaniels and Dachshunds. These breeding programs use auscultation to identify the presence of a heart murmur or echocardiography to detect and quantify mitral valve prolapse or regurgitation. Dogs that are under a specific age and have developed a heart murmur or echocardiographic findings consistent with CMVI are not allowed to breed. Likewise, offspring from parents that have developed a heart murmur or echocardiographic evidence of early CMVI under a certain age limit are excuded from breeding in some programs. The age limit for potential breeding dogs and parents is very important. It should be set at an age at which dogs with an early onset of CMVI are excluded, but not too high because this may impoverish the breeding population to unacceptable low numbers.[13]

201.1.5 Etiology and Pathogenesis

Little is known about the pathogenesis of the progressive thickening and degeneration of the leaflets. An old theory is that the changes are response-to-injury type lesions, such as that repeated impact to the leaflets (especially the areas of apposition) results in slowly progressing changes.[30] Probably, one or more primary inciting factors increase the risk of disease in predisposed animals as not all dogs develop atrioventricular valve myxomatous degeneration. The nature of these primary initiating factors are currently not known, although certain abnormalities of collagen and other extracellular matrix components have been suggested.[13] It has been suggested that a primary defect leads to abnormal valve motion, that is, prolapse of the leaflets, which in turn increase the shear stress imposed on them, both directly through the abnormal leaflet apposition and indirectly through the increased regurgitant flow.[15,19] It likely plays an important role for the progression of the disease that the endothelium is damaged or even missing in diseased areas[25,31], because endothelial cells are known to communicate extensively with subendothelial cells (e.g., valvular interstitial cells). Specifically, endothelial damage may lead to an imbalance in local concentrations of growth-promoting and growth-inhibiting substances produced by endothelial cells. For instance, associations have been found between disease severity and the expression of endothelin receptors and nitric oxide synthase.[32,33] Future research into local disease mechanisms may suggest ways of treating the actual disease rather than merely the resulting circulatory disturbances.

201.1.6 Pathophysiology

Proper mitral valve closure requires an anatomically and functionally intact valve apparatus. Mitral regurgitation (MR) can be due to alterations of the valve leaflets, dilatation of the atrio-ventricular annulus, rupture of chordae tendineae, or inappropriate contraction of the papillary muscles. More than one of these factors can usually be identified when CMVI is present. The consequences of CMVI depend on several factors[34]: the reduction in forward flow, the regurgitant volume, the size and compliance of the left atrium and the pulmonary vascular bed, the development of tachyarrhythmias (atrial or ventricular) or thromboembolism, and rupture of the left atrial wall.

Primary MR of lesser degree does not induce any apparent change in indices of cardiac size or function. The forward stroke volume is maintained, and the small regurgitant volume is easily accepted by the left atrium. With progression of the valve lesions, the regurgitant part of the total left ventricular stroke volume increases, but several cardiac and non-cardiac (e.g., renal, neurohumoral, and vascular) compensatory mechanisms contribute to maintain the forward stroke volume.[13,34] The left ventricle compensates for the loss of forward stroke volume by increasing the end diastolic volume (preload) and, to some extent by increased heart rate.[35,36] However, the heart rate is usually not significantly changed until advanced stages of CMVI, when it increases.[34,36] The increased preload causes an increased force of contraction according to the Frank-Starling mechanism.[37] The resistance to ventricular emptying is reduced in the first stages of ejection because the regurgitant volume is ejected into the left atrium at low pressure, before sufficient pressure is generated at lower volume to open the aortic valve and cause forward ejection into the aorta. These mechanisms lead to exaggerated motion of the left ventricle (hyperkinesia). Myocardial systolic function is relatively well preserved because the ejection into the left atrium at low pressure require relatively little work by the left ventricle. Patients may tolerate even severe CMVI for years.[7,34] Nevertheless, because of chronic volume overload and the fact that the hypertrophy, while necessary, is a pathologic remodeling, myocardial contractility decreases slowly, even in clinically compensated dogs, but progressively and inexorably.[7,35,38] Arteriosclerosis may complicate the condition by being the cause for multiple small myocardial infarctions, further decreases in contractility, and increased risk of congestive heart failure or sudden death.[28,29]

1024

1025

The left atrium has an important function by allowing the regurgitant volume to be absorbed within the atrial cavity, and it protects the pulmonary vascular bed from hypertension.[39] Increased left atrial pressure results in pulmonary venous congestion and edema. The effect of regurgitant volume on left atrial pressure and volume and consequently pulmonary capillary pressure, depends on the left atrial size, as well as on the compliance of the left atrial wall. Consequently, left atrial compliance is determined by the rate of increase in regurgitant volume, which itself is determined by the rate of progression of CMVI, and by remodeling in response to the volume overload. Maintained left ventricular compliance allows filling at low pressures with the large volume overload of MR, and is a result of the remodeling that is inherent in eccentric hypertrophy. In cases with slowly progressing CMVI, there is often a drastic enlargement of the left atrium, whereas pulmonary congestion and pulmonary edema develop late. The edema is also delayed by the development of a more effective lymphatic drainage of the pulmonary interstitium in chronic pulmonary venous hypertension.[40] The enlarged left atrium may induce coughing by compression of the left main stem bronchus that lies dorsal to the left atrium. In cases with acutely increased MR, as in rupture of a tendinous cord, the left atrium is unable to adapt, which results in a rapid elevation of left atrial pressure. Pulmonary capillary pressure subsequently increases, which leads to pulmonary congestion and edema.

Advanced cases of CMVI may be complicated by processes that are related to increased left atrial size and pressure.[7,41] The left atrium may rupture and cause cardiac tamponade; right-sided heart failure may develop as a consequence of concurrent tricuspid valve insufficiency and/or pulmonary artery hypertension; and tachyarrhythmias may develop as a consequence of ultrastructural changes in the myocardium. These complications are discussed later.

201.1.7 Clinical Signs

The progress of CMVI from the detection of a soft heart murmur to end-stage is often a matter of years in small dogs. Some large dogs appear to be less tolerant to CMVI. In these dogs, the disease has a more drastic progression with more severe clinical signs than in small dogs. The first clinical signs of decompensation are usually mild but may be aggravated within days or sometimes weeks. Since these signs are vague and not specific for decompensated heart failure, the differential diagnostic challenge in CMVI is often not if the disease is present, but whether or not CMVI is responsible for the clinical signs. The signs relate to the presence and degree of one or several of the following pathophysiologic events, listed in order of their relative importance: (1) elevated left atrial and pulmonary venous pressure, which results in respiratory distress and cough due to pulmonary edema and main-stem bronchial compression; (2) reduced left ventricular or right ventricular forward flow, which results in weakness and reduced stamina; (3) right-sided heart failure, which results in pleural effusion and ascites; (4) acute decompensation with fulminant pulmonary edema or ventricular fibrillation, which causes sudden death.

Mild to moderate CMVI is usually not associated with any signs of disease. Most dogs with CMVI are free of clinical signs for most of the time they have a murmur, although exercise intolerance might be noted. Cough is the most common presenting complaint in CMVI. Although this sign is not specific for heart disease or heart failure, it should merit further evaluation. In the case of advanced CMVI, the cough may be caused by pressure of the left atrium on the left mainstem bronchus, by pulmonary congestion and edema or, most commonly, a combination.[20] With pulmonary edema present, other common clinical signs are tachypnea and dyspnea. The dogs are often anxious and restless during the night while they lie in lateral recumbency (orthopnea) and prefer sternal positioning. In more advanced cases respiratory sounds, often wheezes, may be audible. These dogs are often inactive and have varying degrees of inappetence. Cardiac cachexia may develop, although loss of body weight may be masked by concurrent fluid retention and edema. Dogs with left mainstem bronchial compression but without pulmonary congestion or edema may have coughing spells at any time during the day, especially during physical exercise or excitement. Otherwise they do not demonstrate clinical signs.

Syncope is encountered in some dogs with CMVI. Syncope may be associated with a tachyarrhythmia, but the course of events often resembles that which is described in vasovagal syncope.[42] The frequency of the syncope vary from occasional spells to several attacks per day. Other causes of syncope include tussive fainting that may occur in conjunction with paroxysm of coughing or exercise in the presence of pulmonary hypertension.[20]

201.1.8 Physical Examination

A mid-systolic click is frequently encountered in early stages of CMVI (Figure 201-3, *A*),[43,44] although it may be difficult to detect by auscultation. The presence of this sound is dependent on heart rate and body position.[43] A systolic click may be accompanied by a low-intensity systolic murmur. The murmur is most

frequently early systolic but may be late systolic or may in some dogs vary between the two. With progression, the most prominent clinical finding is a holosystolic heart murmur. The sound begins as a soft apical systolic murmur on the left side of the thorax and may be intermittent and sometimes audible only during inspiration (Figure 201-3, *B*). In the early stages of CMVI, the murmur can often be augmented by physical maneuvers, such as a short run.[43] With further progression, the sound becomes holosystolic and more intense (Figures 201-3, *C*, and 201-3, *D*)[13,15,43–45] and may radiate over to the right side of the thorax. A thrill may be palpated over the left thoracic wall (cardiac apical area) and the apical beat may be pronounced. Musical murmurs (whoop sounds) of high intensity occur less frequently. This murmur does not indicate the severity of CMVI (Figure 201-3, *E*).[44] There is usually a shift in the relative intensity of S1 and S2 (see Figure 201-3, *D*).[45] In the absence of significant myocardial failure, the first heart sound is usually enhanced, whereas the second heart sound becomes less intense.[20,44,45] A low-intensity third heart sound is often present, but this sound is often difficult to detect by auscultation (see Figure 201-3, *D*).[44,45] The presence of a clearly audible third (gallop) sound is a strong indicator for myocardial failure.[44] In cases of severe heart failure, the heart sounds and murmurs may be muffled by pleural effusion or cardiac tamponade. Thus even though auscultatory findings may be suggestive, the clinician must rely on the supporting historical, clinical, echocardiographic, and radiographic data to determine the hemodynamic significance of the insufficiency.

The presence of sinus arrhythmia in advanced CMVI indicates that decompensated heart failure is absent.[36] The heart rate increases in response to decreased forward cardiac output as decompensation develops, and the heart rate becomes more regular. A rapid and irregular heart rate is indicative of arrhythmia. The most common form of ectopy is atrial premature contractions. In more advanced CMVI, supraventricular tachycardia, atrial fibrillation, and ventricular premature contractions may be encountered.

Figure 201-3 ECG lead II (upper registration) and phonocardiograms (middle and lower registrations) in dogs with different stages of CMVI. Recordings were obtained from the following dogs: **(A)** a dog with a systolic click (C) and an intermittent early systolic murmur (M), **(B)** a dog with an interrmittent systolic murmur (M), **(C)** a dog with a continuous holosystolic murmur (M), **(D)** a dog in end-stage MR with a loud first heart sound (S1), a dampened second heart sound (S2), a systolic murmur (M) and a prominent third heart sound (S3), **(E)** a dog with a comparably uncommon high intensity musical murmur (M) where the intensity of the murmur does not reflect the severity of MR. (**A**, **B**, **C**, and **D** From Häggström J: Chronic valvular disease in Cavalier King Charles spaniels—epidemiology, inheritance and pathophysiology, thesis, Swedish University of Agricultural Sciences, Uppsala, 1996. **E** from Kvart C, Häggström J: Cardiac auscultation and phonocardiography in dogs, horses and cats, Uppsala, 2002.)

With sinus rhythm the femoral arterial pulse is usually normal. Weak pulses may be noted in heart failure. Weak and variable pulses with deficits can also be observed with rhythm disturbances. If tamponade occurs, owing to a tear in the left atrium and pericardial hemorrhage, the femoral pulse will be weak. Jugular venous distention may be present in severe heart failure, pulmonary hypertension, or pericardial effusion.

In cases of CMVI without signs of heart failure, the lung sounds are expected to be normal. Crackles, snaps, and popping sounds, best heard at end of inspiration, may be detected in advanced CMVI with pulmonary interstitial edema. Similar findings are common in dogs with small airway disease,[46] and if concurrent it may be a diagnostic challenge to determine the cause of the clinical signs. In more severe cases with alveolar edema, the pulmonary sounds are usually more pronounced and they may be auscultated even without a stethoscope.

Mucous membranes are usually normal, even in cases with pulmonary edema but may be cyanotic, grayish, or ashen in advanced cases of heart failure. Ascites in isolated CMVI is uncommon, but progressed CMVI often

tends to involve the right side of the heart as a consequence of pulmonary hypertension or development of a tachyarrhythmia. In these dogs, ascites, hepatic, and splenic enlargement are common.

201.1.9 Electrocardiographic Findings

Electrocardiographic findings in CMVI vary from normal tracings to marked abnormalities in rate, rhythm, or configuration of complexes. With the exception to document and classify a certain arrhythmia, the ECG is of limited use in the diagnosis or management of CMVI. ECG is an insensitive indicator of cardiac enlargement and cannot detect heart failure or pulmonary edema.

Sinus arrhythmia is usually preserved during the early course of CMVI. In heart failure, sinus tachycardia and a loss of sinus arrhythmia are common.[36] Decompensated heart failure from CMVI should be questioned in a coughing patient with sinus arrhythmia. Cats with MR usually maintain sinus rhythm, although atrial fibrillation and/or ventricular ectopy may develop.

Most ECG abnormalities associated with CMVI are the result of accentuations of the normal ECG. The mean electrical axis in the frontal plane often remains within the normal range throughout the progression of the disease. In cases with significant left atrial enlargement, the P-wave may be prolonged. In cases of significant left ventricular enlargement, the QRS complex may be prolonged and the R wave amplitude in lead II increased,[47] but the former is generally a more reliable criteria to detect left ventricular enlargement.

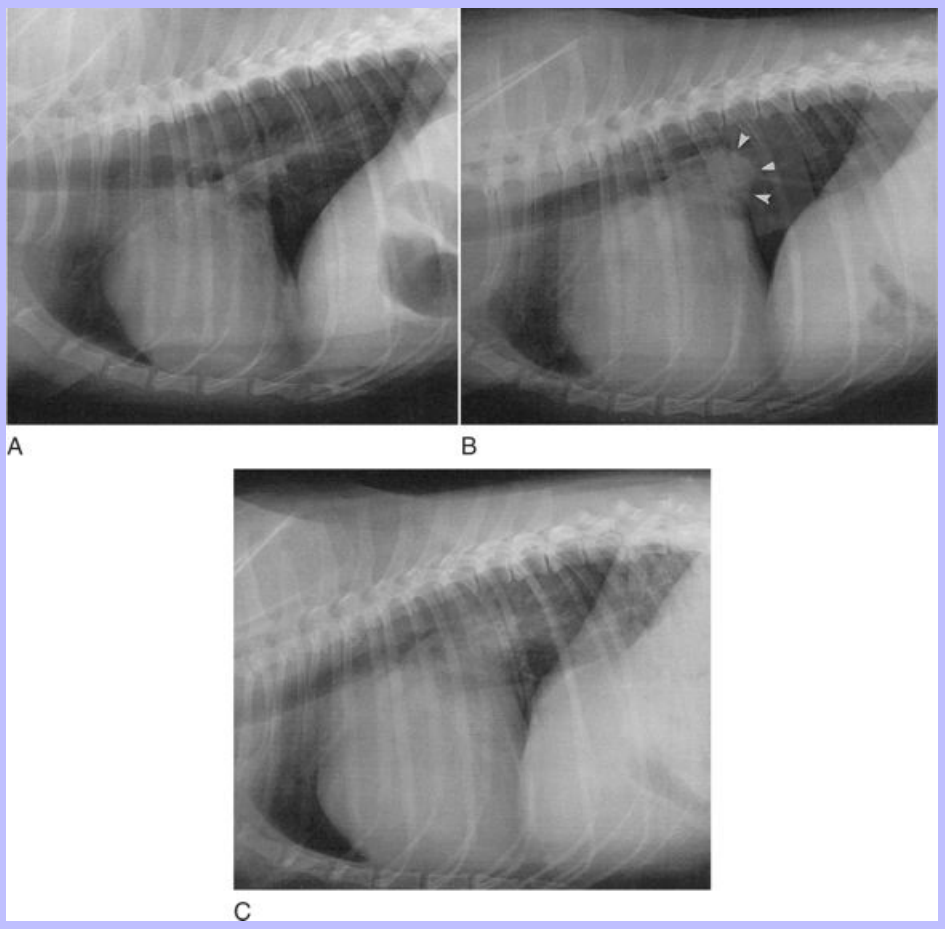
Supraventricular premature beats are common in CMVI. In most cases, this finding is of little hemodynamic significance. Atrial fibrillation, paroxysmal supraventricular tachycardia, atrioventricular dissociation, ventricular premature beats, and ventricular tachycardia are less common. These arrhythmias are most often encountered in progressed cases and hence often indicate a poor prognosis.

201.1.10 Radiographic Findings

The value of radiography is in assessment of the hemodynamic consequences of CMVI (global cardiac size and presence of pulmomary congestion and edema). It helps to exclude other possible causes for the clinical signs: presence of pulmonary congestion and edema is of particular interest in geriatric dogs. Two orthogonal projections should be obtained: lateral and dorsoventral or ventrodorsal. Absolute straight positioning is essential for accurate evaluation of heart size and shape and position of the main bronchi. In dogs with CMVI, important structures to evaluate are the left atrium, the left ventricle, the mainstem bronchi, the pulmonary vessels, and the lungfield. Dogs with a low degree of CMVI usually have a normal heart size, normal lung fields, and normal vascular markings.

Left atrial enlargement is one of the earliest and most consistent radiologic features of CMVI. The left atrium and left ventricle continue to enlarge with progression of the disease. Signs of left atrial and left ventricular enlargement in lateral projection include dorsal elevation of the caudal portion of the trachea and carina; dorsal displacement of the left mainstem bronchus; visible prominence of the left atrium causing the caudal border of the heart to appear straight or bulge dorsocaudally (Figure 201-4). In the dorsoventral (or ventrodorsal) projection, the enlarged left atrial appendage may be identified as a bulge in the left cranial part of the cardiac border (between the 2 and 3 o'clock positions). The border of the enlarged left ventricle appears rounded and there may be a shift of the cardiac apex to the left or right. In advanced cases of decompensated CMVI, pleural effusion, ascites, and enlargement of the liver and spleen are commonly identified as signs of associated right heart failure.

Figure 201-4 Radiographs in left lateral projection of a dog with CMVI: **(A)** The dog was at this time asymptomatic, and the radiograph shows a slight left atrial enlargement and normal vascular perfusion. **B,** Radiograph of the same dog 4 years later. The dog had developed exercise intolerance and persistent cough. Visible are marked left atrial *(white arrows)* and left ventricular enlargement and elevation and slight compression of the left mainstem bronchus, whereas the vascular markings are within normal limits. **C,** Six months later the dog had also developed dyspnea and had suffered episodes of syncope. In addition to the findings in previous radiograph **(B)**, there is a more obvious compression of the left mainstem bronchus and evidence of pulmonary congestion and interstitial edema. (Courtesy Kerstin Hansson, Uppsala, Sweden.)



During the progression of CMVI, radiographic signs of pulmonary congestion and edema usually develop. Pulmonary edema and congestion is more likely to be present in a dog with significant heart enlargement (indicating advanced CMVI) than in a dog with normal or slightly increased heart size. However, the degree of cardiac enlargement is poorly related to the severity of pulmonary congestion and edema (see Pathophysiology). Because many dogs with significant CMVI and enlarged hearts have not developed decompensated heart failure, therapy should be based primarily on clinical signs and the presence of pulmonary edema and congestion, not the degree of cardiac enlargement. Pulmonary venous distension, when present, is an early indication of pulmonary congestion; the diameter of the veins is greater than that of the corresponding pulmonary arteries and they often become tortuous (especially in cats). However, venous distention is not a consistent finding even in dogs with pulmonary edema, and in some dogs, the outlining of the distended vein is indistinct as interstitial edema partially obscures the pulmonary vessels. With progression, interstitial and alveolar edema develop. In dogs, alveolar edema is often first detected in the perihilar region and the dorsal parts of the caudal lung lobes, sometimes more prominent on the right side, but acute edema may involve the cranial lobes. In cats, the location of a cardiogenic pulmonary edema is not as predictable as in dogs. It commonly has an ill-defined, patchy appearance.

Pulmonary findings may be inconclusive, since early radiographic changes of pulmonary interstitial edema and bronchial pattern resemble the radiographic appearance of chronic airway disease. The tendency is to overdiagnose pulmonary edema of heart failure. It is therefore important, if possible, to have series of radiographs and evaluate other evidence of left-sided heart failure that should be present by the time pulmonary edema has developed, such as venous distention, before diagnosis is determined.

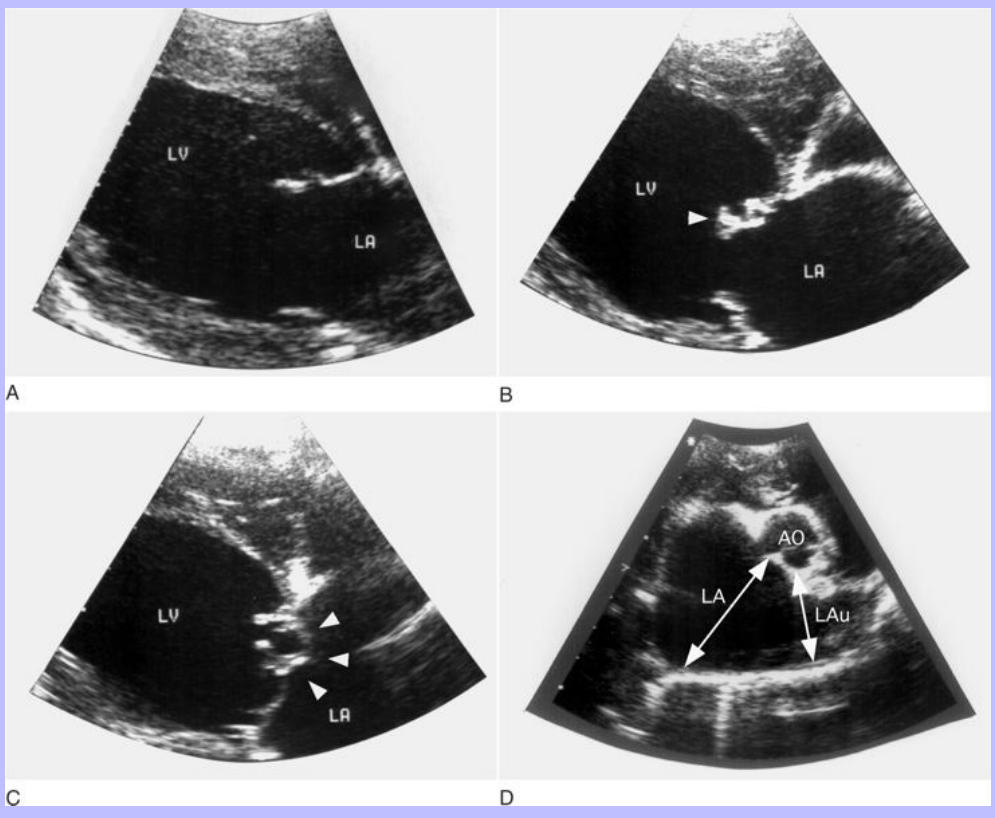
201.1.1.1 Echocardiographic Findings

Echocardiography is useful for obtaining a diagnosis of CMVI, and thereafter to monitor the condition, although it cannot diagnose the presence of heart failure. Two-dimensional echocardiography allows the ultrasonographer to evaluate the anatomy of the mitral valve and to identify leaflet thickening and leaflet protrusion into the left atrium. A systolic bulging of one or both leaflets to the atrial side of the mitral annulus is an early indication of affected valves and it may be present in dogs with or without mitral regurgitation (MR).[15,48] The presence and severity of protrusion of the leaflets may be measured in the right parasternal long axis view.[16,48]

In cases with insufficient valves, the degree of displacement is reported to relate well with the severity of MR.[15,16,48] With progression, the degenerative changes become more prominent and the leaflets often have an irregular “club-like” appearance with greatest thickening at the tip (Figure 201-5, *B*). The gross pathologic changes of the two leaflets (anterior and posterior) are often equally severe at postmortem examination, but the degenerative changes commonly appear more prominent on the anterior leaflet in the right parasternal long axis view on the echocardiogram.

Figure 201-5 Echocardiographic right parasternal long-axis views of the left atrium *(LA)* and left ventricle *(LV)* during diastole **(A** and **B)** and systole **(C),** in a normal dog **(A),** and in the same dog with CMVI **(B** and **C)**. The mitral valve appears thickened **(B)** *(arrowhead)*, and there is systolic displacement of both leaflets to the atrial side of the mitral annulus **(C)**. Figure **D** shows the left atrium in a right parasternal short axis view at the aortic valve *(AO)* level of a dog with severely enlarged left atrium. The *arrows* demonstrate the difference in LA diameter obtained by measuring the greatest diameter and the diameter often used in M-mode. *Lau*, Left auricle.



It is important to examine the entire valve as the lesions are often quite unevenly distributed. Chordal thickening may be identified and systolic displacement (prolapse) of the leaflets or a valve flail may be evident (Figure 201-5, *C*). Valve flail is when the edge of a leaflet or, in severe cases, a complete leaflet moves into the left atrium in systole. The finding of a valve flail leads to the suspicion of chordal rupture, which may occasionally be identified in the left atrium or in the left ventricle.[24]

The left atrium is an important structure to evaluate with MR because its size reflects disease severity. The general "rule of thumb" is that the larger the left atrium, the greater is the degree of MR present, but there are exceptions (see Pathophysiology). Although the left atrium may be examined from a right parasternal long axis view and a left apical four chamber view, the best view is the the right parasternal short axis view with the aortic root, the left atrial body and the auricle in view (Figure 201-5, *D*). The most useful information from this view is the left atrial size because it can be compared with the size of the aortic root, which is relatively constant for a given dog size. The normal ratio of the left atrial diameter to the aortic root (LA/Ao) in M-mode is reported to be between 0.8 to 1.2.[49] With the more traditional M-mode method, however, the left atrial dimension measured is not the largest that can be obtained, as it measures the diameter of the left atrial appendage or underestimates the diameter of the left atrial body. In dogs with MR, the diameter of the left atrial body may be considerably greater than that of the left atrial appendage (see Figure 201-5, *D*).[50] The normal range for 2D La/Ao values is reported to be 0.84 to 1.27 in Cavalier King Charles spaniels and 0.86 to 1.59 in a mixture of breeds.[50,51] In the authors' experience, a 2D La/Ao greater than 1.5 represents an enlarged left atrium in all breeds. This limit is presumably lower in specific breeds. Early cases of CMVI with a small degree of MR have no echocardiographic signs of left atrial enlargement. With progression of CMVI the left atrial dimension increases and dogs in congestive heart failure often have a left atrial to aortic root ratio of 2 or greater.[52]

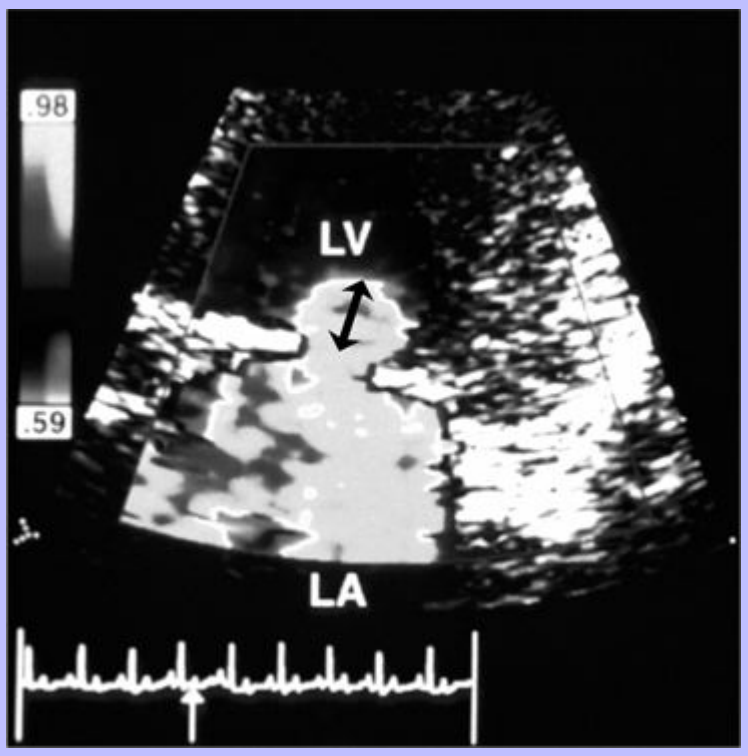
Evaluation of left ventricular size and motion is important in MR and measurements are often obtained in the M-mode. Mild MR usually does not lead to abnormal dimensions. With progression, the left ventricular-end-diastolic short axis dimension increases, whereas the end-systolic dimension does not increase at the same rate. The left ventricular wall thickness is usually within normal limits. The increased size of the left ventricle combined with a normal wall thickness indicates that volume overload and eccentric hypertrophy are present. An increase in left ventricular end-diastolic dimension in the presence of normal or minimally increased left ventricular end-systolic dimension is a consequence of increased preload and rapid left ventricular emptying into the low-pressure left atrium.[7,53] In MR, values of ejection phase indices (e.g., left ventricular fractional shortening, ejection fraction, and mean velocity of circumferential shortening) are often normal (mild MR) or greater than normal (moderate to severe MR). Therefore in the setting of moderate or severe MR, a normal fractional shortening represents a significant reduction of myocardial contractility. End-systolic volume indices (e.g., left ventricular end-systolic short axis dimension or end-systolic volume index) more accurately estimate myocardial contractility in MR.[7,53] However, when heart failure is present and the sympathetic nervous system is activated to increase apparent contractility, even these measurements overestimate intrinsic myocardial contractility.[38]

End-systolic dimension may increase in small dogs with end-stage CMVI, but increase appears to be more common in large dogs that present with heart failure and severe MR but with a fractional shortening in the normal range or slightly increased. In these dogs, the mitral valve leaflets may or may not look as severely affected as in small dogs. Often, they look less affected, and it is currently an enigma why these dogs present with severe MR and prominent myocardial failure. The large dogs with MR and myocardial failure may be confused with DCM, but DCM may be questioned in a dog with normal or slightly depressed fractional shortening. It has been suggested that these dogs may actually suffer from congenital mitral dysplasia rather than myxomatous degeneration.[54] Mild pericardial effusion may be present in dogs with heart failure, whereas significant pericardial effusion should raise the suspicion of another disease or of a complication of CMVI such as left atrial rupture. Mild pleural effusion may also be evident in dogs with heart failure.

It is rare, even in severe cases of CMVI, to detect incomplete closure of the leaflets as means of confirmation of the presence of MR. Instead, the valvular insufficiency may be detected and quantified by spectral or color-flow Doppler.[43] Ideally, the regurgitant flow should be aligned with the ultrasound beam and this is most often acheived in the left apical four-chamber view. As the flow direction depends on the orientation of the regurgitant orifice which, in turn depends on the leaflet morphology, other views may also give good alignment. Spectral Doppler may be used to identify the regurgitant jet when color-Doppler mapping is not available. Furthermore, spectral Doppler gives information of the velocity of the regurgitant jet and velocity time tracings may help in estimating regurgitant volume (see below). Typically, dogs with CMVI without myocardial failure have a velocity of the regurgitant jet of 5 to 6 m/sec.[54] However, the velocity may be increased in individuals with systemic hypertension and decreased in individuals with hypotension, significantly increased left atrial pressure or myocardial failure.

Color-flow echocardiography confirms the presence of a regurgitant jet and the size of the jet can be compared with the size of the left atrium. This measurement is semiquantitative in dogs and cats. A small jet rules out moderate to severe MR, but it is difficult to discriminate between moderate and severe regurgitation from the jet size. Small jets in the vicinity of the mitral valve should not be overinterpreted in dogs without any other valve abnormality, as trivial regurgitation may often be detected in normal dogs.[55] Recently, it was demonstrated that the regurgitant fraction may be quantified with use of the proximal isovelocity surface area (PISA) color-flow method in dogs with MR (Figure 201-6).[56,57] In MR, blood flow converges on the ventricular side of the mitral valve orifice before it passes the regurgitant orifice, and this area is characterized on the color-Doppler echocardiogram as a hemisphere. Based on the values of the radius of this hemisphere, the aliasing velocity, the maximal velocity of the regurgitant jet, and the velocity time integral of the regurgitant flow (the latter two are obtained from spectral Doppler measurements), the regurgitant stroke volume may be calculated. The regurgitant fraction is obtained by dividing the regurgitant volume with the sum of the forward and regurgitant stroke volumes. Although this method has significant advantages compared to other methods of measuring regurgitant fraction, it has several practical limitations and may not be readily applicable in all cases of MR.

Figure 201-6 Zoomed color-flow Doppler image of the mitral valve in a left apical 4-chamber view showing the hemicircle of the flow convergence on the ventricular side of the mitral valve. The radius of the proximal isovelocity region is measured from the ventricular side of the mitral valve leaflets to the edge of the hemisphere (*double-sided arrow*). The radius of the hemisphere is used to calculate the regurgitant fraction of the total stroke volume. There is also evidence of significant regurgitation into the left atrium. *LV*, left ventricular chamber; *LA*, left atrial chamber. (From Kittleson MD, Brown WA: Regurgitant fraction measured by using the proximal isovelocity surface area in dogs with chronic myxomatous mitral valve disease, *J Vet Intern Med* 17:84, 2003.)



The mitral regurgitant stroke volume may also be estimated indirectly using the difference between total stroke volume and forward stroke volume into the aorta. The total stroke volume may be estimated using M-mode measurements of left ventricular size, and the forward stroke volume may be estimated by multiplying the aortic cross sectional area with the velocity time integral obtained from the spectral Doppler tracing of the aortic flow. Alternatively, the total stroke volume may be estimated by multiplying the annular

cross-sectional area of the mitral valve obtained from the two-dimensional mode with the velocity time integral obtained from the spectral Doppler tracing of the diastolic flow over the valve. Both these methods involve multiple measurements, each with its own errors, which means that they will only provide estimates of regurgitant volume. Measurements of regurgitant fraction in dogs with moderate to severe MR indicate that they can eject more than 75% of the total stroke volume into the left atrium, which is remarkable.

At present, none of the Doppler methods (subjective estimation of jet size, spectral Doppler methods, and the PISA method) have been shown to be more reliable indicators of disease severity than left atrial size in dogs and cats with MR. Spectral Doppler may be used to study the transmitral flow during diastole. Significant mitral regurgitation is usually associated with increased diastolic filling velocities as a consequence of increased diastolic transmitral flow.[58] Furthermore, abnormal diastolic ventricular function as a consequence of severe volume overload may be detected. It is important to time the events when evaluating the transmitral flow to separate systolic regurgitation from diastolic to avoid a false-positive diagnosis of clinically significant mitral regurgitation. Diastolic regurgitation is common in cases with bradycardia or arrhythmias and probably indicates small reverse pressure gradients during cardiac filling.[59]

201.1.12 Differential Diagnosis

The signalment, clinical signs, and physical examination findings are often such that they strongly suggest CMVI. Although the usual cause for MR is myxomatous degeneration, other causes are noteworthy: dilated and hypertrophic cardiomyopathy; widespread arteriosclerosis with myocardial infarcts; bacterial endocarditis of the mitral valve; undiscovered congenital heart disease, such as mitral valve dysplasia and patent ductus arteriosus (PDA). Early cases of CMVI may have an early systolic heart murmur that may be confused with slight aortic or pulmonic stenosis or physiologic flow murmur. Often the early or late systolic murmur due to MR is accompanied by a systolic click, which is an indicator for early myxomatous degeneration and mitral valve prolapse. The signalment, point of maximal intensity of the murmur, and echocardiography are distinctions between slight MR and slight aortic or pulmonic stenosis and physiologic flow murmurs. Furthermore, dogs with slight MR are usually old and the murmur has maximal intensity over the mitral area, whereas dogs with physiologic flow murmurs or aortic or pulmonic stenosis are usually young and have a murmur with maximal intensity over the heart base. The exclusion of dilated cardiomyopathy and hypertrophic cardiomyopathy requires echocardiographic examination. However, it may not be possible to discriminate CMVI from DCM in some medium-and large-sized dogs, such as Cocker spaniels, which present with valvular abnormalities, significant MR, left ventricular and left atrial enlargement and a normal to subnormal fractional shortening. Measurement of biochemical markers of myocardial damage, such as Troponins, may aid in diagnosing myocardial infarcts, provided that the myocardial damage was recent and significant.[60]

The echocardiographic appearance of a mitral valve affected with endocarditis may appear very similar to nodular thickening of valve leaflets characteristic for myxomatous degeneration. However, lesions of endocarditis may be more echogenic and more isolated. The signalment usually helps to distinguish between these two diseases. Bacterial endocarditis occurs most frequently in large dogs; CMVI is more common in small dogs; dogs with bacterial endocarditis often have a history of fever, arthritis, systemic disease, a recently developed heart murmur, and clinical signs that may indicate thromboembolic disease. Dogs with CMVI are usually older, often have had a heart murmur for years, and do not have fever or signs of systemic disease. Bilateral regurgitation is commonly encountered, but isolated tricuspid regurgitation does occur. In these cases, the heart murmur may radiate to the left side of the thorax.

Although CMVI may readily be diagnosed in a patient with clinical signs, the true diagnostic challenge lies in determining if decompensated heart failure is the underlying cause. Most dogs with CMVI are older, small to medium-sized dogs, and many of these dogs exercise little. Thus exercise intolerance may be difficult to identify and, if present, difficult to attribute to the heart condition as obesity, chronic joint disease, and other disease may be present. Furthermore, the hallmark of left side heart failure, coughing and dyspnea, may be caused by several conditions, such as small airway disease, tracheal instability, pulmonary fibrosis, neoplasia, heartworm disease, and pneumonia. Many of these differential diagnoses can be excluded by different clinical tests, particularly radiography, but in some cases, the results may be inclusive. In these cases, a 48-to 72-hour trial diuretic therapy with repeat radiographs may help to identify the underlying etiology. In addition, "bedside" assays of natriuretic peptides (ANP and BNP) will soon be available to aid in diagnosis of such cases.

201.1.13 Management

Ideally, therapy of CMVI would halt the progression of the valvular degeneration. Improvement of valvular function by surgical repair or valve replacement would likewise stop further deterioration. However, no therapy is currently known to inhibit or prevent the valvular degeneration, and surgery is usually not technically, economically, or ethically possible in canine and feline patients. The management of CMVI is therefore concerned with improving quality of life, by ameliorating the clinical signs and improving survival. This usually means that therapy is tailored for the individual patient, owner, and practitioner and often involves concurrent treatment with two or more drugs once signs of heart failure are evident. Management of CMVI will be discussed in five groups of patients: those without overt signs of heart failure (asymptomatic), those with left mainstem bronchial compression, those with syncope, those with mild to moderate heart failure, those with recurrent heart failure, and those with severe and fulminant heart failure. Possible complications are discussed separately. It is unusual to treat cases of isolated CMVI in cats and details of drug dosages for cats are therefore not included in this section.

1030

1031

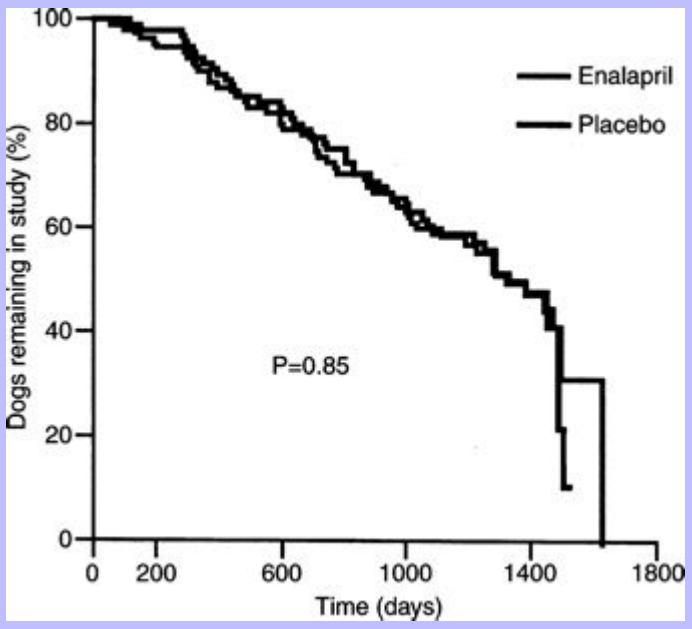
201.1.13.1 Asymptomatic Disease

The stage when a patient starts to show clinical signs of CMVI, that is, have developed decompensated heart failure, is the end of a process started much earlier with the onset of valve leakage. The valvular leakage was compensated through a variety of mechanisms but as the leakage increases the valves eventually became incapable of preventing pulmonary capillary pressures from exceeding the threshold for pulmonary edema, and of maintaining forward cardiac output. It is likely that minor signs of reduced activity and mobility are present even before overt signs of heart failure develop. However, it is very difficult to objectively evaluate the presence of slight to moderately reduced exercise capacity in most dogs with CMVI, as they are often old small companion dogs, which if obese, have little, if any, demand on their exercise capacity. Furthermore, other concurrent diseases in the locomotor system or elsewhere are common and restrict exercise. Thus vague clinical signs such as slightly reduced exercise capacity in a typical dog with progressed CMVI may or may not be attributable to CMVI.

This dilemma leads to the questions of when to start therapy, and if therapy before the onset of decompensated heart failure is beneficial, ineffective, or harmful. ACE-inhibitors are frequently prescribed to dogs with CMVI before the onset on heart failure. At present, however, there is no evidence that administration of any medication to a patient with asymptomatic CMVI has a preventive effect on development and progression of clinical signs of heart failure or improves survival. Two large placebo-controlled multicenter trials, the SVEP and the VetProof trials,[14,61] have been conducted to study

the effect of monotherapy of the ACE-inhibitor enalapril on the progression of clinical signs in asymptomatic CMVI in dogs. Both failed to show a significant difference between the placebo and the treatment groups in time from onset of therapy to confirmed congestive heart failure (Figure 201-7).[14,61] The two trials differ in the following features: the SVEP trial included only dogs of one breed (Cavalier King Charles spaniels) whereas the VetProof trial included a variety of breeds. The dogs in the VetProof trial were more frequently progressed cases of CMVI than the dogs in the SVEP trial, and the SVEP trial comprised more dogs than the VetProof trial (229 versus 139 dogs). Suggested reasons for the non-significant findings in these trials include lack of activation of circulating RAAS activity in asymptomatic animals,[62] low concentration of angiotensin II receptors in the canine mitral valve,[63] or lack of effect of ACE-inhibitors on myocardial remodeling and progressive ventricular dilatation in MR.[64]

Figure 201-7 The SVEP study investigated the effect of enalapril on preventing decompensated heart failure in dogs with asymptomatic CMVI. The graph shows the percentage of dogs included in the enalapril and the placebo groups, respectively, versus time. The difference in number of days in the study between placebo-and enalapril treated dogs was not significant. (From Kvart C et al: Efficacy of enalapril for prevention of congestive heart failure in dogs with myxomatous valve disease and asymptomatic mitral regurgitation, *J Vet Intern Med* 16:80, 2002.)



Owners of dogs with progressed asymptomatic CMVI should be instructed about signs of developing heart failure and, in case of breeding, about the fact that the disease is significantly influenced by genetic factors.

The disease may be monitored at regular intervals of 3 to 12 months if significant cardiomegaly is present. Milder cases do not warrant frequent monitoring (see Significance and Progression). Frequently asked questions from owners of dogs with asymptomatic CMVI are if exercise should be restricted and if dietary measures should be instituted. At present there is little evidence-based information concerning the effects of exercise or diet on the progression of CMVI in dogs. Dogs with mild CMVI do not need any dietary or exercise restriction. However, from the pathophysiologic standpoint, strenuous exercise or diets with high sodium content should be avoided in progressed CMVI as this may promote pulmonary edema. Furthermore, it is the authors' experience that dogs with advanced asymptomatic CMVI usually tolerate comparably long walks at their own pace and do better if obesity is avoided.

201.1.13.2

Patients with Left Mainstem Bronchial Compression Without Pulmonary Congestion and Edema

Severe left atrial enlargement may produce coughing even in the absence of pulmonary congestion and edema by compression of the left mainstem bronchi, which may be identified on the lateral radiograph. With significant coughing, therapy is aimed at suppression of the cough reflex or reduction of the influence of the underlying cause for the compression, the left atrial enlargement. Cough suppressants such as butorphanol (0.55 to 1.1 mg/kg q6-12h PO), hydrocodone bitartrate (0.22 mg/kg q4-8h PO), or dextromethorphan (0.5 to 2 mg/kg q6-8h PO) may alleviate the coughing in some cases. Dogs with evidence of concurrent tracheal instability or chronic small airway disease may improve with a bronchodilator, or a brief course of glucocorticoids. Different xanthine derivatives, such as aminophylline (8 to 11 mg/kg q6-8h) and theophylline (Theo-Dur (sustained duration) 20 mg/kg q12h PO, Detriphylline (Choledyl) (sustained action) 25 to 30 mg/kg q12h PO), are commonly used bronchodilators, although the efficacy of these drugs varies considerably between individuals. Beta 2-receptor agonists such as terbutaline and albuterol should be used with caution in CMVI dogs, as these drugs may produce unwanted elevation in heart rate and contractility as a consequence of myocardial beta 2-receptor stimulation. A reduction of left atrial size may be obtained either by reduction of the regurgitation or by reduction of pulmonary venous pressure. Regurgitation can be decreased by reducing aortic impedance with an arterial dilator or by contracting blood volume with a diuretic.

ACE-inhibitors or a directly acting arterial vasodilator, such as hydralazine, may reduce systemic arterial resistance.[65] The ACE-inhibitors are substantially weaker arterial vasodilators than hydralazine.[65] Side effects of ACE-inhibitors are infrequent, but monitoring of renal function and serum electrolytes, particularly potassium, may be indicated.

Hydralazine has been widely used in patients with CMVI at an initial dosage of 0.5 mg/kg every 12 hours PO. The dosage is increased at daily to weekly intervals to an appropriate maintenance dose of 1 to 2 mg/kg every 12 hours PO, or until hypotension develops, detected either by blood pressure measurements or by clinical signs. Clinical hypotension is defined as a mean arterial blood pressure of less than 50 to 60 mm Hg or a systolic blood pressure below 90 mm Hg.[54] Reflex tachycardia may develop in response to hypotension, and gastrointestinal problems are sometimes observed. In tachycardia, digoxin may be considered in order to limit the resting heart rate. As a consequence of hypotension, hydralazine may induce fluid retention and thereby is needed in the form of a diuretic.[66] Patients that receive hydralazine should routinely be monitored, including having the owner check the heart rate at home and having renal function assessed periodically. Diuretic mono-therapy may be considered to decrease the MR by contracting the blood volume and thereby the left ventricular size. However, diuretics activate the renin-angiotensin-aldosterone system (RAAS),[66] and in the long term may cause electrolyte disturbances.

1031 1032

Accordingly, these drugs are often reserved for patients with signs of pulmonary congestion and edema or patients in which cough suppressants, glucocortocoids, and vasodilators have failed to alleviate clinical signs.

201.1.13.3 Patients with Syncopes but Without Pulmonary Congestion and Edema

With advancing CMVI it is not uncommon that episodes of syncope develop in otherwise asymptomatic dogs (see Clinical Signs). These episodes vary in frequency from isolated to multiple events every day. In dogs with CMVI with syncope, it is important to ascertain that the patient is actually fainting and not suffering from neurologic or metabolic disease. Furthermore, it is important to rule out the presence of congestive heart failure or a bradyarrhythmia such as third degree AV-block or a tachyarrhythmia such as atrial fibrillation. Although ventricular tachyarrhythmias do occur in dogs with advanced CMVI, supraventricular tachyarrhythmia is far more common. Typically, the 24-hour (Holter) ECG shows episodes of a rapid supraventricular rhythm immediately followed by a bradycardia during which the dog faints. Management of these dogs often includes digoxin to control the supraventricular tachyarrhythmia. In fact, the frequency of syncopes may often be controlled at lower doses, such as 50%, of digoxin than the recommended dose (which is 0.22 mg/m2 q12h PO). The place for beta-blockers in controlling episodes of fainting in CMVI dogs is not clear. Reports indicate positive results of carvedilol in some dogs.[67] However, beta-blockers may reduce myocardial performance and some CMVI dogs do not tolerate this type of therapy.

201.1.13.4 Patients with Pulmonary Edema Secondary to CMVI

Considering the pathophysiology of CMVI, therapy should be directed toward (1) reduction of the venous pressures to alleviate edema and effusions, (2) maintainance of adequate cardiac output to prevent signs of weakness, lethargy and prerenal azotemia, (3) reduction of the cardiac workload and regurgitation, and (4) protection of the heart from negative long-term effects of neurohormones. Cases with mild pulmonary edema may be managed on an outpatient basis with regular re-examinations. Cases with moderate to severe pulmonary edema may need intensive care, including cage-rest and sometimes oxygen supplementation.

201.1.13.5 Mild to Moderate Heart Failure

Patients with mild to moderate heart failure usually present with cough, tachypnea, and dyspnea. It is not common for an untreated dog in congestive heart failure to present initially with isolated significant ascites. Signs of congestive heart failure are usually present on thoracic radiographs as pulmonary venous congestion and increased pulmonary opacity. In some cases, it may be difficult to appreciate mild edema owing to obesity, chest conformation, underinflated lungs, or presence of age-related changes. Radiographs from the patient obtained before the onset of clinical signs may be helpful for comparison. Dogs with mild to moderate heart failure should be treated. Treatment can often be managed on an outpatient basis and should include a diuretic, such as furosemide, and an ACE-inhibitor. The place of digoxin and other positive inotropes are more controversial for treating dogs with mild to moderate heart failure (see below). The dosage of furosemide should preferably be based on clinical signs rather than radiographic findings. A patient may breathe with ease even in the presence of radiologic signs of interstitial edema, or vice versa. The usual course of treatment of a case with mild to moderate heart failure is an initial intensive treatment with furosemide (2 to 4 mg/kg q8-12h) for 2 to 3 days, after which the dosage of the diuretic is decreased to a maintenance level, such as 1 to 2 mg/kg every 12 to 48 hours or lower. More severe cases of heart failure may require higher dosages. It is important to use an appropriate dosage of diuretic to relieve clinical signs

but to avoid an unnecessarily high maintenance dosage. Overzealous use of diuretics may lead to weakness, hypotension, syncope, aggravation of prerenal azotemia, and acid-base and electrolyte imbalances. Often the owner can be instructed to vary the dosage, within a fixed dose range, according to the need of the dog.

The dosage of ACE-inhibitor (e.g., enalapril, benazepril, lisinopril, ramipril, and imidapril) is usually fixed and depends on the specific ACE-inhibitor used. ACE-inhibitors are indicated in advanced CMVI with heart failure in combination with diuretics, because dogs in large placebo-controlled clinical trials receiving an ACE-inhibitor have been shown to have less severe clinical signs of disease, better exercise tolerance,[68–70] and live longer than those not receiving an ACE-inhibitor.[68–70] In the dose range that is recommended for use in dogs and cats, the vasodilating actions of the drugs are not prominent and side effects associated with hypotension, such as fainting and syncope, are rare.[14,65,69,70] A reason for this may be that the short-term effects of ACE-inhibitors on the circulation are dependent on the activity of the RAAS prior to administration of the drug, the higher activity the more pronounced effect of the drug.[62] In combination with diuretics, such as furosemide, the ACE-inhibitors have synergistic effect with the diuretic by counteracting the reflectory stimulation of RAAS that occurs in diuretic therapy. Thus they decrease the tendency for fluid retention and counteract a peripheral vasoconstriction and other negative effects on the heart.

Digoxin is controversial in treating dogs with CMVI. There is generally a lack of scientific evidence supporting the use of digoxin. Many cardiologists, however, initiate digoxin therapy when signs of heart failure first appear. Although digoxin is a comparably weak positive inotrope and myocardial failure may not be a prominent feature of CMVI until progressed stages, digoxin has a place in heart failure therapy by reducing reflex tachycardia, by normalizing baroreceptor activity and by reducing central sympathetic activity.[71] Thus digoxin may be useful to reduce the heart rate, such as when hydralazine is administered, or in supraventricular tachycardia such as atrial fibrillation, and to abolish or limit the frequency of syncope (see above).

The place for a positive inotrope in the management of CMVI is controversial, since in small dogs signs of left-side heart failure usually precede overt myocardial failure. Nevertheless, the combined calcium sensitizer/PDE III inhibitor pimobendan is now approved for veterinary use in dogs with DCM and CMVI in many European countries, Canada, and Australia at a dose of 0.25 mg/kg every 12 hours PO. Data from controlled clinical trials of pimobendan in veterinary patients is available, although its efficacy is less documented in CMVI than in DCM. Recently, two controlled clinical trials (the PITCH trial and a recently completed study from UK) were presented (unpublished).[72,73] The results indicate that dogs with CMVI receiving pimobendan as adjunct therapy to diuretics show less severe signs of heart failure and are less likely to die or reach the treatment failure end-point than those receiving an ACE-inhibitor and diuretics. Many practitioners using pimobendan have experienced a dramatic improvement in overall clinical status in some CVMI dogs, even in dogs without overt myocardial failure. The reason for this may be that pimobendan, in addition to being a positive inotrope, has arterial vasodilating properties and differs from the pure PDE III antagonists (such as milrinone) in that it increases myocardial contractility with minimal increase in myocardial energy consumption. Furthermore, positive inotropes may theoretically reduce the MR by decreasing the size of the left ventricle and the mitral valve annulus through a more complete emptying of the left ventricle. However, the increased contractility may also theoretically lead to an increased systolic pressure gradient across the mitral valve and thereby generate increased regurgitation in some cases with high peripheral vascular resistance and increase the risk for chordal rupture in affected dogs. Therefore some cardiologists initiate pimobendan as adjunct therapy to other heart failure treatment in CMVI dogs only when echocardiographic evidence of reduced myocardial performance (increased left ventricular end-systolic dimension) is evident. Whether or not this treatment strategy is the optimal use of

calcium sensitizers has not been evaluated. Some cases of CMVI with evidence of myocardial failure have evidence of disseminated myocardial micro-infarctions, most commonly as a consequence of widespread arteriosclerosis.[28,29] Some of these patients might benefit from prophylactic antithrombotic and antiplatelelet therapy, although this has not been evaluated in veterinary medicine.

The way dogs with mild to moderate heart failure are managed after initiation of therapy varies. Typically, the dog is re-examined after 1 to 2 weeks of therapy, if the dog is managed on an outpatient basis, to monitor therapeutic outcome and to establish a suitable maintenance dosage of diuretic. Should the treatment response be satisfactory after this visit, dogs may often be managed by phone contacts and re-examinations every 3 to 6 months. More severe cases may require more frequent monitoring of the disease. In areas with a seasonal climate it may be valuable to re-examine the dog before the temperature increases and instruct the owner to avoid high ambient temperatures. The use of low-sodium diets as complementary therapy in heart failure is controversial. Currently, there are no clinical studies to support that they are beneficial in managing heart failure in dogs and cats. However, dogs with symptomatic CMVI should avoid excessive intake of sodium. Dogs that are stable on their heart failure therapy usually tolerate walks at their own pace, but strenuous exercise should be avoided.

201.1.13.6 Recurrent Heart Failure

Once an appropriate maintenance dosage of furosemide has been set in a CMVI patient with decompensated heart failure, the dosage has to be gradually increased, often over weeks or years. Reasons for increasing the dosage often include recurrent dyspnea caused by pulmonary edema or the development of ascites. Severe ascites, which compromises respiration, may require abdominocentesis. Many CMVI cases with less severe ascites respond to an increased dose of diuretics. Even in case of abdominocentesis, the diuretic dosage should be increased as the ascites will re-occur without changed medication after evacuation. When the dosage of furosemide has reached a level of approximately 4 to 5 mg/kg every 8 to 12 hours, sequential blocking of the nephron should be considered by adding another diuretic. The drug of choice is spironolactone (1 to 3 mg q12-24h PO) which is an aldosterone antagonist and a potassium-sparing diuretic. A thiazide, such as hydrochloro-thiazide (2 to 4 mg/kg q12h PO), or triamterene (1 to 2 mg/kg q12h PO) or amiloride (0.1 to 0.3 mg/kg q24h PO), may also be considered. The documentation of triamterene and amiloride in veterinary medicine is limited.

Because the furosemide treatment precedes and is used concomitantly with these drugs, the risk of hyperkalemia is low, even when they are added to a patient that is currently treated with an ACE-inhibitor. The risk of inducing prerenal azotemia, hypotension, and acid-base and electrolyte imbalances increases with the intensity of the diuretic treatment. However, the practitioner usually has to accept some degree of these disturbances when treating a patient with heart failure and, although common, they seldom result in clinical problems. A calcium senzitizer (pimobendan) is often introduced in cases with recurrent heart failure, as echocardiographic evidence of systolic dysfunction often has developed (see above).

201.1.13.7 Severe and Life-Threatening (Fulminant) Heart Failure

The causes of acute severe heart failure are often a ruptured major tendinous chord, development of atrial fibrillation, undertreatment of existing heart failure, or intense physical activity, such as chasing birds or cats, in the presence of significant CMVI. Patients with severe heart failure have radiographic evidence of severe interstitial or alveolar edema and have significant clinical signs of heart failure at rest. They are often severely dyspneic and tachypneic and have respiratory rates in the range of 40 to 90. They may cough white or pink froth, which is edema fluid. These dogs require immediate hospitalization and aggressive

treatment. However, euthanasia should also be considered, if the dog is already on high doses of diuretics and other heart failure therapy, owing to the poor long-term prognosis. It is important not to stress dogs with severe or fulminant heart failure as stress may lead to death. Therefore thoracic radiographs and other diagnostic procedures may have to wait until the dog has been stabilized.

Dogs with significant dyspnea benefit from intravenous injections of furosemide at a relatively high dose (4 to 6 mg/kg q2-6h IV). The furosemide may be administered intramuscularly should placement of an intravenous catheter not be possible. Dogs with fulminant pulmonary edema may require Herculean furosemide doses at 6 to 8 mg/kg every 2 to 8 hours IV over the first 24 hours. The exact dosage of furosemide depends not only on severity of clinical signs but also on whether or not the dog is already on oral furosemide treatment. Oxygen therapy is always beneficial in hypoxemic patients and it can preferably be administered using an oxygen cage provided that the temperature can be controlled inside the cage. Nasal inflation or a facial mask may also be used provided that the animal accepts them without struggle. Once the dog has received furosemide and oxygen treatment, an arterial vasodilator and a positive inotrope may be considered to stabilize the patient.

Commonly used vasodilating agents are hydralazine per os or intravenous nitroprusside (2.0–10 mg/kg/min). Of these two vasodilators, hydralazine is most commonly used. Owing to the severity of heart failure, dogs without previous vasodilating therapy may receive an initial dose of hydralazine of 1 to 2 mg/kg PO. Titration of the hydralazine dosage as described above is indicated in dogs already on an ACE-inhibitor and blood pressure should be monitored to detect hypotension. Nitroprusside can only be administered as an intravenous infusion, which requires an intravenous catheter. This potent vasodilator has actions on both the venous and arterial circulation. However, it is not easy to control the effects of nitroprusside and the dosage has to be titrated under careful blood-pressure monitoring to avoid serious hypotension and to ensure efficacy. These disadvantages have prevented nitroprusside from being a commonly used arterial vasodilator.

A positive inotrope such as dobutamine, or more commonly the calcium-sensitizer pimobendan (0.25 mg/kg q12h PO), may be considered to stabilize the patient with fulminant heart failure. Pimobendan may be administered together with furosemide without any arterial vasodilator as the drug has vasodilating properties itself. The dose of any concurrently administered arterial vasodilator has to be adjusted. Dobutamine is administered as a constant infusion usually in combination with nitroprusside. One problem with dobutamine that limits its use is that the patient needs to be weaned from IV to oral therapy within 1 to 2 days.

1033 1034

Patients with severe or fulminant heart failure need frequent initial monitoring of the respiratory rate because it reflects the clinical response to the furosemide treatment. Significantly decreased respiratory rate within the first hours indicates successful therapy, whereas absence of change indicate that furosemide is required at a higher dose or more frequently. Once the respiratory rate has decreased, the dose of furosemide may be reduced according to the status of the animal and clinical judgment. Abnormal laboratory findings such as pre-renal azotemia, electrolyte imbalances and dehydration are common after high doses of furosemide. Again, these abnormalities are seldom a clinical problem and the laboratory values often tend to shift towards normal with clinical improvement and as the dog starts to eat and drink. Dehydration is usually not severe even after intensive furosemide treatment and intravenous rehydration should be performed slowly and with caution in cases where it is needed, as the volume challenge may produce pulmonary edema.

201.1.14 Complications

201.1.14.1 Acute Exacerbation of Pulmonary Congestion and Edema due to Ruptured Chordae Tendineae

Ruptured chordae tendineae (RCT) may be suspected in all dogs that suffer from CMVI with drastic aggravation of pulmonary congestion and edema, whereas RCT is a rare finding in cats. It is not unusual for the RCT to be a result of extra-ordinary stress or exercise (e.g., chasing cats or birds). The most important ruptures involve those of first order chordae that are attached to the septal leaflet, and these patients are expected to die rapidly from acute volume overload and fulminant pulmonary edema. Ruptures of lesser order chordae or perhaps first order chordae that are attached to the free wall leaflet may result in minor clinical signs or none at all. Significant RCT causes acutely increased MR, and the clinical findings may differ from those encountered in chronic MR. Due to the acute increase in MR, there may be a marked increase in left atrial and pulmonary venous pressures leading to acute pulmonary edema, pulmonary artery hypertension and right heart failure.[34,39,41]

The physical examination of these patients often reveals a heart murmur of lower intensity than that of chronic MR, an S3 gallop is more likely to be present, and jugular venous distention is more likely to be present with pulsations. The radiographic and echocardiographic findings of cardiac size vary, depending on how far the CMVI had progressed before the onset of RCT. Doppler echocardiography shows severe MR, and a flail segment of the mitral valve leaflet may be detected using two-dimensional views. Thoracic radiographs show a markedly increased interstitial and alveolar pattern with distention of the pulmonary veins. These patients require intensive care to stabilize the condition, and thereafter maintainance therapy for CMVI (see under Management section). As long as a first order chordae attaching to the septal leaflet has not occurred, many of these cases may sustain with the aid of appropriate medication.

201.1.14.2 Right-Sided Heart Failure due to Pulmonary Hypertension

Many patients with long-standing history of CMVI develop right-sided heart failure. It is presumed that this condition develops as a consequence of concurrent chronic tricuspid insufficiency attributable to myxomatous degeneration, or the development pulmonary hypertension, or a combination of both. In CMVI, the pulmonary hypertension is believed to develop secondary to the persistent elevation of the left atrial and pulmonary venous pressures, but concurrent chronic airway disease may also contribute. Because the right ventricle is thinner and more compliant than the left ventricle, it can accept relatively large increases in volume but not in pressure.[74] Even small increases in pulmonary artery pressure cause sharp decreases in right ventricular stroke volume.[74] Individuals with pulmonary hypertension are sensitive to exercise, with signs of weakness or collapse, even at mild exercise. A physical examination may reveal evidence of right heart failure, such as ascites, pleural effusion, hepatic and splenic congestion, and distention of the jugular veins with abnormal pulsations. The presence and degree of pulmonary hypertension may be indirectly quantitated by Doppler echocardiography (see later section on TVI).

Individuals with pulmonary hypertension may be difficult to manage. The goal of therapy is to eliminate contributing factors and restrict even mild exercise. Oxygen supplementation is indicated in cases of acute collapse. Since persistently increased left atrial and pulmonary vein pressures are in large part responsible for the condition, therapy should be directed as for CMVI with pulmonary congestion (see Management). At present, there is no vasodilator available that specifically acts on the pulmonary artery, but it appears

that hydralazine may be one of the better drugs in this aspect.[41] In humans, several endothelin-receptor antagonists are either launched or in Phase II or III clinical trials for treatment of pulmonary hypertension. So far, the experiences with these drugs in dogs are limited. Bronchodilator therapy may also be indicated, and methylxanthines and beta 2-selective agonists may be considered in these cases. Aggressive diuretic treatment may be required to resolve ascites, if present.

201.1.14.3 Acute Exacerbation of Pulmonary Congestion due to Tachyarrhythmia

An enlarged left atrium predisposes to supraventricular premature beats, atrial fibrillation, and supraventricular tachycardia. Ventricular arrhythmias are less common but may occur in progressed cases. A tachycardia with a ventricular rate greater than 180 bpm is of hemodynamic significance. These patients often have a long-standing history of CMVI, with an acute onset of pulmonary edema. In addition to other findings characteristic of CMVI, these cases have a change in cardiac rhythm. The goal of therapy is to relieve the pulmonary edema, as described earlier under management, and to reduce heart rate to an acceptable rate for improving cardiac output. Digoxin is the drug of choice in cases with supraventricular tachycardia. Should this fail to control heart rate, diltiazem (0.5 to 1.5 mg/kg q8h PO) or a beta1-receptor antagonist such as, atenolol (6.25 to 12.5 mg/kg q12h PO) or metoprolol (0.5 to 1 mg/kg q8-12h PO), could be added. It should be noted that some individuals with CMVI are highly dependent on sympathetic drive so that these drugs may not be well tolerated in the recommended dose range. Therefore both types of drugs should be initiated at the lowest possible dose and then gradually increased with careful monitoring.

201.1.14.4 Left Atrial Rupture and Cardiac Tamponade

As a consequence of the left atrial dilatation in CMVI the left atrium becomes thin walled and more vulnerable to increases in pressure, such as in the case of a ruptured tendinous chord or trauma. Endocardial splitting is a frequent postmortem finding in dogs with a history of long-standing CMVI.[7] The significance of this finding is that it may progress to rupture of the left atrium with the sudden development of hemopericardium, cardiac tamponade, and sudden death. Most cases with atrial rupture and cardiac tamponade are expected to die suddenly. There is often a history of trauma, excitement, or physical exercise, preceding the atrial rupture and sudden death. For those dogs that survive the initial event, clinical signs of cardiac tamponade together with signs of CMVI can be found. Thus acute development of ascites, collapse, or marked exercise intolerance are to be expected. The physical examination may reveal signs of pericardial effusion (see separate chapter) together with evidence of CMVI. Echocardiography is often required for definite diagnosis by identifying the presence of significant pericardial effusion, whereas the left atrial tear is often difficult to detect. Treatment of atrial rupture with hemopericardium and cardiac tamponade is usually futile. Immediate pericardiocentesis is indicated, and pericardial fluid should be removed to alleviate the tamponade without removing so much that further bleeding is stimulated. If the bleeding continues after pericardiocentesis, the final option is emergency thoracotomy with pericardiectomy and closure of the tear, but the prognosis for this procedure is poor to grave.

1034
1035

201.2 TRICUSPID VALVE INSUFFICIENCY

Since the advent of Doppler echocardiography, tricuspid valve insufficiency (TVI) has been recognized as a common incidental finding in dogs and cats.[75] TVI of clinical significance most often occurs concomitantly with chronic CMVI as a consequence of primary valvular changes, secondary right ventricular enlargement, or both.[7] In these circumstances, the degenerative changes of the tricuspid valve apparatus are identical to those found in

CMVI (see Pathology section).[7] Other conditions that may affect the tricuspid valve apparatus itself include infective endocarditis and, more seldom, chordal rupture.[7,44,54] Secondary or functional TVI may occur as a consequence of right ventricular dilatation in all conditions associated with an acquired increase in right ventricular pressure. These include heartworm disease, pulmonary thromboembolism, pulmonary hypertension secondary to left heart disease, and idiopathic pulmonary hypertension. In addition, secondary TVI occurs in biventricular or right ventricular dilated cardiomyopathy and in congenital pulmonic stenosis. TVI occurs in cats with cardiomyopathy and hyperthyroidism.[76]

201.2.1 Consequences (Pathophysiology)

TVI, in the absence of concurrent obstruction of the pulmonary valve or pulmonary artery hypertension, is comparably well tolerated.[77] However, because the right ventricle is designed to contract against a low-pressure artery, it is vulnerable to increases in pressure. It responds poorly to the increased work; even relatively small acute increases in pulmonary artery pressure cause sharp decreases in right ventricular stroke volume.[74] Thus TVI is of significance if pulmonary hypertension is present. In addition to the right ventricular dilatation, right atrial enlargement develops and adds to the tricuspid annular dilatation and TVI. Enlargement of this chamber may result in atrial tachyarrhythmias, such as atrial fibrillation and supraventricular tachycardia. As a consequence of increased right atrial pressure, ascites, pleural effusion (especially in cats), pericardial effusion, hepatomegaly, and splenomegaly may develop.

201.2.2 Clinical Signs

Isolated TVI does not commonly result in clinical signs of disease.[7,41,54] Evidence of reduced exercise tolerance, weakness, or syncope occur mainly in instances with pulmonary hypertension, such as secondary to CMVI or tachyarrhythmia. It is common for these animals to show signs of right heart failure that may include respiratory distress due to pleural effusion; abdominal distention due to ascites, hepatomegaly, or splenomegaly; or gastrointestinal signs such as diarrhea, vomiting, and anorexia.

201.2.3 Physical Examination

Significant TVI is characterized by a holosystolic murmur with varying intensity and with the point of maximal intensity over the tricuspid area, and, in some cases, by the presence of venous distention and pulsations in the jugular veins. The heart sounds may be muffled by pleural effusion. Abdominal distention may be present with ascites, hepatomegaly, or splenomegaly. A rapid irregular heart rhythm and femoral artery pulse are observed in the presence of tachyarrhythmia, and pulse deficits may be detected. A weak femoral artery pulse may be found in cases with pulmonary hypertension or left-side heart failure.

201.2.4 Electrocardiographic Findings

ECG has a low sensitivity in detecting right atrial and right ventricular enlargement secondary to primary TVI.[7] In significant TVI with pulmonary hypertension, the ECG changes may include evidence of right atrial enlargement (tall P wave), a right ventricular enlargement pattern, and a right deviation of the mean electrical axis.[47] However, even in severe cases of TVI and pulmonary hypertension secondary to CMVI, these signs may not be obvious because of the concurrent changes to the left cardiac side. In these cases, the recording

may only show evidence of left side involvement.[7,41] Arrhythmias, such as supraventricular premature beats, atrial fibrillation, and ventricular premature beats, may be noted.

201.2.5 Radiographic Findings

Mild right atrial and ventricular enlargement are usually not associated with detectable radiologic signs. Signs of moderate to severe right atrial enlargement in lateral projection include bulging of the right atrium in the craniodorsal direction. This causes the cranial border of the heart to appear straight rather than convex and elevates the trachea as it courses dorsally over the right atrium. In addition to elevations of the trachea and caudal vena cava, signs of right ventricular enlargement include increased sternal contact and rounding of the right heart border. In the dorsoventral (or ventrodorsal) projection, the enlarged right atrium may be identified as a bulge in the right cranial part of the cardiac border (in the 9 to 12 o'clock position). The border of the enlarged right ventricle appears rounded and, in severe enlargement, it may resemble an inverted “D” sign. There is a shift of the cardiac apex to the left. Signs of right heart failure may be observed including pleural effusion, abdominal effusion, hepatomegaly, and splenomegaly. If biventricular failure occurs, the global cardiac size will be increased and signs of left heart failure may be present.

201.2.6 Echocardiographic Findings

Echocardiography is useful to detect increased right atrial and right ventricular size and for evaluation of tricuspid valve morphology. Thus it is an important tool to rule out differential diagnoses, such as an undiscovered congenital heart defect. The echocardiographic appearance of the tricuspid valve with myxomatous degeneration is similar in two-dimensional mode to myxomatous lesions on the mitral valve already described (see CMVI Echocardiography section). With the use of color-flow Doppler, TVI may be detected and semiquantified. The right atrium is, however, not as easily accessible as the left atrium owing to the anatomy, and the orientation of TVI jets is not consistent. The Doppler echocardiographic findings in TVI are similar to those of MR with a few exceptions. Trivial, physiologic TVI is common in dogs and this regurgitation is usually silent to auscultation. Spectral Doppler may be used to estimate right ventricular stroke volume and to identify pulmonary hypertension by estimation of right ventricular systolic pressure and pulmonary arterial systolic and diastolic pressures.[54] The right ventricular pressure is estimated by finding a tricuspid regurgitant jet and measure its peak velocity by continuous-wave Doppler. TVI jet velocities generally peaks at approximately 2.6 m/sec, unless there is elevation of right ventricular pressure that forces blood at a higher velocity, usually above 3 m/sec.[58] The pressure gradient between the right atrium and ventricle may be calculated with use of the peak velocity of the regurgitant jet and the modified Bernouilli equation.[78] The right ventricular pressure is obtained by adding an estimate of the right atrial pressure to the pressure gradient over the AV-valve. It has been suggested that appropriate estimates of right atrial pressure is 5 mm Hg in patients without right heart failure and 10 to 15 mm Hg in patients with right heart failure.[54] Similarly, the peak velocity of a pulmonic valve regurgitation and an estimate of right ventricular diastolic pressure may be used to predict pulmonary artery diastolic pressure.[79]

1035 1036

201.2.7 Management

Because primary TVI is usually relatively benign, patients with clinical signs of right-sided heart failure with suspected TVI must be thoroughly evaluated for concurrent conditions that may mimic or exaggerate TVI. Examples of these include congenital heart defects, heartworm disease, CMVI, pulmonary hypertension, pericardial effusion, restrictive pericarditis, and mitral valve stenosis. The signs of right heart failure, that is,

abdominal and pleural effusions, may be alleviated with diuretic treatment and often involves two or more drugs to obtain sequential blocking of the nephron (see CMVI under Management), but abdominocentesis may be required. If tachyarrhythmia is present, successful management depends on controlling the increased heart rate or preferably abolishing the tachyarrhythmia.

201.3 SEMILUNAR VALVE INSUFFICIENCY

With the advent of color flow echocardiography, a low degree of aortic and, more commonly, pulmonic valve insufficiency are frequently detected.[75] This finding may be of no clinical significance but in others it occurs with different types of congenital heart disease. Aortic valve insufficiency (AVI) occurs most often in dogs as a consequence of subaortic stenosis and pulmonic valve insufficiency (PVI) of pulmonic valve stenosis.[7,41,54] Acquired AVI of clinical significance, except in association with bacterial endocarditis (see Infective Endocarditis), is a rare disorder in dogs and cats. PVI is observed in the majority of cases with pulmonary artery hypertension, and secondary to pulmonary artery dilatation, such as in PDA and severe heartworm disease. Isolated PVI as cause of clinical signs is extremely rare. Although myxomatous degeneration is sometimes evident at postmortem on one or both semilunar valves,[7,41,54] it is not expected to have caused significant insufficiency associated with clinical signs.

201.4 INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) is a life-threatening disorder that results from microorganisms that colonize the cardiac endocardium, which commonly causes destruction of valves or other structures within the heart. Bacteremia is by far the most common etiology, with the mitral and aortic valve most frequently affected.[80] Vegetation may cause thromboembolism or metastatic infections, which involve multiple body organs and produce a large variety of clinical signs which makes diagnosis difficult. The incidence of infective endocarditis in necropsied dogs has been reported to range from 0.06% to 6.6%.[41,81] Evaluation of clinical data from university animal hospitals points to IE as a comparably rare condition with incidences ranging from 0.04% to 0.13%.[82] Medium to large breed, mainly purebred, middle-aged male dogs are reported to be predisposed.[80] The incidence in cats, based on clinical experience, is considered to be 7 to 10 times lower than in dogs.[82,23] Animals with congenital heart disease have a low incidence of IE[41,80], but associations have been reported with subaortic stenosis[84] and occasionally with PDA.[85] IE has not been found to have any association with CMVI in dogs.[13,41,81]

201.4.1 Pathology

Vegetation associated with by IE mainly affects the left heart with the highest incidence involving the mitral valve.[86] Involvement of the right heart or mural endocardium is uncommon.[86] Pathologic findings vary and depend on the virulence of the infecting organism, the duration of infection, and the immunologic response. Intracardiac vegetation consists of different layers of fibrin, platelets, bacteria, red and white cells, and is often covered by an intact endothelium. Bacteria may continue to grow despite antibiotic therapy owing to the location deep within the vegetation and a slow metabolic rate (Figure 201-8).[87] Necrosis and destruction of the valve stroma or chordae tendineae proceed rapidly in peracute or acute IE, which causes valvular insufficiency and cardiac failure.

201.4.2 Etiology and Pathogenesis

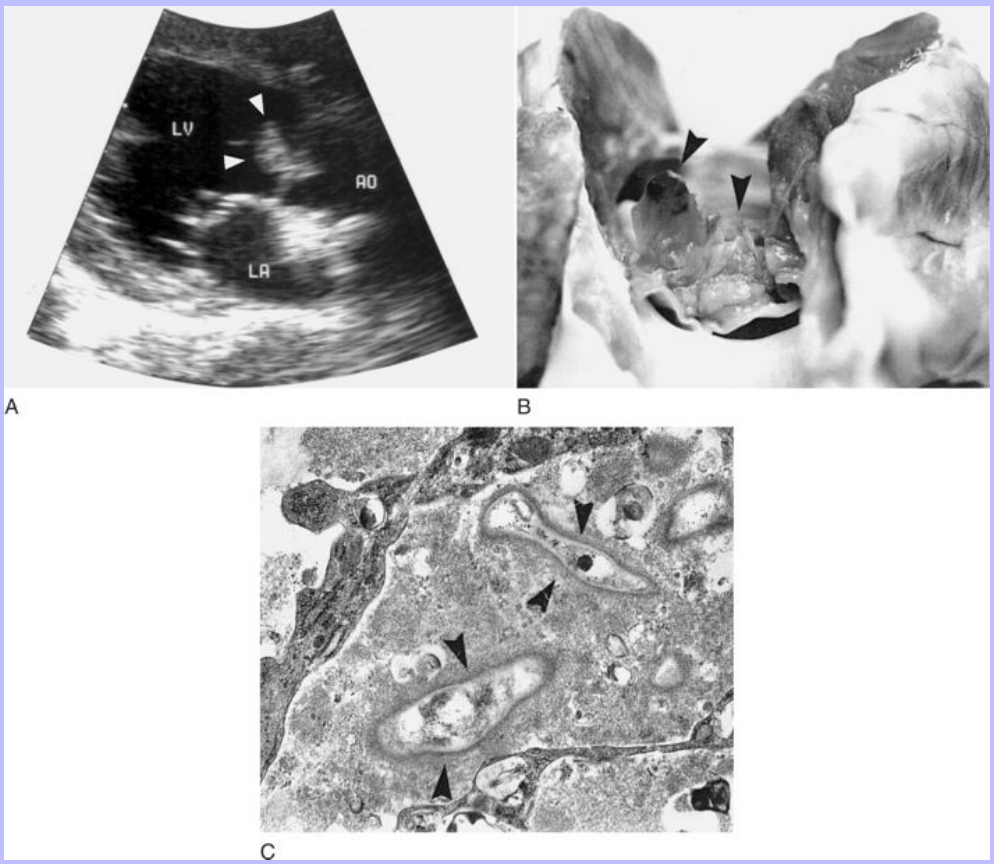
Transient or persistent bacteremia is a prerequisite for the development of IE. A large number of bacteria have been associated with bacteremia[88] (see section on Blood Culture below) and some are known to cause IE.[86,88] Most bacteria require predisposing factors to cause IE, such as depression of the immunosystem or endothelial damage, sometimes with depositions of platelet-fibrin complexes, to adhere to the valve and create IE.[87] The origin of the bacteremia may be active infection localized somewhere within the body.[88] A proportion of cases with IE has no clinically detectable source of infection.[86,88] Possible routes for bacteria to reach and infect the endocardium are by direct contact with the surface endothelium via the bloodstream or from capillaries within the valve (vasculitis).[89]

The consequences of IE depend on several factors: virulence of the infective agent; site of infection; degree of valvular destruction; influence of vegetation on valvular function; production of exo-or endotoxins; interaction with the immunosystem with the formation of immunocomplexes[90]; and development of thromboembolism and metastatic infections. Gram-negative bacteremia results often in a peracute or acute clinical manifestation, whereas gram-positive bacteremia typically results in a subacute or chronic condition. The vegetation may cause valvular insufficiency or obstruction. The destruction of valvular tissue is caused by the action of bacteria or the cellular response from the immunologic system. Deposition of immunocomplexes in different organs may cause glomerulonephritis, myositis, or polyarthritis.[90] Septic embolization that produces clinical signs is uncommon but 84% of affected dogs had evidence of systemic embolization at necropsy and glomerulonephritis was reported in 16% of 44 dogs with IE.[80]

201.4.3 Case History and Clinical Signs

The diagnosis of IE can easily be overlooked because the case history and clinical signs are not specific and there may be an absence of predisposing factors to raise the suspicion of IE. Clinical signs are variable and occur in different combinations. Commonly reported signs include lethargy, weakness, fever (sometimes recurrent), anorexia, weight loss, GI disturbances, and lameness.[80,90] Stiffness and pain originating from joints or muscles may be caused by immunomediated responses and abdominal pain may be caused by secondary renal or splenic infarction, septic embolization, or abscess formation. If the condition leads to severe valvular damage, especially of the aortic valve, signs of cardiac failure and syncope from arrhythmias may occur. Predisposing factors that in combination with the clinical signs above, should raise the suspicion of IE are immunosuppressive drug therapy, such as corticosteroids[88,91]; aortic stenosis[84]; recent surgery, especially in conjunction with trauma to mucosal surfaces in the oral or genital tract and infections in these body regions, especially prostatitis; indwelling catheters, infected wounds, abscesses, or pyoderma.[88]

Figure 201-8 **A,** Echocardiographic long axis view from a 3-year-old male boxer. The dog had previously been diagnosed with slight aortic stenosis but had recently suffered recurrent episodes of fewer and lethargy. An irregular-shaped echogenic mass was attached to the aortic valve *(white arrowheads)*. **B,** A valvular vegetation *(arrowheads)* localized to the base of the aortic valve leaflet was evident at postmortem examination. **C,** Electron micrograph showing two rod-shaped bacteria *(arrowheads)* about 1μ in diameter located intracellularly in a phagocytic cell found within the vegetation (original magnification × 35000). (Courtesy L. Jönsson and T. Nikkile, Upsala, Sweden.)



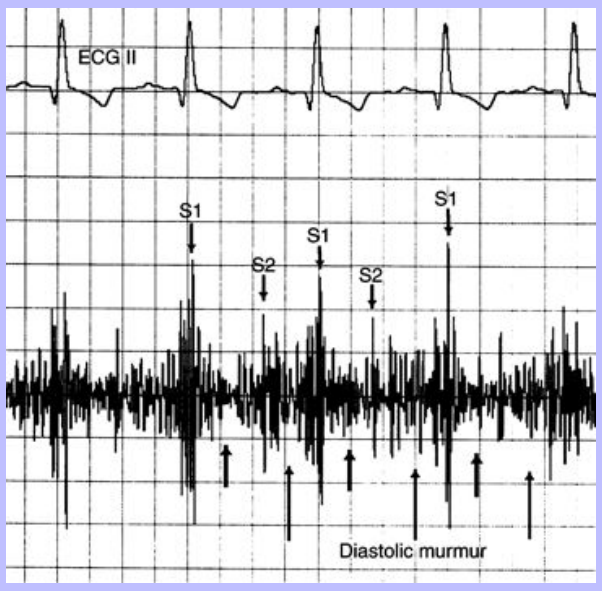
201.4.4 Physical Examination

Most clinical signs lack specificity for IE. However, fever, heart murmur (particularly if newly developed), and lameness are considered classical signs. Fever is reported to occur in 80% to 90% in dogs with IE.[80]

Absence of fever is reported to be more common in cases with aortic valve involvement[86] but may also be attributed to treatment with antibiotics or corticosteroids. Since aortic insufficiency is otherwise uncommon in dogs, the finding of a diastolic murmur (Figure 201-9) and bounding peripheral pulse should raise the suspicion of IE of the aortic valve. Systolic murmurs may be caused by destruction of the mitral valve, which results in MR or vegetations that obstruct the aortic outflow tract, which leads to stenosis.[80] These murmurs are, in contrast to diastolic murmurs, poor indicators of IE since they frequently occur in dogs with other conditions, such as CMVI and aortic stenosis. It should be noted that 26% of dogs with IE are reported to lack audible murmurs.[80] Lameness is also an inconsistent finding in IE with an incidence of 34% in one study.[81] A range of other physical findings may be present, depending on which organs are affected by circulating immunocomplexes or septic embolization. Possible findings are pain reactions from muscles or abdomen (spleen, intestines, or kidneys), cold extremities, cyanosis, and skin necrosis from severe embolization and a variety of neurologic disturbances if the central nervous system is affected.

1037 1038

Figure 201-9 Phonocardiogram (PCG) and ECG lead II recorded from a dog with a diastolic murmur from aortic regurgitation caused by IE. A systolic murmur from mitral regurgitation is also present *(thick arrows)*, which in combination with the diastolic murmur from aortic regurgitation causes the auscultatory finding of a continuous murmur easily be misinterpreted to be caused by PDA. The PCG rules out the diagnosis of PDA as the lowest murmur intensity recorded is around the second heart sound (S2). Continous murmurs caused by PDA usually has maximal intensity at the location for S2.[44] The PCG is filtered with a nominal frequency of 100 Hz. *S1*, First heart sound; *S2*, second heart sound.



201.4.5 Blood Culture

Positive blood cultures are crucial evidence of IE. The theory that bacteremia from IE is intermittent has changed in recent years to the opinion that, if existent, it is continuous.[87] Thus negative or intermittent positive cultures are unusual when collection and handling of samples is conducted properly.[87] The time for sampling is probably not critical, but a constant finding through repeat samplings is valuable to exclude sample contamination. The technique for obtaining samples aseptically and anaerobically is important and described in detail below. In cases of positive blood culture, it is important to evaluate if the microorganism is consistent with the diagnosis of IE.

Microorganisms known to cause IE in dogs are, in order of reported incidence, *Staphylococcus aureus, E. coli*, betahemolytic streptococci, *Pseudomonas aeroginosa*, *Corynebacterium* spp., *Erysipelothrix rhusiopathiae (tonsillarium)*[86], and *Bartonella vinsonii*.[92] *B. vinsonii* and related proteobacteria has recently been recognized as a potential cause for endocarditis in dogs. They have been found in dogs with cardiac arrhythmias, endocarditis, or myocarditis.[93] *Bartonella* spp. are also a potential cause for IE in cats.[94] Furthermore, *Bartonella* spp. have been reported to occasionally cause IE in immunocompromised (but also immunocompetent) humans, with the cat serving as the major reservoir (cat scratch disease). The recommended antibiotic therapy when the resistance is unknown is erythromycin or doxycycline. Immediate antibiotic therapy of humans after significant dog or cat bites may furthermore be motivated as commensals, such as *Capnocytophaga canimorsus*, in the saliva of dogs and cats have been reported to occasionally cause septicemia with a mortality as high as 30%.[95,96] Negative blood cultures are fairly common and may be due to antibiotic therapy, chronic situations with “incapsulated” infections, noninfective IE (only platelets and fibrin in vegetation), or failure to grow organisms from samples. Some bacteria may grow slowly and samples should not be regarded as definitely negative until they have been incubated for 10 days. More common is a rapid growth of microorganisms with 90% of cultures positive within 72 hours of incubation.[97]

201.4.5.1 Obtaining Blood Cultures

The referral laboratory should be contacted concerning the preferred type of preprepared vials before obtaining a sample; special additives are available if the patient has been on antibiotics. Pediatric vials are useful because less blood is required but volumes in the range of 20 to 30 mL increase the chance for growth. To avoid contamination, strictly aseptic sampling should be observed which includes thorough shaving and disinfection of the sampling site and strict use of sterile gloves. Three samples with adequately filled vials from different puncture sites should be collected. If samples are collected with a syringe, suction should cease before withdrawal of the needle from the patient to avoid contamination with skin bacteria and a new sterile needle should be used for the transfer of blood into the bottles. The bottles should be prewarmed to 37° C and, after sampling, incubated at the same temperature. Sampling through indwelling catheters should be avoided but may be used as a second choice. The former recommendation to draw samples over 24-hour periods has changed, since multiple simultaneously drawn samples in humans have been shown to be equally sensitive.[87]

201.4.6 Electrocardiographic Findings

Arrhythmia is reported to occur in 50% to 75% of dogs with IE.[80,86] Ventricular premature beats and tachyarrhythmias are the most commonly encountered arrhythmias, but they are usually not life threatening.

Deviation in the ST-segment suggests myocardial hypoxia and may indicate coronary artery embolism or ischemia from heart failure. Evidence of chamber enlargement may occur in chronic IE. All the mentioned ECG abnormalities are, however, nonspecific.

201.4.7 Radiographic Findings

Radiography often does not add any information specific for IE. In cases of chronic IE with aortic or mitral insufficiency, left-sided cardiac enlargement may be detected. Calcified deposits on the valve leaflets are occasionally observed in chronic cases.

201.4.8 Echocardiographic Findings

Echocardiography has significantly improved the possibility of diagnosis and monitoring of animals with IE.[88] Valvular vegetations may be detected using two-dimensional echocardiography, although minor lesions may be difficult to distinguish from myxomatous lesions. M-mode can be used to measure secondary changes in cardiac size and to detect abnormal mitral valve motion such as fluttering from aortic regurgitation. Mitral or aortic regurgitation may be detected using continous or color-flow Doppler echocardiography.

201.4.9 Other Laboratory Findings

Mild anemia is found in 50% to 60% of cases with IE.[80,86] The anemia is similar to those from other infections, usually being normocytic and normochromic. Leukocytosis is found in about 80% of dogs with IE, usually due to neutrophilia and monocytosis (left shift). Other findings that may be encountered include elevated blood urea nitrogen (BUN) due to embolization, metastatic infection, heart failure, or immune-mediated disease. Urine analysis may reveal pyuria, bacteriuria, or proteinuria. Elevated serum alkaline phosphatase may be found, probably caused by circulating endotoxins[88] and reduced hepatic function, which may cause hypoalbuminemia.[81] The serum glucose concentration may be decreased and serologic tests for immuno-mediated disease, such as Coombs test, may be positive.[88]

1038

1039

201.4.10 Diagnosis

Since the clinical signs of IE are often a result of complications, rather than reflecting the intracardiac infection, the diagnosis may easily be overlooked. Major criteria for IE are positive blood cultures with typical microorganisms for IE from two separate samples plus evidence of cardiac involvement.[87] The localization and severity of cardiac lesions is confirmed by echocardiographic visualization of vegetations. In the absence of positive cultures, a tentative diagnosis of IE can be made if there is clinical and laboratory evidence of systemic infection, such as fever and leukocytosis plus cardiac involvement and possibly signs of embolization.

201.4.11 Management

The goal of therapy is to eradicate the infective microorganism and to treat all secondary complications. A successful outcome of the therapy is based on early diagnosis and immediate and aggressive treatment. Only bactericidal antibiotics capable of penetrating fibrin should be considered. The antibiotic concentration in serum and deep within vegetations should exceed the organisms minimal inhibitory concentration (MIC), but

preferably also the minimum bactericidal concentration (MBC), continuously or throughout most of the interval between doses. Treatment should continue for at least 6 weeks to eradicate dormant microorganisms.[87]

201.4.11.1 Management of Cases with Tentative Diagnosis of IE

A blood culture (see section above) and an antibiotic sensitivity profile should be obtained. While results from cultures and sensitivity tests are awaited, intravenous treatment with a high dosage of bactericidal antibiotic IV, such as cephalosporins (second generation), should be initiated. Alternatives to cephalosporins are combinations of ampicillin or amoxicillin for gram-positive organisms and gentamicin or amikacin for gram-negative organisms. An alternative to gentamicin and amikacin, which are potentially toxic and only recommended to be used for at most one week, is enrofloxacin for suspected gram-negative IE. Enrofloxacin is bactericidal and may penetrate myocardium and heart valves and is also indicated for treating *Bartonella* infections. Choice of anti-biotic should preferably depend on the suspected source of infection and the estimated resistance pattern for the primary infection. Practitioners should try to identify the source of infection and treat it as aggressively as possible, such as use of surgical drainage or debridement.[98] Possible secondary problems should be identified, such as heart or renal failure that need therapy or may impair the prognosis.

For dogs with heart failure from aortic regurgitation, hydralazine titered to an adequate reduction of arterial blood pressure is effective and should be considered as a part of medical therapy. When results are available from blood cultures, appropriate antibiotics are selected and aggressive IV treatment continued for 5 to 10 days while renal function is monitored. If results from cultures are negative, the decision to continue antibiotic therapy should be based on clinical improvement. Depending on the early outcome of therapy, subcutaneous administration may substitute a 5 to 10 days IV treatment, and later be superseded by oral preparations. The duration of therapy should be at least 6 weeks on the effective antibiotic. Frequent clinical examinations, blood screening, and urine analyses should be performed during that period.

201.4.12 Prognosis

Factors that indicate a poor prognosis include late diagnosis and late start of therapy; vegetations on valves (especially the aortic)[86]; gram-negative infections, heart or renal failure that do not respond to therapy; septic embolization or metastatic infection; elevation of serum alkaline phosphatase and hypo-albuminemia (70% mortality is reported if this is found in cases with IE)[81]; concurrent treatment with corticosteroids, regardless if antibiotics are given simultaneously[80,91]; treatment with bacteriostatic antibiotics or premature termination of anti-biotic therapy. Factors that indicate a more favorable prognosis include only mitral valve involvement (47% of dogs are reported to survive)[80]; gram-positive infections, origin of infection being the skin, abscesses, cellulitis, or wound infections.[88]

201.4.13 Prevention

Prophylactic antibiotics may be indicated 1 to 2 hours before and 12 to 24 hours after diagnostic or surgical procedures when turbulent blood flow is suspected to have damaged the endocardium, such as aortic stenosis, PDA, or VSD. In these cases, early treatment of all manifest infections is important to avoid bacteremia and reduce the risk for IE, and caution should be observed when bleeding or infection is anticipated or evident in the oral, urogenital, intestinal, or respiratory tract. Amoxicillin may be the first choice, but other antibio-tics,

such as clindamycin or cephalosporins, may also be considered depending on the organ system involved and site of infection.[87]

202 # CHAPTER • 202 Electrocardiography and Cardiac Arrhythmias

Etienne Côté

Stephen J. Ettinger

The diagnostic test of choice for clinical evaluation of cardiac arrhythmias is the electrocardiogram (ECG).[1–5] The ECG also has invaluable applications in monitoring patients with systemic abnormalities, including electrolyte disturbances and hypoxia. Additionally, abnormalities in the dimensions of various components of the ECG may serve as a rough guide for evaluating structural heart disease. These ECG morphologic criteria are rarely based on controlled studies identifying specificity and sensitivity, however, and ECG parameters for dogs or cats by breed, body type, age, and sex are not comprehensively established. An abnormal heart may have a normal ECG and vice versa. Therefore the ECG, like a blood count, is not an absolute indicator of normalcy or disease, and deviations from normal suggest but do not identify structural cardiac abnormalities (Boxes 202-1 and 202-2).

202.1 ## CARDIAC CONDUCTION SYSTEM AND ELECTROCARDIOGRAPHY

Each component of an ECG tracing reflects an electrical event occurring in a specific part of the heart.[1,2,5,6] The sequence of electrical events follows specific anatomic pathways within the heart, and in health, does so precisely and consistently (Figure 202-1).

202.1.1 202.1.1 ### Box • 202-1 Criteria for the Normal Canine Electrocardiogram (ECG)* (Note: Patient in right lateral recumbency; no ECG filtering†)

Heart rate: 70 to 160 beats per minute (bpm) in adult dogs; 60 to 140 bpm in giant breeds; up to 180 bpm in toy breeds; up to 220 bpm in puppies

Heart rhythm: normal sinus rhythm (NSR); respiratory sinus arrhythmia (RSA); wandering SA pacemaker common (cyclic changes in the R-R interval can be associated with cyclic alterations in P-wave amplitude)

P wave: up to 0.4 mV in amplitude; up to 0.04 sec duration (0.05 sec in large breeds); positive in leads II and aVF; positive or isoelectric in lead I

P-R interval: 0.06 to 0.13 sec (inversely related to heart rate)

QRS complex: ‡positive in leads II and aVF, negative in lead V_{10}; mean electrical axis (MEA), frontal plane: +40° to+100°

Amplitude: maximum R wave 2.5 to 3.0 mV in leads II, III, and aVF (dogs > 2 years of age); R in rV_2 or V_{10} < 3 mV; V_2 and V_4 < 5.0 mV; minimum amplitude R wave leads II, III, and aVF is 0.5 mV;

duration: up to 0.05 sec (0.06 sec in large breeds) S in V_4 not deeper than 0.7 mV; QRS negative in V_{10}

Q-T segment: 0.15 to 0.25 sec; varies with heart rate

S-T segment and T wave: S-T segment free of marked coving (repolarization changes); S-T segment depression not > 0.2 mV in limb leads and not > 0.25 mV in chest leads; S-T segment elevation not > 0.15 mV in leads II and III; T wave positive in lead V_1 (rV_2) and negative in V_{10} (except in the Chihuahua); T wave amplitude not > 25% of amplitude of the R wave; T waves may be positive, negative, or biphasic

* Represents commonly encountered values for dogs and cats. The ECG is extremely variable; serial ECGs are recommended. Measurements outside these ranges suggest but do not identify cardiac disease. Values from references 1, 2, 5, and personal experience.

† Dvir E, Lobetti R: Effect of electrocardiographic filters on the R-amplitude of canine electrocardiograms. *Vet Rec* 150:171-176, 2002.

‡ Detweiler DK: The dog electrocardiogram: a critical review. *In* MacFarlane PW, Veitch Lawrie TD (eds): Comprehensive Electrocardiology: Theory and Practice in Health and Disease. Oxford, UK, Pergamon Press, 1989, pp 1267–1329; Hurst JW: Naming of the waves in the ECG, with a brief account of their genesis. *Circulation* 98:1937–1942, 1998.

Initiation of the normal heartbeat occurs in the *sinoatrial (SA) node*, located in the dorsolateral right atrium (RA), and spreads through both atria, forming the *P wave* on the ECG (Figure 202-2). Specifically, part of the electrical spread from the SA node travels along three sets of specialized fibers in the atria, the internodal pathways,[7] which converge on the *atrioventricular (AV) node* in the floor of the RA. Thus the outward movement of electrical activity from the SA node both activates the muscular contraction of the atria and carries a sequence of electrical impulses to be transmitted to the ventricles.

At the level of the AV node, the electrical impulse depolarizing the heart is purposefully delayed, allowing the atria to finish contracting. The period of relative electrical quiescence during which the impulse slowly passes through the AV node is reflected on the ECG as a flat segment between the P wave and QRS complex. In addition to transmitting impulses from the atria to the ventricles, the healthy AV node acts as a *gatekeeper*, blocking unwanted atrial impulses from crossing to and activating the ventricles, such as when these impulses are premature or excessive (e.g., atrial fibrillation [AFib]). In normal individuals, the unidirectionally conducting fibers of the AV node-His bundle complex make up the only electrical connection between the atria and the ventricles.

1040

1041

202.1.3
202.1.2 Box • 202-2 Criteria for the Normal Feline Electrocardiogram (ECG)* (Note: Patient in right lateral recumbency; no ECG filtering†)

Heart rate: up to 240 beats per minute (bpm) (usually 140–180 bpm)

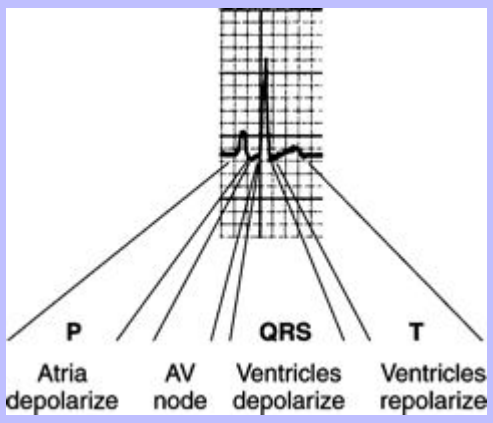
Heart rhythm: normal sinus rhythm (NSR) or physiologic sinus tachycardia (STach)
P wave: positive and up to 0.2 mV in leads II and aVF; may be positive or isoelectric in lead I; should not exceed 0.04 sec (rate dependent) in duration
P-R interval: 0.04 to 0.09 sec duration (inversely related to heart rate)
QRS complex: † more variable than in the canine; the mean electrical axis (MEA) in the frontal plane is often irrelevant and may be isoelectric in all frontal plane limb leads; MEA most commonly from 0° to +160° (frontal plane); amplitude of the R wave is usually low; maximum is 0.9 mV; duration: under 0.04 sec
Q-T segment: 0.12–0.18 sec duration; varies inversely with heart rate
S-T segment and T wave: S-T segment and T wave should be small and free of repolarization changes, marked depression, or elevation; T waves usually positive, occasionally negative or biphasic; up to 0.3 mV height
Precordial leads: few established rules exist for the V leads in cats; R in V_4 should not exceed 1.0 mV

* Represents commonly encountered numbers for dogs and cats. The ECG is extremely variable; serial ECGs are recommended. Measurements outside these ranges suggest but do not identify cardiac disease. Values from references 3, 5, 10, 14, and personal experience.

† Schrope DP et al: Effects of electrocardiograph frequency filters on P-QRS-T amplitudes of the feline electrocardiogram. *Am J Vet Res* 56:1534–1540, 1995.

Having crossed through the AV node, the electrical impulse of a normal heartbeat travels rapidly and uniformly through the ventricles via the *His-Purkinje* system.[8] This network of conductive fibers ensures that the impulse is carried quickly and distributed uniformly, such that the ventricles depolarize in a synchronized fashion. The fibers begin as a thick shaft, the *His bundle*, that accepts transmission from the AV node and crosses through the endocardial cushion to the ventricles. The His bundle quickly divides into *right and left bundle branches* (RBB and LBB), directed to their respective ventricles, and the left bundle in turn divides into *left anterior, left posterior, and septal fascicles*. The clinical relevance of this division relates to interruptions of electrical conduction through these bundles, which can occur under various pathologic, and occasionally normal, conditions (see Bundle Branch Blocks, following). Overall, depolarization of the ventricles is apparent on the ECG as the *QRS complex*. When the ventricles have completely finished depolarizing, a sequence of repolarization returns the myocardial cells to their resting state. This repolarization sequence, which follows in the wake of the depolarization sequence, is seen as the *T wave* on the ECG.

Figure 202-1 A heartbeat on the electrocardiogram (ECG). Correlation with electrical activity in anatomic regions of the heart.



202.2 CLINICAL USE OF ELECTROCARDIOGRAPHIC LEADS AND MEAN ELECTRICAL AXIS

202.2.1 Electrocardiographic Leads

In practical terms, an ECG lead is nothing more than one perspective on the electrical activity of the heart. That is, different leads offer different vantage points on the same electrical events that take place during a heartbeat.[9] Therefore an ECG showing multiple leads can be thought of as an ECG with multiple observers reporting the electrical activity of the heart from different positions (Figures 202-3 to 202-5).

Having multiple observation points (multiple leads) is important because all cardiac electrical events are not always apparent in all leads. Indeed, important information about the heartbeat is often visible in some ECG leads but not in others. This is because any ECG lead is characterized by the ability to sense only electrical activity traveling toward or away from it. The drawback of this characteristic is that electrical activity coursing through a three-dimensional structure like the heart often occurs in a direction that is neither toward nor away from a particular lead and therefore is perceived partially, or suboptimally, in any one lead alone. At an extreme, electrical activity that occurs exactly perpendicular to a lead (i.e., the electrical activity moves in a direction that is in no way toward or away from the lead) registers nothing (isoelectric ECG) for that lead, regardless of how normal or strong the electrical activity.

1041
1042

Figure 202-2 Electrocardiogram (ECG) dimensions and nomenclature for a normal heartbeat.

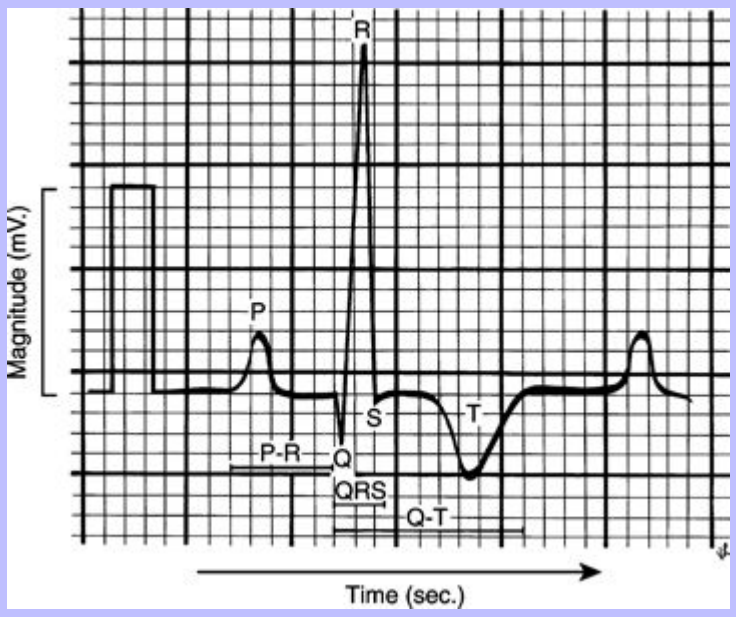


Figure 202-3 The positive pole of an electrocardiogram (ECG) lead as observer. The overall thrust of electrical energy for one beat of the ventricles is oriented caudally and slightly leftward (i.e., directly toward the positive pole of lead II [eye]) in the normal dog. Therefore a large, positive QRS complex is registered in that lead.

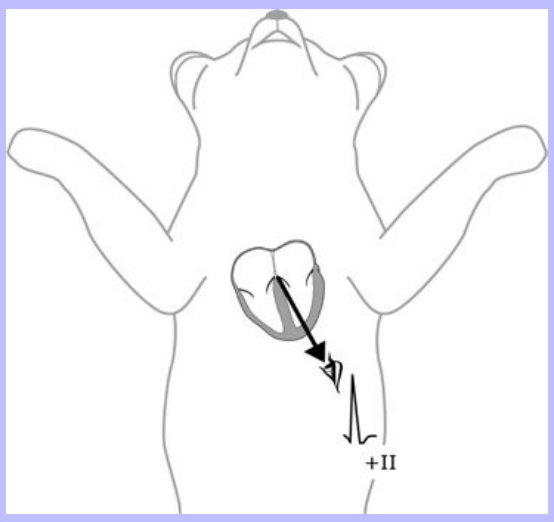

Figure 202-4 Same normal heart as in Figure 202-3. The observer at the positive pole of lead aVR registers an overall thrust of electrical energy directed away from it. Therefore lead aVR displays a large (deep) negative QRS complex.

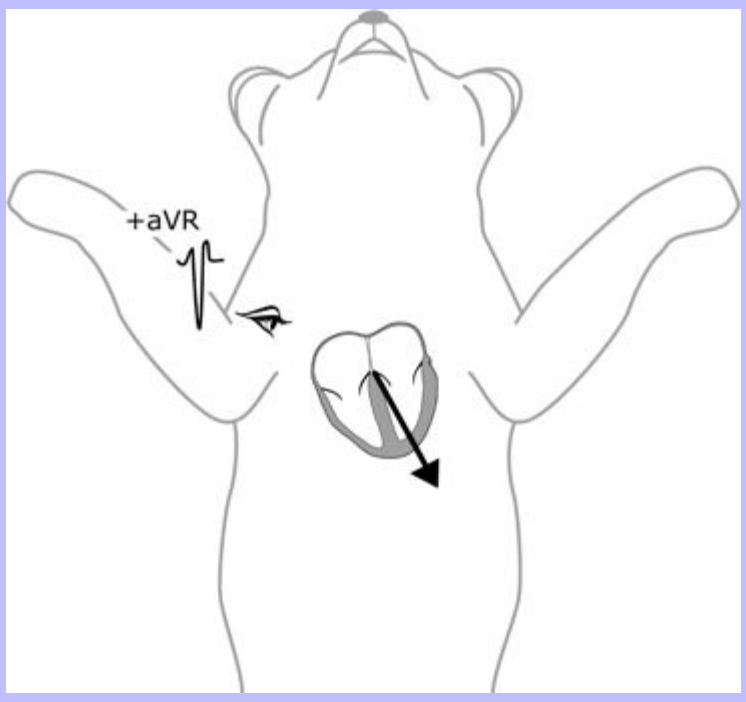

Figure 202-5 Typical appearance of QRS complexes in the six limb leads when the mean electrical axis (MEA) is in the normal range for dogs (here: +60 degrees). The reader should note that the overall size and polarity of each QRS reflects the amount and direction of electrical energy detected by the positive pole (observer) of each lead. This is the basic principle that allows the clinician to understand the overall direction of electrical thrust (MEA) based on observing QRS complexes in all leads of a patient's electrocardiogram (ECG).[9]

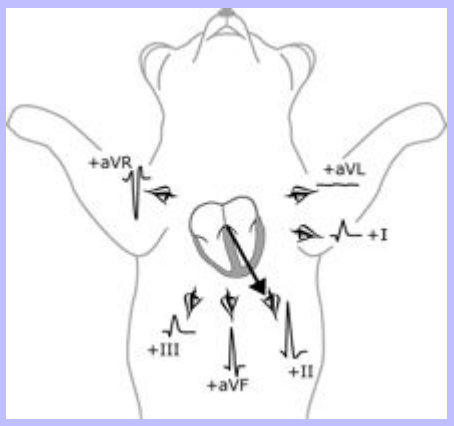
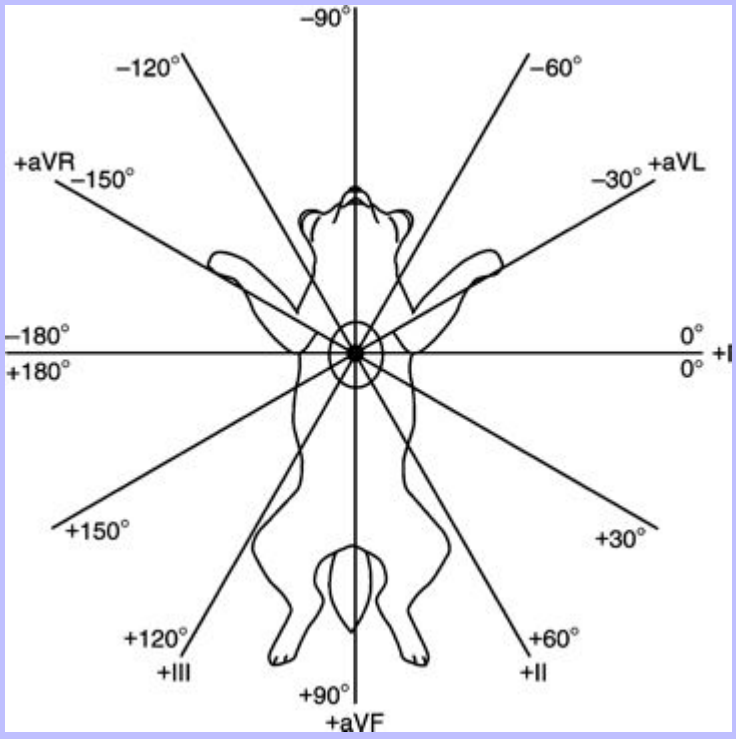


Electrical activity that travels directly toward the positive pole of a lead creates a strong positive deflection (wave) above the baseline on the ECG for that lead (see Figure 202-3). Similarly, electrical activity that travels directly away from the positive pole of a lead registers a strong negative ECG wave, below the baseline (see Figure 202-4). Intermediate orientations of electrical activity create waves that are of intermediate degrees of positivity or negativity, depending on the magnitude of the positive or negative component of the electrical activity that is detectable on that lead. For example, an impulse traveling *almost* directly toward the positive pole of a lead will create a large positive wave (see Figure 202-5, lead aVF) but not quite as tall as when the energy is traveling fully toward the positive pole of the lead (see Figure 202-5, lead II). All leads register the amount of positivity or negativity generated by that impulse relative to their positive pole and record a wave in proportion to that. The lead that is almost 90 degrees away from the direction of the electrical activity will record little to no activity (i.e., almost isoelectric line; see Figure 202-5, lead [aVL]), and the positive pole of the lead that is closest to 180 degrees away from the direction of electrical activity will register a very large, negative complex (see Figure 202-5, lead [aVR]).

Therefore it can be seen that using multiple leads for an ECG has two major advantages (Figure 202-6). First, the leads directly and proportionally perceive the amount of energy (i.e., number of cells depolarizing, the smoothness of conduction) involved in depolarization. Thus left ventricular (LV) hypertrophy may be suspected when QRS complexes are abnormally tall in lead II, for example, because the amount of energy transmitted in the normal direction (toward the LV) is greater due to the increased myocardial mass. Right ventricular (RV) hypertrophy can be suspected when the bulk of ventricular electrical activity is directed

abnormally toward the right heart (see discussion of right axis deviation, following). Second, having multiple leads solves the problem of any single lead's "blindness" to perpendicularity. Posting numerous observers at regular stations around the heart (i.e., having multiple leads) ensures that some leads inevitably will perceive the heart's electrical energy better than others and therefore will show larger, more easily interpreted waves and complexes (see Figure 202-5). Therefore on any ECG that shows multiple leads, the clinician will usually find it easiest to interpret the rhythm by first scanning the different leads to see which ones offer the clearest (i.e., largest and with the least artifact) P waves, QRS complexes, and T waves.

Figure 202-6 Location and names of electrocardiogram (ECG) limb leads in the standard hexaxial system (frontal plane).



It is worth noting that by convention the diagram that shows the position of the 6 standard ECG limb leads is visualized in a ventral-dorsal orientation—or seen from above when the patient is in dorsal recumbency (see Figure 202-6). Each lead is named according to the location of its positive pole. The points around the circumference of the map, unfortunately, are named in a confusing manner. The change from +180 degrees to −180 degrees at the 9 o'clock position is a meaningless designation that has no implication regarding the positivity or negativity of the electrical energy or leads in the upper (cranial) half of the circle, and a much less confusing approach would have been simply to continue numbering the points from +180 degrees to +359 degrees. A more detailed description of this basic series of concepts may be found in most comprehensive books on electrocardiography.[2,4,5,9,10]

202.2.2 Mean Electrical Axis

As the ventricles depolarize, the sequential activation of the cardiomyocytes creates an overall direction or thrust of electrical activity in the ventricles. This electrical activity is best detected by an ECG lead most closely oriented with the direction of the electrical activity, as described previously. The sum total of electrical energy for all the depolarizations in one beat of the ventricles represents the final tally of individual depolarizations, with impulses headed in the same direction adding to each other and impulses headed away from each other canceling each other out. Therefore in a normal heart, the sum total of electrical energy expended for one beat of the ventricles has an overall thrust that is leftward (because the left ventricle [LV] is larger than the right) and caudal (because more energy is directed toward the apex of the heart during initial activation than travels back toward the base at the end of ventricular activation). This sum total, or overall thrust, of electrical energy, is also called the *mean electrical axis* (MEA) (see Figures 202-3 to 202-6).

The direction and thrust of electrical energy (MEA) is characteristic for an individual and, barring an intermittent intraventricular conduction abnormality, is constant from beat to beat on an ECG tracing. In normal individuals, the MEA, as just mentioned, points leftward and caudally because that is the overall direction in which the normal ventricles point (see Figure 202-5). However, the sum total of electrical energy for one beat of the ventricles (the MEA) may change if the heart changes in shape. For example, if a patient's RV becomes pathologically enlarged to a sufficient degree, the bulk of electrical energy for ventricular depolarization may be directed move towards the right instead of the left. This is called a *right axis shift* or *right-axis deviation*. In such a case an ECG with multiple leads in a clinical patient could show QRS complexes that were more positive than usual in the right-sided lead (aVR) and QRS complexes that were more negative than usual in the left-sided leads (aVL, I, and II) (Figures 202-7 and 202-8). This simple ECG finding would increase the suspicion of disorders that cause RV enlargement. As a second example, conduction through the RV involves passage of the electrical impulse along the right bundle branch (RBB) for rapid spread through the RV. Hampered conduction through the RBB, a phenomenon called *RBB block*, redirects the electrical impulse, a variation that is visible on the ECG (see Bundle Branch Blocks, following; see Figure 202-45).[11] As a result of RBB block, the incompletely depolarized RV is depolarized late, and slightly less efficiently, by impulses redirected from the LV. This “swing” of electrical energy reorients the overall thrust of electrical energy for that beat of the ventricles toward the right, creating a right axis deviation. Therefore the two main differential diagnoses for right axis deviation in a patient with sinus rhythm are (1) RV hypertrophy and (2) RBB block. Left axis deviations occur uncommonly because the bulk of electrical activity already is directed toward the left in the normal heart. LV hypertrophy does not alter the direction of thrust of overall electrical activity from the left-caudal direction but often will increase its magnitude (e.g., taller R waves in lead II). Left anterior fascicular (LAF) block is an example of a conduction abnormality within the ventricles that is compensated for with a thrust of energy in the left dorsal direction, which can cause a left axis shift (see Figure 202-46 for an example).[12]

Figure 202-7 In this heart, marked right ventricular (RV) hypertrophy is present. The greater myocardial mass directs the overall thrust of ventricular activity rightward. This physiologic phenomenon is revealed on a standard electrocardiogram (ECG): the positive pole of a lead aVR registers more electrical energy directed toward it, and its QRS complex is markedly more positive than normal, whereas leads aVL, I, II, and aVF are more negative than normal because the thrust of energy travels away from them. These findings represent a right-axis deviation.

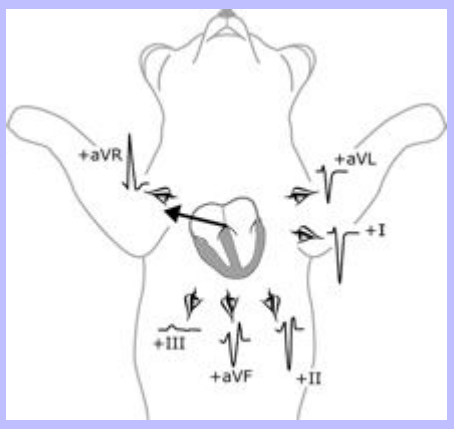


Figure 202-8 Right axis deviation. The mean electrical axis (MEA) is +150 degrees. Precordial leads also indicate a predominance of electrical activity to the right (rV2, marked "V1"; V_4 marked "V3"). Right ventricular (RV) hypertrophy was confirmed echocardiographically in this young miniature Schnauzer dog with severe pulmonic stenosis (25 mm/sec, 1 cm = 1 mV).

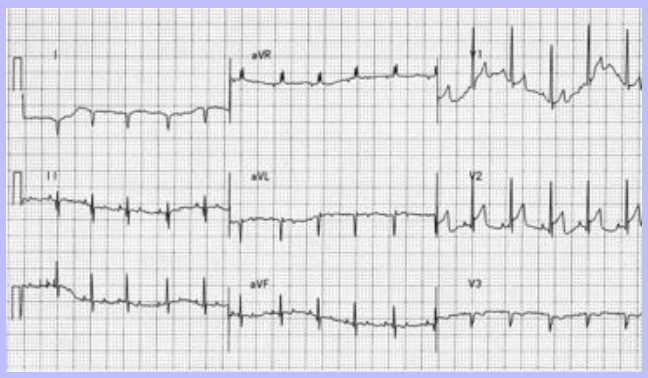


The concept of using the polarity and size of ECG deflections to infer the orientation of electrical thrust applies to the atria (P waves) and to the ventricles. Variations in atrial MEA have been associated with atrial enlargement or intra-atrial conduction abnormalities, yet as with the ventricles, MEA is at best a rough index, and its accuracy for assessing morphology appears to have been widely surpassed by that of other diagnostic modalities such as echocardiography.

Using vectorial enhancement, the ECG machine uses the three electrode wires connected to patients undergoing an ECG (the fourth is an electrical ground) to assess electrical activity from three additional perspectives (aVR, aVL, and aVF) in addition to I, II, and III, for a total of six different perspectives. The six positions, or leads, are evenly spaced 30 degrees apart and are called the *limb leads* (see Figure 202-6).

MEA can be calculated on an ECG in several ways, allowing the clinician to understand the overall direction of electrical thrust in the ventricles. Probably the simplest is to look for the lead with the most positive QRS complex. This represents the lead toward which the bulk of electrical activity is most directly oriented (i.e., the MEA). An equally effective, converse approach is to find the most isoelectric lead, namely the lead that perceives the least electrical energy. Because the isoelectric lead is the lead that is least aligned with the thrust of electrical activity, then the lead 90 degrees to it must be the lead with the most electrical activity. The MEA is therefore the positive pole of the lead perpendicular to the isoelectric lead, in the direction that corresponds to positive QRS complexes. Finally, the classic way of determining MEA consists of calculating the surface area of the QRS complexes of two ECG leads (as the number of small boxes within the complexes). On the ECG axis map (see Figure 202-6), one then places a marker on the lines of each of the two leads examined. The distance of the two markers away from the center of the diagram is the number of small boxes that made up the surface area of each of the two examined leads. From the markers on each of these two leads' lines, a perpendicular line is drawn such that the two perpendiculars meet. A line from the center of the axis map to the point where the perpendiculars cross indicates the MEA. When MEA is correctly determined by any technique, all leads “agree” and are consistent with one direction of thrust of electrical activity, because the leads are only offering different perspectives on the same cardiac electrical activity. Any contradictory, nonsensical information in this regard is usually explained by erroneous connection of the electrode wires (ECG lead-patient limb mismatch).

Determining which is the “most positive QRS complex” or “most isoelectric lead” must take into account that the negative elements of a QRS complex cancel out an equivalent amount of the positive elements on the ECG tracing. Therefore it is a QRS complex's net positivity or negativity that is assessed. For instance, if lead II shows the tallest R wave and no Q or S wave, and lead aVF shows an identically tall R wave but some small Q and/or S waves as well, then the QRS is considered to be smaller in lead aVF; therefore the MEA is closer to +60 degrees than to +90 degrees (see Figure 202-5). By the same principle, a QRS complex that is wide is considered “bigger” (greater surface area) than a narrow QRS complex of the same height.

On an ECG, the cardiac rhythm is not affected by a patient's posture. However, the MEA is markedly altered by the position of the limbs, and a consistent approach to patient restraint is essential (by convention: right lateral recumbency, with limbs held perpendicular to the long axis of the patient's body). Changes in recumbency or in limb position can markedly and misleadingly alter the MEA.[6,14,15] This artifact was nicely illustrated in an experiment in which dogs in right lateral recumbency had an ECG done with one forelimb held forward and the other drawn back, and then the leg positions were reversed. A marked, but artifactual, change in MEA was observed.[15] Therefore in the ambulatory patient, no information can be inferred regarding MEA (see Ambulatory Electrocardiogram, following).

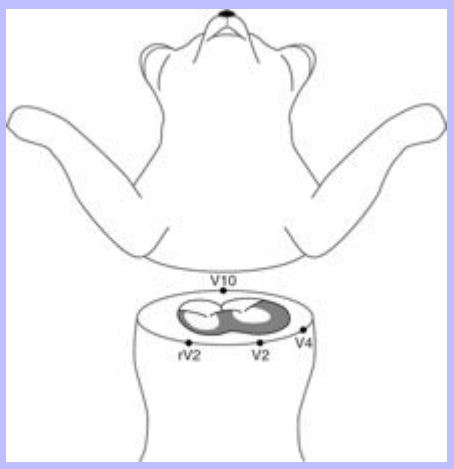
202.2.3 Precordial Leads

The concept of designing ECG leads to "survey" the electrical activity of the heart from multiple angles is a sound one, but even with a lead at every 30 degrees, a major shortcoming still exists. The six limb leads (I, II, III, aVR, aVL, aVF) may cover the entire frontal plane of the body (see Figure 202-6), but electrical energy traveling through a three-dimensional structure like the heart may travel "outward" or "inward" (i.e., in a dorsal or ventral direction). In such a situation, none of the six leads perceives the electrical activity as going clearly toward or away from any positive pole; electrical activity is perpendicular to all of them and therefore is invisible to all. The solution to this problem is the precordial leads (chest leads, thoracic leads, V leads). With precordial leads the ability to perceive electrical activity of the heart extends to three dimensions, because the ECG clips for precordial leads are placed circumferentially around the chest. Thus the precordial leads (rV_2, V_2, V_4, and V_{10}) assess electrical activity in the transverse (lateral and ventral-dorsal) plane (Figure 202-9). Precordial leads provide essential information that may not be apparent in the limb leads (frontal plane) (Figure 202-10) but they are more susceptible to artifact caused by chest wall motion (Figure 202-11).

1044

1045

Figure 202-9 Precordial leads. Using the summation of limb leads as one "virtual" pole in the center of the chest, the positive poles of precordial leads are positioned to register electrical energy in the transverse plane as follows: right fifth intercostal space, just lateral to the sternum (rV2, or CV5RL), left sixth intercostal space, just lateral to the sternum (V2, or CV6LL), left sixth costochondral junction (V4, or CV6LU), and dorsal midline directly dorsal to lead V4 (V10), approximately over the seventh thoracic vertebra.[9]



202.2.4 Combining Mean Electrical Axis and Electrocardiographic Leads: Understanding the Direction and Force of Electrical Activity in a Heartbeat

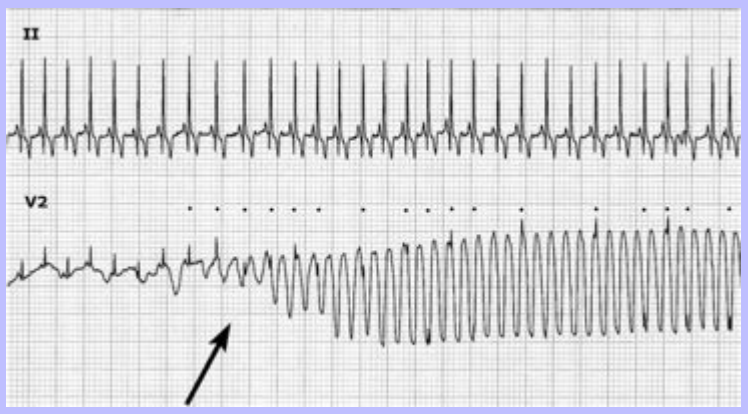
From the explanations given previously, it should be seen as logical that lead II is routinely used for evaluating the ECG in small animals. This is because the positive pole of lead II (i.e., the point from which a lead II "observer" detects electrical activity) is at + 60 degrees, or in the left caudal region (see Figures 202-5 and 202-6). This is in the middle of the normal range of MEA for healthy dogs and cats.[2,5] The LV receives more energy than the right, and the overall thrust of electrical energy is caudal, so the positive pole of lead II is likely to perceive a large thrust of electrical energy toward it in normal small animals and thus display a clear ECG with large, visible QRS complexes (see Figure 202-3). The same can be said for atrial activity and the P waves. However, interindividual variation reveals the limitation of using only lead II. Certain patients may fail to provide the desired information in a specific lead (see Figure 202-10).

Deviation of the QRS MEA denotes an abnormal orientation of the sum total of ventricular electrical energy.[1,2,5] Normal MEA is +30 degrees clockwise to +110 degrees for the dog, and zero degrees clockwise to +160 degrees for the cat. The most common causes of right axis deviation (MEA to the right of normal [from +110 degrees clockwise to −90 degrees in the dog]) are RV hypertrophy and enlargement (see Figure 202-7 and 202-8), RBB block (see Figure 202-45), and ventricular ectopy of LV origin (see Figure 202-32)—all conditions in which the bulk of ventricular electrical activity travels toward the RV. Left axis deviation (MEA to the left of normal [from +30 degrees clockwise to −90 degrees in the dog]) is rare and can be caused by LAF block (see Figure 202-46) or experimental transection of the left bundle branch. In cats the wide range of normal for MEA and the substantial overlap between normal and abnormal limits the usefulness of MEA, and some cardiologists omit it altogether. It can also be seen that a premature ventricular complex (PVC, VPC) originating from the LV, for example, will spread outward (i.e., toward the right) and thus presents a thrust of energy that is directed rightward. This radical difference in orientation of electrical thrust explains why classic PVCs of LV origin are commonly *bizarre looking*: they are oriented away from the positive pole of lead II, so are predominantly negative in that lead (i.e., bizarre in shape). PVCs also are usually wider than sinus beats because they spread from an ectopic focus through ventricular myocardium, not along the rapidly conductive fibers of the His-Purkinje system as normal beats would. This slower conduction means the QRS complex will be wider on the ECG (takes longer to be traced). Because the His-Purkinje system is more widely developed in the LV, PVCs of RV origin are more apt to propagate along on it and thus RV PVCs often are only slightly different from normal sinus QRS complexes.

1045 1046

Figure 202-10 Deficiencies of limb leads and utility of precordial leads. **A,** This electrocardiogram (ECG) from an adult male Doberman dog with a chief complaint of dyspnea could be misinterpreted as indicating atrial fibrillation (AFib) because no P waves are seen in the limb leads and a fine, undulating baseline is present. However, P waves are clearly present, as seen in lead V2. This ECG shows normal sinus rhythm (NSR), not AFib. The P waves are isoelectric to the limb leads, indicating that the overall thrust of atrial electrical activity was oriented ventrally, toward lead V2 (Figure 202-9). The fine baseline undulations are motion artifact. The erroneous suspicion of AFib also was at odds with the regular rhythm and pulse noted on physical examination. Mild variation in R wave amplitude, as seen toward the end of the lead II rhythm strip at bottom, can occur with aberrant ventricular conduction or as an artifact of ECG filtration. Simultaneously recorded nine-lead tracing and rhythm strip (25 mm/sec, 1 cm = 1 mV). **b**, Sinus rhythm with motion artifact mimicking atrial flutter or fibrillation. Unlike true atrial flutter or fibrillation, the QRS complexes occur at regular intervals. P waves *(dots)* are seen, especially when the dog stops shivering at the end of the tracing (lead I, 25 mm/sec, 1 cm = 1 mV). (*B*, tracing courtesy of Sophia David, AHT.)

Figure 202-11 Artifact affecting a ventricular (precordial) lead; leads II and V_2 recorded simultaneously. In this dog, the cyclical chest excursions of panting *(onset: arrow)* can disrupt the ECG similar to ventricular arrhythmias. A closer inspection of lead V_2 reveals the persistence of superimposed, normally timed QRS complexes *(dots)*, many of which can be seen and none of which would occur if the rhythm were VT. This artifact is absent in the limb leads, which do not move with panting as does the chest wall. Speed: 5 mm/sec; scale: 10 mm/mV.



Despite the incontestable superiority of echocardiography over ECG for assessing cardiac size and structure, the ECG continues to provide clues about abnormal heart size or shape. It can increase the index of suspicion for cardiac disease or can help to refine the differential diagnosis before an echocardiogram is performed. For example, heart diseases causing RV enlargement continue to be noted as causing a right axis deviation in many or most affected patients, including those with pulmonic stenosis (right axis deviation in 19 of 21 patients [90%][16]), right-to-left patent ductus arteriosus (right axis deviation in eight of eight patients [100%][17,18]), and cor pulmonale.[19]

202.2.5 Confounding Factors

Sources of error may alter the apparent MEA and result in an erroneous diagnosis. Changes in position of the limbs[14,15] and of the position of the heart within the chest (e.g., pericardial effusion [see Figure 202-17], peritoneopericardial diaphragmatic hernia, intrapericardial mass, or body motion in ambulatory ECG) change the perspective from which ECG leads perceive the heart's electrical activity, often causing the false appearance of changes in the MEA.

202.3 NORMAL ELECTROCARDIOGRAM

Extremely fit dogs with athletic hearts, such as Alaskan sled dogs, deviate substantially from the "normal" ranges listed at the beginning of the chapter (see Box 202-1).[20] In most normal dogs, heart rates range between 60 and 160/min. Rates above these limits are classified as *tachycardias*, and below 70 beats per minute (bpm) are *bradycardias*. Bursts of sinus tachycardia (STach) of up to 300 bpm have been identified for brief periods in normal dogs.[1] In healthy cats in the hospital setting, the normal heart rate extends up to 260 bpm, with a median of 180 bpm.[21] The low limit of normal varies, depending on whether the patient is at home or in the hospital. Generally 130 to 150 bpm would be considered low-normal for a healthy cat in a clinical environment.[21] Ambulatory electrocardiographic testing provides an excellent opportunity to evaluate the real heart rate across the species and identifies a higher prevalence of arrhythmias than conventional monitoring.[22–25]

Figure 202-12 Respiratory sinus arrhythmia (RSA) and wandering pacemaker (WP). Lead II, 25 mm/sec, 1 cm = 1 mV.

The *P wave* is the first deflection on the ECG after isoelectric diastole (baseline after T wave) (see Figures 202-1 and 202-2).[13] It should be positive in leads II and aVF, and isoelectric or positive in lead I. It may be negative in leads III, aVR, aVL, V_2, and V_{10}. The first half of the P wave represents RA activation, and the second half represents left atrial (LA) activation. The spread of atrial excitation begins in the upper portion of the RA at the SA node and spreads across the atrium, depolarizing the LA. The maximum normal amplitude of the P wave in any limb lead is 0.4 mV in the dog and 0.2 mV in the cat. The amplitude of the P wave may increase during inspiration and with increased heart rate. High vagal tone also allows the exact pacemaking site within the SA node to change. Higher centers are responsible for early activation, and lower centers closer to the AV node produce lower rates and lower amplitude P waves.[1] This vagally mediated change in the origin of the pacemaking site in the SA node is a normal feature of canine ECGs and is called a *wandering pacemaker* (WP) (Figure 202-12). The amplitude of the P wave may also vary between tracings due to changes in the position of the heart and of the ECG clips.

The duration of the P wave should not exceed 0.04 second in the dog (0.05 second in larger breeds) and 0.04 second in the cat. Notching of the P wave is not significant unless the duration of the wave exceeds stated limits, in which case it may indicate LA enlargement *(P mitrale)* (Figure 202-13). Conversely, P waves of increased amplitude, especially with a peaked shape, have been associated with enlargement or hypoxia of the RA *(P pulmonale)* (see Figure 202-13).

The morphology and amplitude of the canine P wave are more variable than in other animals, especially in the limb leads. The mean P wave MEA in normal dogs is within 90 degrees of the ventricular MEA in the frontal plane.

The *P-R segment* is the isoelectric period that follows the P wave on the ECG (see Figures 202-1 and 202-2). It is measured from the end of the P wave to the beginning of the first deflection away from the baseline, indicating

ventricular activity. During the P-R segment, the electrical impulse is being conducted slowly through the AV node. Atrial repolarization occurs during this period and into the QRS; atrial repolarization generally is too low in amplitude (or occurs too far into the QRS complex) to be detected on surface recordings, except in rare cases in which an atrial repolarization wave, or T_a wave, is seen within the PR segment (see Figure 202-13).[26] T_a waves distort the baseline of the PR segment and usually are indicative of atrial enlargement, hypoxia, or electrolyte changes.

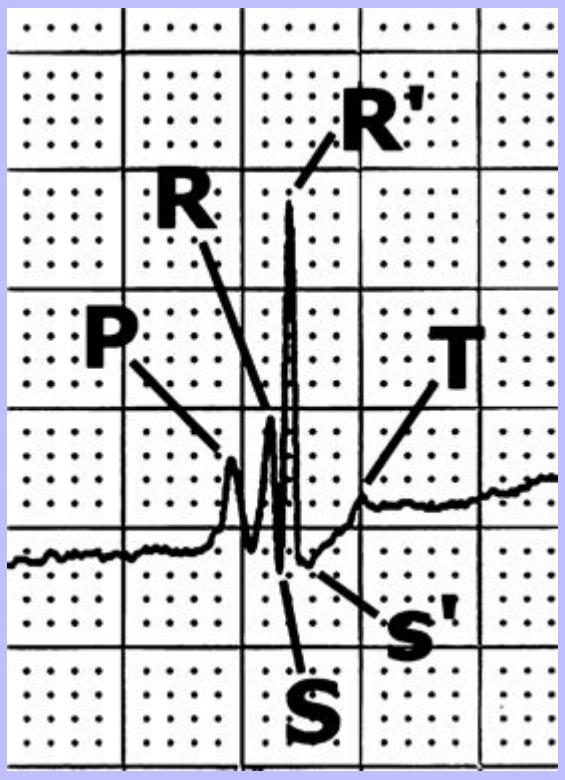
1046
1047

Figure 202-13 P wave abnormalities. Lead II, 25 mm/sec, 1 cm = 1 mV.

The period from the onset of the P wave to the onset of the QRS complex is the *P-R interval* (see Figure 202-2). The duration of the P-R interval varies inversely with the heart rate. With rapid heart rates it may be 0.04 second but usually varies from 0.06 second to 0.14 second (dog) and from 0.04 to 0.09 second (cat). Normal dogs vary considerably. Prolongation of the PR interval is first-degree heart block, an electrocardiographic—but not hemodynamically important—term (see Atrioventricular Block, following). Short P-R intervals suggest rapid heart rates or accessory pathways that bypass normal A-V conduction (see Pre-Excitation Syndromes, following).

The *QRS complex* is the ECG representation of ventricular depolarization (see Figures 202-1 and 202-2).[13] It occurs immediately after the P-R interval. The components of the QRS complex are named for their sequence of occurrence, not for correlations with activation of specific parts of the ventricles. The Q wave is the first negative deflection occurring before a positive wave after the isoelectric P-R segment. The R wave is the first positive deflection after the P-R segment, regardless of whether or not a Q wave precedes it. The S wave is a negative deflection occurring after a (Q) or (R) deflection (or both). If no positive waves are present, the negative deflection is called a *QS complex* (e.g., lead I in Figure 202-8). Additional positive or negative deflections that occur in the QRS complex after the R or S wave has returned to the baseline (producing "splintered" QRS complexes) are called *prime* (R′; S′) *waves* (Figure 202-14).[13] Any of the following ventricular patterns may arise: QR, QS, RS, R, QRS, plus prime deflections. If the wave amplitude is small (i.e., < 0.5 mV), it is written as a small letter (e.g., *q*); if it is greater than 0.5 mV, a capital letter is used (e.g., *Q*).[1,13] These types of complexes occur under various conditions. For example, an association with congenital tricuspid valve malformations in Labrador retrievers is known to exist.[27]

Figure 202-14 Example of a splintered QRS complex. The exact description is an RSR's' complex. The short P-R interval also suggests pre-excitation. Lead II, 25 mm/sec, 1 cm = 1 mV.



The size of QRS complexes (and P waves) is significantly affected by the presence or absence of filters on the ECG machine. Use of routine ECG filtration in one canine study produced a median 51% reduction in QRS amplitude,[28] with the greatest amount of artifactual attenuation noted in smaller dogs and in tracings with narrower QRS complexes. Marked filtration effects also have been noted in feline ECGs.[29] Therefore the presence or absence of filtration should be recorded on ECG tracings whenever possible.

LV muscle mass normally exceeds RV mass. Depolarization of the LV overwhelmingly controls the magnitude and direction of the forces of the QRS complex in the dog and the cat. Ventricular activation occurs in three smooth, transitional phases: (1) initial, (2) main, and (3) terminal. The interventricular septum, except for the basilar region, is depolarized first, followed by bilateral apical and central endocardial to epicardial activation until a single cone of depolarized muscle surrounds each cavity. Terminal electrical activity proceeds from apex to base, exciting the basal septum and basal and lateral LV. The electrical thrust (vector) is directed from left to right in the interventricular septum, then endocardium to the epicardium, depolarizing the free (lateral) ventricular walls, and finally basally in the upper walls and septum (ventricular outflow tracts).[1,2,5,30] The durations of these phases are normally 0.01 second, 0.025 to 0.035 second, and 0.01 second, respectively, in the

dog.[30,31] They are proportionate but shorter in the cat, where the entire QRS complex duration is usually between 0.02 and 0.03 second.

Prolongation of the QRS complex beyond 0.05 second (0.06 second in large breeds) indicates delayed ventricular depolarization. In cats, durations exceeding 0.04 second are unusual. Ventricular hypertrophy, bundle branch block (BBB), electrolyte disorders, formation of ventricular ectopic beats (either premature or escape rhythms; see discussion of premature ventricular complexes and conduction disorders, following), and aberrantly conducted beats (e.g., RBB block) can result in prolonged complexes.

More specifically, the initial ventricular electrical thrust, or vector, when the impulse first emerges from the AV node and begins to travel in the His bundle, is oriented rightward, craniad, and ventrad. Leads I and V_{10} should therefore each have a Q wave, indicating an initial rightward (lead I) and ventrad (lead V_{10}) force. The Q wave in canine leads II and aVF represent cranially directed initial forces (duration under 0.01 second). The initial vector is directed cranially for only a short period prior to turning caudad. If a Q wave is present in older dogs in leads I, II, III, and aVF, and if its amplitude is greater than −0.5 mV in lead II, it is probably abnormal and specifically suggests the possibilities of RV enlargement or RBB block.

The main portion of the QRS complex reflects depolarization of the LV and RV free walls. The main ECG deflection is formed by depolarization of the LV wall directed to the left, caudad, and ventrad, producing an R wave in leads I, II, III, and aVF (leftward and caudad) and a Q wave in lead V_{10} (ventrad).

The terminal force of the QRS complex represents dorsal basal (apicobasilar) depolarization. The force is either rightward or leftward, depending on the extent to which the basal region of the LV lies to one side of the midline. If part of the dorsal basal region lies electrically to the right side of the thorax, then the terminal electrical forces will be directed cranially and to the right, producing a small S wave in leads I, II, III, and aVF. This $S_1S_2S_3$ pattern sometimes is noted with severe heartworm disease and other causes of marked RV hypertrophy (Figure 202-15). Normally no S wave occurs in lead I and it may also be absent in lead II. Lead V_{10} should always have a Qr complex, the small *r* wave representing the terminal dorsal basal depolarization of the ventricles. 1047 1048

Figure 202-15 S waves *(arrows)* seen in leads I, II, and III ($S_1S_2S_3$ pattern). This is a manifestation of the final forces of ventricular depolarization being directed cranially (S waves in leads II and III) and to the right (S waves in leads I and II). Classically it has been associated with right ventricular (RV) hypertrophy, as in this 6-year-old Husky dog with severe heartworm disease (25 mm/sec, 1 cm = 1 mV).

The upper-normal limit of amplitude of the canine R wave is 2.5 mV; above 3.0 mV is virtually always abnormal except in some young dogs. Abnormally tall R waves in lead II suggest LV enlargement. R waves of amplitude less than 0.5 mV in leads I, II, and III are small.[1] Consistently diminished R wave amplitude suggests pericardial or pleural effusion (or both), intrathoracic mass, severe pulmonary disease, hypovolemia, hypothyroidism, hypothermia, acute hemorrhage,[32] or obesity. These associations are true only if QRS complexes are diminished in all leads, including the V leads. Otherwise, QRS complexes may simply be small in one lead because they are larger in other leads (i.e., the MEA is directed elsewhere; see Mean Electrical Axis). Cyclic changes in heart rate may cause cyclic variations in QRS complex size. A pattern of alternating change in R-wave height from beat to beat is seen in some dogs with pericardial effusion (Figure 202-17). This finding, called *electrical alternans*, results from the swinging motion of the beating heart within a distended, fluid-filled pericardial sac.

Figure 202-16 Normal sinus rhythm (NSR) in a cat. Heart rate: 140 beats per minute (bpm). Mean electrical axis (MEA): +85 degrees. Left ventricular (LV) hypertrophy is also suspected based on the tall R Waves in lead II and was confirmed echocardiographically. The fifth precordial lead is inserted between V_2 and V_4 as described by Harpster[10] (25 mm/sec, 1 cm = 1 mV).

Figure 202-17 Electrical alternans. Lead II, 25 mm/sec, 1 cm = 1 mV.

Occasionally the QRS complex is nearly isoelectric in all six limb leads, a variation of normal referred to as a *horizontal heart*. The MEA is indeterminate in the frontal plane, and normal MEA parameters cannot be used; however, the precordial leads often still give useful information regarding left-right and dorsal-ventral orientation of the electrical thrust. The rhythm durations of waves, complexes, and intervals are not altered by the horizontal heart situation.

The Q-T interval begins with the onset of the QRS complex, ends when the T wave returns to baseline, and denotes the entire period of ventricular electrical activity (see Figure 202-2).[2,13] The duration of the Q-T interval varies directly with the preceding RR interval. Nevertheless, and despite wide variations in heart rate in the dog, the Q-T interval does not vary during respiratory sinus arrhythmia (RSA).[33] Measurements of the Q-T interval have traditionally been corrected ($Q\text{-}T_c$) for the effect of heart rate using the Bazett formula:

$$Q\text{-}T_c = \text{Q-T interval/square root of R-R interval}$$

This formula may overcorrect at rapid heart rates and undercorrect at lower heart rates and is dependent on identification of the exact duration of the T wave, which may be challenging in some ECGs. Clinically the Q-T interval may be assessed routinely without correction and, when that is required, the formula is the simplest adequate method. In small animal practice, Q-T interval prolongation is usually associated with certain medications[34] specific medical conditions[34,35] but not the arrhythmogenic cardiomyopathy of boxer dogs.[36] Amiodarone, a class III antiarrhythmic agent (see Therapy of Arrhythmias, following) is known in human beings and in dogs to prolong the Q-T interval when administered over long periods of time.[37] This effect is due to its effect on potassium ion channels (I_{to} transient outward K+ current and others). Such electrocardiographic changes have been linked to proarrhythmia in humans, although this association has not been clearly demonstrated clinically in dogs or cats. Some veterinarians are called upon to evaluate Q-T intervals critically because their work involves research laboratory studies that test the effects of drugs on such ECG changes as Q-T interval prolongation. In this instance the reader may wish to pursue specific information on Q-T interval corrections and nonclinical electrocardiology.[1,34,38,39] Regardless of context, marked prolongation of the Q-T interval can be an issue of concern; it raises the possibility of such acute, “malignant” arrhythmias as torsades de pointes (TdP, see Figure 202-38) and ventricular fibrillation (VF, see Figure 202-37).

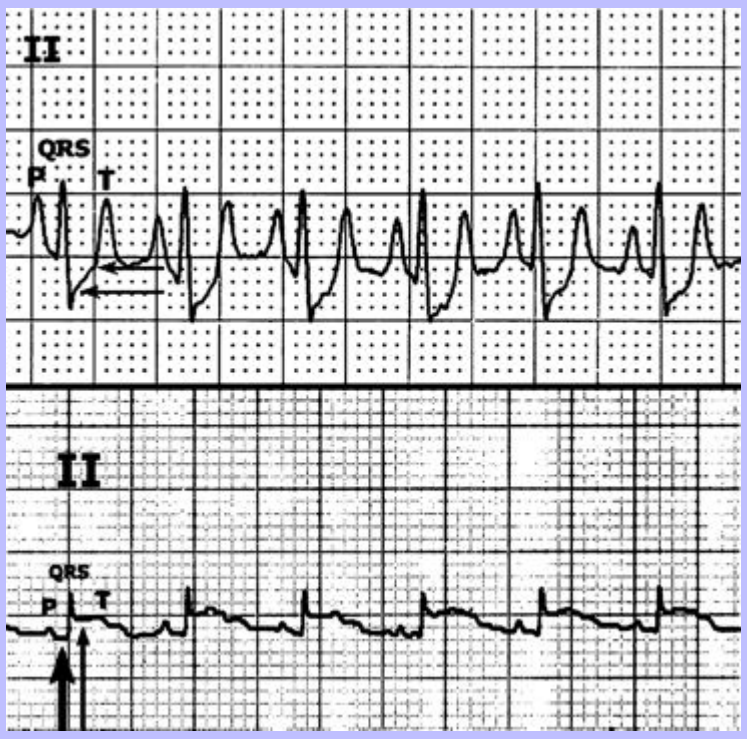
1048

1049

The S-T segment and T wave represent ventricular repolarization (see Figures 202-1 and 202-2).[13] The S-T segment, which represents the slower phase of repolarization and its predominance of slow calcium channel activity, begins with the end of the QRS complex (i.e., the J or junctional point or wave) and ends with the first deflection of the T wave.[2,34] The T wave represents the most rapid period of ventricular repolarization, during which potassium briskly leaks out of the cell. It ends when the wave returns to the isoelectric baseline. The S-T segment and T wave should be examined for depression or elevation from the baseline, either of which may be associated with myocardial hypoxia, nonspecific electrolyte changes, or cardiac hypertrophy (Figure 202-18). The degree of ST deviation appears to vary cyclically with the R-R interval, and deviation increases with shorter preceding R-R intervals.[1] Abnormal deviations of the S-T segment are defined as a depression of 0.2 mV or elevation of 0.15 mV in leads II and III, or they are defined as a depression or elevation of 0.3 mV in lead V_4. A subjective appearance of a delayed return to baseline in the S-T segment (i.e., an S wave that has an oblique or curved terminal upstroke) is referred to as *S-T segment slurring* or *coving* (see Figure 202-18). Like S-T elevation or depression, S-T slurring most often suggests myocardial hypoxia, particularly when it is new (e.g., intraoperative ECG demonstrating its sudden onset). In a study comparing normal and sick cats, S-T changes were frequently reported in cats with identifiable cardiac disease. Abnormal S-T segments occurred in 70% of cats with congenital heart disease, in 43% to 47% of cats with cardiomyopathy, and only in 10% of normal cats.[40,41]

The T wave may be concordant or discordant in normal dogs, meaning that its polarity may be in the same direction or in the opposite direction, respectively, compared with the QRS complex. The polarity of the T wave depends on the direction of repolarization within the ventricular wall (from epicardium to endocardium, or vice versa) and is of no known clinical importance in small animals at this time. In healthy human beings, the QRS complex and T wave are usually concordant, and this important interspecies difference has led physicians and nurses to misinterpret canine ECGs with QRS-T discordance as abnormal (because QRS-T discordance is sometimes a feature of myocardial infarction in people). Normally the T wave is positive in lead V_2 and negative in V_{10} or else RV hypertrophy is suggested (exception: Chihuahua). If the amplitude of the T wave is greater than 25% of that of the R wave (Q wave if it is deeper), LV enlargement may be suspected. These links between T wave morphology and cardiac structure appear to be fairly insensitive and nonspecific, and their utility has been essentially replaced by echocardiography.

Figure 202-18 ST segment changes in two cats. *Upper panel*, ST segment depression. The two arrows should completely overlap. ST segment coving, or slurring, also is present (50 mm/sec, 2 cm = 1 mV). *Lower panel*, ST segment elevation. The height of the ST segment *(small arrow)* should be the same as the baseline *(large arrow)*. Lead II, 25 mm/sec, 1 cm = 0.5 mV.



202.3.1 Technical Aspects of the Electrocardiograph

Techniques for obtaining the ECG are discussed in Chapter 90. By convention, paper speed is 50 mm/sec in small animals, although the paper speed commonly used in human cardiology, 25 mm/sec, may be used in veterinary medicine if the heart rate is 120 bpm or lower. The usual amplitude setting is 1 cm = 1 mV, and this is halved or doubled if the patient's tracing shows unusually large or small deflections, respectively.

202.3.2 Evolution of the Electrocardiograph

At birth the MEA of the normal canine ECG is directed rightward, cranially, and ventrally. Over the first 3 months of life this orientation slowly changes in the normal dog to leftward, caudal, and ventrad. A similar pattern of evolution exists for kittens.[42] The criteria used for establishing a “normal” ECG are not the same for a dog less than 12 weeks of age as they are for an older dog.[43] In a study of normal dogs raised on regular or

calorie-restricted diets from adulthood until death, no changes were observed with advancing age on the annual ECGs of dogs in either group during the dogs' lifetimes.[44]

202.4 DIAGNOSTIC MANIPULATIONS WITH ELECTROCARDIOGRAPHY

202.4.1 Vagal Maneuver

Artificially increasing a patient's vagal tone has potential value both diagnostically and therapeutically. Diagnostically, slowing the heart rate and increasing AV nodal refractoriness through vagal maneuvers may slow a rapid tachycardia, allowing some of its features to be more apparent and facilitating the ECG diagnosis (Figure 202-19). Therapeutically, an increase in vagal tone that interrupts macro re-entrant circuits can briefly reduce an excessively high ventricular rate through AV block (as described for atrial flutter later in the chapter) or can terminate such arrhythmias as AV nodal re-entrant tachycardia and orthodromic AV reciprocating tachycardia (see Pre-Excitation Syndromes, following).

Carotid sinus massage (gentle, sustained compression of the carotid sinuses, located just caudal to the dorsal aspect of the larynx, often to the point of eliciting a gag reflex) can be applied for 5 to 10 seconds and should be tolerated by the patient (signs of discomfort, resentment, or a marked change in heart rate warrant immediate termination of the vagal maneuver). Because dogs and cats very rarely suffer from carotid artery atherosclerosis, concern for thromboembolic consequences of carotid sinus massage as expressed in human cardiology is unlikely to be relevant to small animal practice. Ocular pressure over closed eyelids is another form of vagal maneuver, but it is contraindicated in patients with ocular problems and subjectively appears to be less effective than carotid sinus massage.

1049

1050

Figure 202-19 Atrial flutter. The diagnosis of atrial flutter is made easier by the initiation of carotid sinus massage *(arrow)*. This vagal maneuver was applied because this dog had a persistently high heart rate in the absence of an identifiable cause (320 beats per minute [bpm], first part of tracing). Carotid sinus massage induces second-degree AV block beginning after the ninth QRS complex *(small asterisk)*. As a result the flutter waves *(F)* are seen more distinctly as separate from the T waves and QRS complexes. Two premature ventricular complexes (PVCs) also are seen in the middle of the tracing. After the AV node has increased in refractoriness, the flutter waves *(F)* are much more clearly seen as distinct from the QRS complexes and T waves and are always evenly spaced, even when buried in a QRS complex *(small arrow)*. Lead aVF, 25 mm/sec, 1 cm = 1 mV.

202.4.2 Atropine Response Test

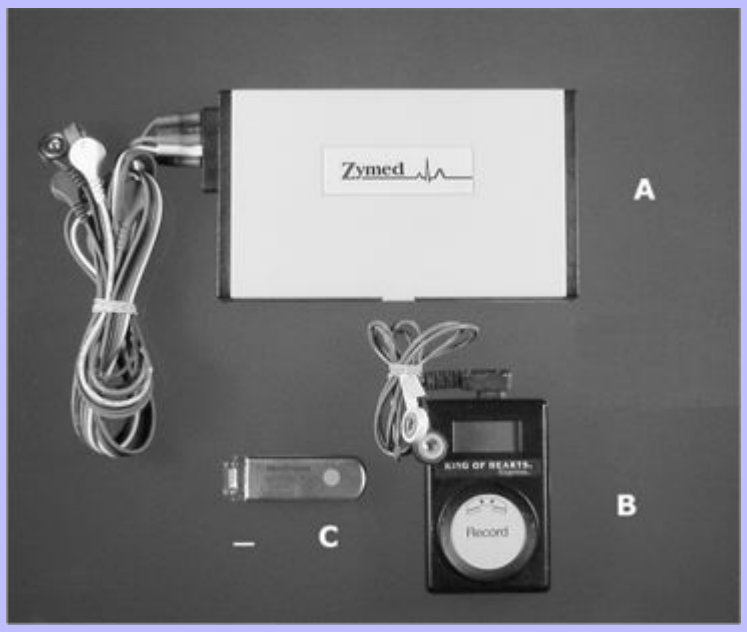
Administration of atropine sulfate 0.02 mg/lb (0.04 mg/kg) intravenously can be used diagnostically to evaluate bradycardias.[3] It allows the differentiation between bradycardias purely of vagal origin (atropine increases the heart rate) and bradycardias caused by intrinsic disturbances of impulse formation or conduction (atropine has no effect). The response occurs within seconds to minutes (always within 15 minutes) after injection.[3] Unfortunately, a positive response to atropine is poorly predictive of response to oral vagolytic drugs such as propantheline bromide in dogs with sick sinus syndrome (SSS).

202.5 AMBULATORY ELECTROCARDIOGRAPHY

In a patient with clinical signs caused by an intermittent cardiac arrhythmia, an ECG performed in the veterinary hospital may or may not be abnormal. Ambulatory ECG offers the possibility of correlating the ECG to the overt clinical manifestations observed by the owner. As a result, ambulatory ECG is valuable for evaluation of patients with episodic clinical signs because it can either rule in an arrhythmic problem (arrhythmia is diagnosed) or rule it out (normal rhythm occurs throughout the episode).[23–25,45–48]

Three types of ambulatory ECG monitors are available (Figure 202-20). Dr. Norman Holter developed the continuous monitor that now bears his name in the 1950s, when the earliest models weighed some 80 lbs (36 kg). Currently, Holter monitors are approximately the size and weight of a VHS videocassette, and they record the ECG continuously for 24 or 48 hours, usually on multiple leads simultaneously.[49,50] An audiocassette inside the monitor typically is used for storing the information during the recording period and must be decoded afterwards in an analyzer machine. Veterinarians can rent Holter monitors from various suppliers, including such on-line sources as www.labcorp.com, www.vetheart.com, www.idexx.com, and www.pdsheart.com. Holter monitor leads are placed on dogs as shown in Figure 202-21. Owners need to maintain a diary of the patient's activities—and lack thereof—during the entire monitoring period to provide a context for analysis of the tracing. For example, a heart rate of 40 bpm may not be unusual for a sleeping dog, but it would be an important finding if it occurred during brisk exercise. A veterinary patient's Holter report, if produced through human cardiology software, should be reviewed carefully.[49] Over-and underinterpretation are common, because software for automated Holter analysis is designed only for human ECGs at this time. Common sources of error from human Holter interpretation programs include inaccurate heart rate counting (undercounting QRS complexes that are too small during body movement or overcounting such as interpreting T waves as QRS complexes) and inaccurate arrhythmia diagnosis (over-or underinterpretation). It remains the veterinarian's obligation to assess the abnormal ECG segments shown in the Holter report and to decide whether the interpretation correlates well with the rest of the patient's information. Continuous in-hospital monitoring systems similarly allow long-term cardiac rhythm monitoring and manual analysis of tracings, and they offer the advantage of immediately displaying ECG information during patient observation and treatment.

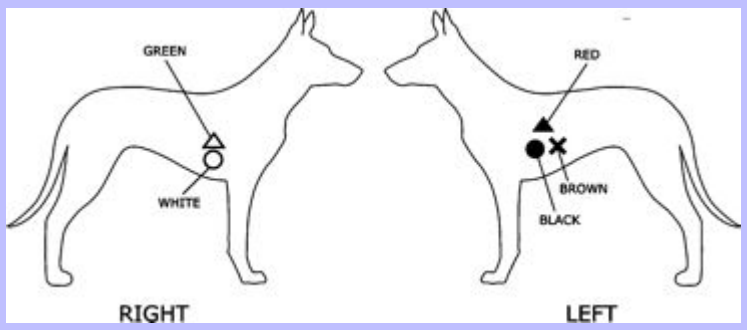
Figure 202-20 Ambulatory heart monitors. **A,** 24-hour (Holter) monitor. **B,** External event monitor. **C,** Implantable event monitor. Scale: white bar = 1 cm.



The second and third types of ambulatory ECG monitors are event monitors (see Figure 202-20). They continuously receive ECG information into a loop memory system, which can usually only retain the information temporarily. When an episode of clinical signs is observed, however, the owner needs to trigger the event monitor. Doing so saves an exact segment of ECG information in the monitor's permanent memory. Several episodes can thus be recorded over a number of days and then decoded either at the veterinary hospital or transtelephonically. Event monitors usually record only one lead, although newer models may record two leads. The difference between the two types of event monitors is that one is external, whereas the other is implanted subcutaneously. External event monitors are approximately the size of a deck of cards and require standard commercial (e.g., AA) batteries that provide 5 to 7 days of monitoring time.[47,48] If the batteries run out, all acquired episodes are deleted. External event monitors are connected to patients using two or three wires attached to cutaneous ECG patches, one on each side of the chest over the heart (modified precordial lead). The memory capacity of external event monitors ranges from 5 to 18 minutes, and the monitors are programmed beforehand to save a selected amount of ECG information (e.g., 45 seconds preceding the push of the button and 15 seconds after it for each triggered episode). They are available for use from various sources, including many of those listed previously for Holter monitors. Internal event monitors are implanted subcutaneously.[51,52] They measure 0.5×2×7 cm, about the size of a man's thumb, have a battery life of 1 year or more, and have a memory capacity of about 1 hour of ECG recording. The information they capture is retrieved after the episode is over, using a handheld unit placed over the area of skin where the monitor is located. The use of both types of event monitors is of proven diagnostic value in humans; both external, and to a much lesser extent so far, internal, monitors are in use in small animal patients.[23–25,47,48,51–53]

1050 1051

Figure 202-21 Electrode patch placement for Holter monitor. Colors correspond to the colors of the connecting tips on the ends of the Holter monitor wires.



Each form of ambulatory ECG monitoring has its relative merits.[47] Holter monitors are superior for screening the number of abnormal heartbeats on the ECG in a fixed 24-or 48-hour period, such as for assessing boxers for familial arrhythmic heart disease or for the evaluation of animals receiving systemic experimental drugs.[23,25,39,45,54] Holter monitors are also superior for therapeutic monitoring of antiarrhythmic drug effects[46] and recently have been shown to provide predictive information regarding the future development of dilated cardiomyopathy in Doberman pinschers, often before the earliest echocardiographic changes.[55,56] Conversely, external event monitors also have a number of advantages: they are smaller and lighter (3.5 oz [100 g], compared with 14 oz [400 g] for a Holter monitor), making them practical for cats and small dogs; they have a longer memory (up to 1 week), which is useful for episodes occurring less frequently; they eliminate some uncertainty of interpretation by directly associating the ECG information with an observed event; and they can transmit information transtelephonically, allowing the monitor to be reset and a new monitoring period to begin without a return visit to the hospital. Both Holter and external event monitors are costly electronic devices carried by patients that can damage them, and owners must be instructed to avoid their pets' exposure to moisture, extremes of temperature, and rough handling of the monitors.

202.6 CLASSIFICATION OF CARDIAC RHYTHM DISTURBANCES

A useful and practical classification scheme is one that separates cardiac arrhythmias into three groups: (1) disturbances of impulse formation (cardiac excitability), (2) disturbances of impulse transmission (cardiac conduction), and (3) complex disturbances involving abnormalities both of excitation and conduction. Some rhythm disturbances fit poorly into any category. Some disturbances of cardiac excitability are secondary to conduction disturbances (e.g., junctional or ventricular escape rhythms). Disturbances are listed according to the anatomic level of their origin (i.e., atrial, junctional, or ventricular).

Excitation disturbances can cause either excessive or inadequate contraction of the heart or its parts. Increased excitability produces extrasystoles (if intermittent) and tachycardia (if sustained). *Ectopy* is the term that describes spontaneous production of impulses anywhere in the heart. Decreased excitability leads to loss of impulse formation with electrical quiescence, resulting in bradycardia or asystole.

Conduction disturbances within the heart are all called *blocks*. Their categorization depends on the anatomic location of the block and its extent or degree. *First-degree block* refers to a slowing of conduction, *second-degree block* implies complete but intermittent interruption, and *third-degree block* involves complete and sustained interruption of conduction. Block can occur at the SA node (rarely identified), the AV node, or in branches of the His bundle (BBBs).

Finally, two disturbances combining excitability and conduction abnormalities are discussed. In pre-excitation, accessory conduction pathways bypass part of the normal A-V conduction pathway. Sick sinus syndrome (SSS) generally involves periods of bradycardia and tachycardia caused by dysfunction of the sinus node and supraventricular and ventricular conductive tissues.

202.6.1 Clinical Impact of Rhythm Disturbances

The rhythm disturbances mentioned previously do not all carry the same clinical importance. Furthermore, interspecies differences are marked. Some are commonly encountered, whereas others are extremely rare. Their clinical impact may range from harmless (some are benign variations of normal) to severely detrimental (potentially life-threatening arrhythmias). In cats, pre-excitation and isorhythmic AV dissociation have been associated with feline cardiomyopathies. In the dog, disturbances of excitability, especially extrasystoles and AFib, are more common than are disturbances of conduction, the majority of which are AV blocks.[1,2,57]

The hemodynamic consequences of cardiac arrhythmias depend on at least eight factors: (1) the ventricular rate, (2) the duration of the abnormal rhythm, (3) the temporal relationship between the atria and ventricles, (4) the sequence of ventricular activation, (5) inherent myocardial and valvular function, (6) cycle length irregularity, (7) drug therapy, and (8) extracardiac influences.[1–3] Ultimately, the sum of these factors—not just the appearance of the ECG—determines the impact of the arrhythmia on the patient. This is the reason that some animals with ventricular tachycardia (VT) are asymptomatic, whereas others are moribund.

202.6.2 Identification of Rhythm Disturbances

Today most clinical electrocardiography in veterinary medicine relies on single-lead, in-hospital ECGs. Multilead ECGs provide an additional level of information that is sometimes indispensable (see Figure 202-10). Ambulatory ECG is an effective and increasingly popular method for detecting intermittent rhythm disturbances or identifying the frequency of arrhythmias over a period of time (see previous discussion).

Rhythm disturbances are identified on the ECG using a methodical four-point examination. First, a rapid, cursory evaluation from left to right of the entire tracing gives a general idea of the cardiac rhythm and an initial diagnostic orientation. This step reveals whether a single rhythm or many rhythms exist. (Are all QRS complexes of the same morphology? Are the R-R intervals the same, or do they vary? If so, does the variation occur in a predictable manner?) One grossly assesses the heart rate (slow, normal, or fast), whether the rhythm is regular or irregular, and detects premature or delayed complexes.

Second, the R-R intervals are evaluated in representative sections of the entire tracing (Figure 202-22). In cats, variability of the R-R interval is not normally seen and is considered pathologic.[58] In dogs, a cyclical (i.e., rhythmic, patterned) variation of the R-R interval, respiratory sinus arrhythmia (RSA), is normal (see Figures 202-12 and 202-22). Irregularly irregular R-R variations are always abnormal in both species (see Figure 202-22).

Figure 202-22 Approach to the recognition of cardiac rhythm disturbances.

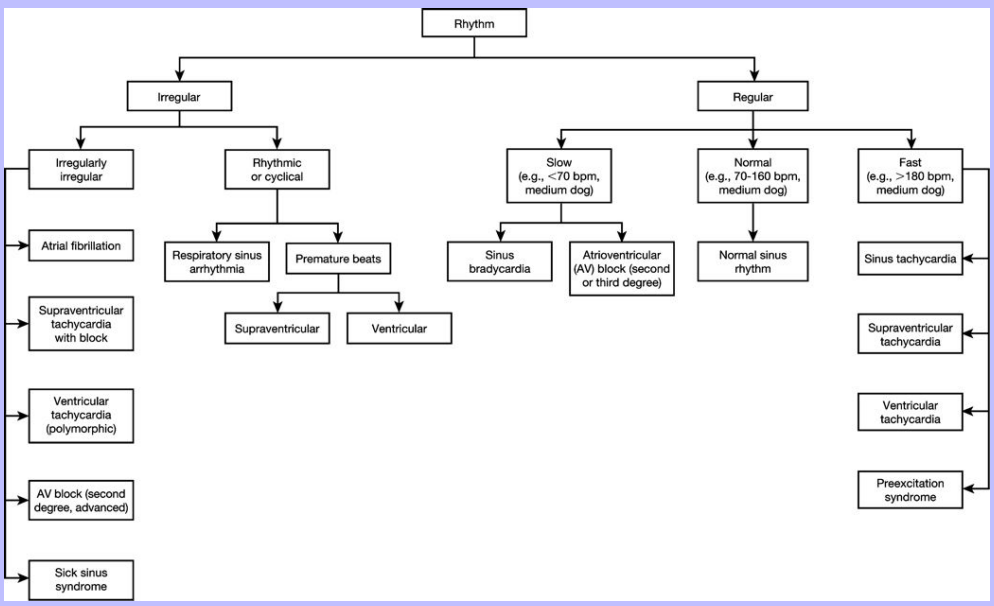


Figure 202-23 Artifact producing a wide, bizarre deflection in a dog. This is not an abnormal depolarization of the ventricles because the T wave is normal. Abnormal depolarization would invariably be followed by different or "abnormal" waves of repolarization (see Figures 202-32, 202-33, 202-35, and 202-36). Lead V_2, 25 mm/sec, 1 cm = 1 mV.

Third, the examination of individual QRS complexes consists of determining whether they are narrow or wide. Narrow QRSs generally identify ventricular depolarization of supraventricular origin (e.g., Figure 202-16). Wide QRSs represent the asynchronous depolarization of the two ventricles, which may be due to the ventricular origin of a depolarization, to BBB, or to pre-excitation (see following). Because repolarization follows directly in the wake of the wave of depolarization, then a QRS complex of abnormal shape should also have a T wave of abnormal or different shape. If the T wave is normal, the possibility of artifact, rather than a truly abnormal QRS, should be considered (Figure 202-23).

Fourth, examination of the P waves (present, absent; positive, negative; see Figure 202-13) provides information on the depolarization of the atria. Examination of the PR interval (1) determines if a P wave exists for every QRS complex and a QRS complex for every P wave (to assess A-V synchrony) and (2) assesses AV nodal conduction (PR interval duration) (see Figure 202-2).

Finally, the basic underlying rhythm and any additional or secondary rhythms that are superimposed are identified. Normally a P wave exists for every QRS complex (an atrial depolarization for every ventricular depolarization). Abnormalities causing more than one P wave for each QRS complex include second-and third-degree AV blocks, and abnormalities producing QRS complexes without P waves include ventricular arrhythmias, AFib, and atrial standstill.

202.6.3 Disturbances of Excitability

An important subdivision involves classifying disturbances of excitability broadly as disturbances of supraventricular excitability,[59,60] including STach, atrial extrasystoles (premature atrial complexes [PACs]), atrial tachycardias, atrial flutter, and AFib; or as disturbances of ventricular excitability, including ventricular extrasystoles (PVCs, VPCs), VT, TdP, ventricular flutter, and VF. The inciting factors that produce the arrhythmias in these two subgroups are often specific to the subgroup, and antiarrhythmic treatment is also sharply different between the two subgroups.

202.6.3.1 Disturbances and Alterations of Sinus Excitability

These arrhythmias are variations of sinus rhythm (see Figure 202-16), and are most commonly linked to normal, autonomic inputs. They may sometimes be abnormal and then are potentially detrimental. For example, STach is a normal and appropriate physiologic phenomenon during exercise, but it is commonly encountered in heart failure where, pathologically, it occurs even at rest.

202.6.3.1.1 Respiratory (normal) sinus arrhythmia (RSA)

In the dog the balance between the sympathetic and parasympathetic inputs to the heart generally tilts in favor of the parasympathetic system. This characteristic is in contrast to the average adult human or cat. This vagal predominance in the dog produces two particular features of sinus rhythm on the canine ECG: (1) RSA and (2) wandering pacemaker (WP).

RSA is the result of vagal effects that occur within the thorax during each respiratory cycle (see Figure 202-12). In dogs it is a normal physiologic phenomenon requiring no treatment. The result is a correlation between heart rate and respiratory rate, with slowing of the heart rate during expiration and acceleration of the heart rate during inspiration. The repeating cyclic nature of this arrhythmia is its hallmark. RSA is first noted in the puppy after 4 weeks of age,[1] generally disappears when the heart rate exceeds 150 bpm,[1,2] and often is enhanced when severe dyspnea is present (pneumothorax, fibrosis, emphysema) due to exaggerated changes in intrathoracic pressure.[1] Interestingly, the presence of RSA may constitute a valuable diagnostic clue in a common clinical situation, namely in the coughing, small-to medium-breed adult dog. It is common for these dogs to have concurrent mitral valvular heart disease (typical murmur is auscultated) and a primary respiratory disorder such as collapsing trachea or chronic bronchitis. It may be difficult to pinpoint whether congestive heart failure (CHF) or a primary respiratory problem is responsible for the animal's cough, yet the need for immediate and long-term

treatment and the prognosis both depend on knowing which disease process is the cause of the cough. The presence of RSA makes decompensated mitral valvular disease as the sole cause of the cough highly unlikely, because the cardiogenic pulmonary edema of CHF would almost invariably bring on increased sympathetic tone and loss of RSA. In cats in the hospital setting, RSA generally is considered pathologic.[58]

In the treatment of CHF with tachycardia (sinus or other supraventricular), successful digitalization may bring about the reappearance of RSA. This return of RSA is due to the reactivation of baroreceptors, which had been downregulated ("exhausted") by the ongoing sympathetic stimulation of heart failure.

202.6.3.1.2

Wandering pacemaker

WP is a normal, physiologic phenomenon in dogs that is not associated with pathologic conditions and requires no treatment (see Figure 202-12). In the dog the origin of depolarization in the heart is not fixed but may move within the RA, between the SA node and the AV node. On the ECG the result is variation in the P wave amplitude, with QRS complexes that retain a normal, supraventricular appearance. This variability in the P wave is often cyclic and often associated with RSA (see Figure 202-12). In this situation the amplitude of the P wave increases with an increased heart rate (inspiration) and decreases with decreased heart rate (expiration), sometimes to the point of disappearance (isoelectric P wave) or, rarely, negativity in leads II, III, and aVF.[1,2] The ECG differential diagnosis for WP includes morphologic abnormalities (e.g., P pulmonale) and supraventricular extrasystoles. In some individuals with marked resting vagal tone (e.g., brachycephalic dogs), an exaggerated but normal RSA and WP may be difficult to distinguish from a pathologic arrhythmia, namely PACs (supraventricular extrasystoles). Both PACs and the combination of WP and RSA produce a P wave of different morphology, a shorter R-R interval, and QRS complexes of normal morphology. Differentiation rests on the degree of prematurity (WP and RSA should not occur so prematurely as to produce a P wave inside the preceding T wave), and the appearance of a series or "paroxysm" of such beats closely coupled to each other (corresponding to multiple supraventricular extrasystoles [i.e., supraventricular tachycardia], not RSA). If neither characteristic is apparent, a Holter monitor can be used for assessing a large number of heartbeats (see previous discussion), or an atropine response test (see previous discussion) can be performed to abolish the vagal effect and seek out persistently premature heartbeats with a different P wave morphology and normal QRS complexes (i.e., PACs, in the absence of vagal tone).

1053

1054

Figure 202-24 Sinus bradycardia (SB) in a dog. The heart rate is 50/min. Lead II, 25 mm/sec, 1 cm = 1 mV.

202.6.3.1.3

Sinus bradycardia

Sinus bradycardia (SB) is a sinus rhythm in which the heart rate is abnormally low (see Boxes 202-1 and 202-2; Figure 202-24). A 1:1 ratio of normal-appearing QRS complexes and P waves exists. Although some approximate normal ranges of heart rate exist for dogs and cats (see Boxes 202-1 and 202-2), the notion of bradycardia varies according to species, body weight, age, and breed, with larger, older, or brachycephalic dogs tending to have slower heart rates than average, and cats having normal heart rates that are markedly influenced by environmental stimuli.

SB generally indicates the physiologic (e.g., brachycephalic, athletic individual) or pathologic (e.g., systemic intoxication) predominance of the parasympathetic system. A diagnostic aid is the response to an intravenous injection of atropine (see previous discussion).[61] In general, only severe bradycardias directly linked to overt clinical signs (syncope, malaise, seizures) warrant specific treatment with drugs or pacemaker implantation, and SB is rarely the primary cause of such clinical manifestations. One exception is the instantaneous transition from a tachycardia to SB (or other bradycardia [e.g., ventricular escape rhythm]; see following) in a debilitated, unstable, often unconscious patient. Such a rapid change may herald an upcoming cardiac arrest and should be addressed with assessment of the patient for underlying causes and preparation for cardiopulmonary resuscitation.[62] (Antiarrhythmic drugs to consider: none; parasympatholytics; sympathomimetics; rarely pacemaker.)

202.6.3.1.4

Sinus tachycardia

STach is a sinus rhythm that occurs at an elevated rate (see Boxes 202-1 and 202-2; Figure 202-25). The wide range of resting heart rates in normal cats and dogs makes the cut-off between NSR and STach an approximate one. In dogs, STach exists when the increase in heart rate (P-QRS-T complexes of normal sinus origin) gives rise to the loss of RSA, the latter being a normal physiologic phenomenon in the dog (see previous discussion; see also Figure 202-12). Diagnosing this arrhythmia on the ECG can be difficult when the heart rate is extremely elevated, causing T and P waves to blend together. Carotid sinus massage, which temporarily slows the heart rate, separates the P and T waves, and clarifies that the tachycardia is of sinus origin (see previous discussion).

Figure 202-25 Sinus tachycardia (STach). The heart rate is 200/min in this dog with chocolate (theobromine) toxicity. Lead II, 25 mm/sec, 1 cm = 1 mV.

The causes of STach are diverse and are all marked by sympathetic predominance over parasympathetic inputs. Treatment of this arrhythmia is therefore aimed at the underlying cause when one exists. To slow a STach is only indicated if the tachycardia itself is producing clinical signs and is poorly controlled with treatment of the underlying disorder. For example, in hyperthyroidism, a beta-blocker may be given concurrently with antithyroid treatment. (Antiarrhythmic drugs to consider: class II.)

202.6.3.2 Disturbances of Atrial Excitability

Disturbances of atrial excitability are common, especially in the dog. Indeed, in the most common forms of heart disease in dogs (endocardiosis, cardiomyopathy, many congenital malformations), atrial distension leads to pathologic disorganization of the atrial tissue, which can then generate atrial hyperexcitability (and possibly conduction disturbances as well).

202.6.3.2.1 Atrial extrasystoles

Atrial extrasystoles (synonyms: PACs or premature atrial contractions, atrial premature complexes or contractions (APCs), atrial premature depolarizations) are premature depolarizations that originate in an ectopic atrial focus (Figure 202-26). Identification of atrial extrasystoles is based on a combination of two or more of the following five abnormalities but always must include the first two points: (1) prematurity of the P-QRS-T sequence; (2) QRS complexes that have a supraventricular appearance, in that they are narrow and comparable in shape to the sinus QRS complexes (rarely, QRS complexes may be absent or widened in cases of atrial extrasystoles that are exceptionally early and thus occur during the total or partial refractory period, respectively); (3) a P wave of different amplitude than sinus P waves, including negative, biphasic, or positive P waves, but always preceding the QRS complexes; (4) a P-R interval that is often different from the sinus PR interval, be it shorter or longer,[2] and (5) a postextrasystolic pause that most often is noncompensatory (Figure 202-27). The pathogenesis of atrial extrasystoles is most commonly related to a structural cardiac (atrial) lesion. Distension of the atria is the main cause of these ectopic foci, but atrial tumors (hemangiosarcoma), hyperthyroidism in the cat, digitalis toxicity, and other systemic disturbances also are recognized causes.[3] Clinical repercussions of atrial extrasystoles are minor, except in cases of multiple repeated bursts (Atrial Tachycardias, following), and the main interest in identifying atrial extrasystoles on an ECG is to add weight to a suspicion of atrial disease. Treatment for atrial extrasystoles is therefore first aimed at addressing the underlying cause rather than resorting to antiarrhythmic drugs specifically.

202.6.3.2.2 Atrial tachycardias

An atrial tachycardia (supraventricular tachycardia) is a series of atrial extrasystoles occurring at a rate greater than sinus rhythm (Figure 202-28). It may be intermittent or continuous, and the impulses may all be transmitted to the ventricles or AV block may be noted in some instances. The exact mechanism of atrial tachycardias can involve micro re-entry (intra-atrial re-entrant tachycardia) or spontaneous automaticity of an ectopic atrial focus (automatic atrial tachycardia).[59,63] Identifying intermittent atrial tachycardias is usually straightforward: the ECG shows a burst of atrial extrasystoles. Establishing a diagnosis of sustained atrial tachycardia may be difficult, however, because P waves may not be clearly evident, each one potentially being buried within the previous QRS complex. Differentiation between sustained atrial tachycardia and “high” ventricular (i.e., originating near the AV node) tachycardia can therefore be helped by exteriorizing the P waves, which can be elicited with a vagal maneuver (see

1054
1055

previous discussion) and subsequent slowing of the tachycardia or even sinus capture (resumption of sinus rhythm). The same goal may also be reached pharmacologically using graded doses of such intravenous agents as propranolol, esmolol, edrophonium, or phenylephrine (Table 202-1). Intravenous adenosine used for this purpose subjectively appears to be much less effective in dogs than in humans. Causes for atrial tachycardias are the same as those listed for atrial extrasystoles (see previous discussion). The clinical impact of an atrial tachycardia depends on its duration, rate, and underlying cardiac lesions. Intermittent AV block can limit the ventricular rate and may lessen clinical impact in cases of rapid atrial tachycardias. Atrial tachycardias often precede the development of AFib. Treatment of the underlying disease is an essential part of managing these arrhythmias. (Antiarrhythmic drugs to consider: digoxin, class II, IV.)

Figure 202-26 Premature atrial complexes (PACs) in a dog. Two PACs are seen in the middle of this lead II strip; the first is more premature than the second one (25 mm/sec; 1 cm = 1 mV). Premature P waves *(arrows)* of a different morphology than the sinus P waves and QRS complexes of the same shape as sinus QRS complexes are noted.

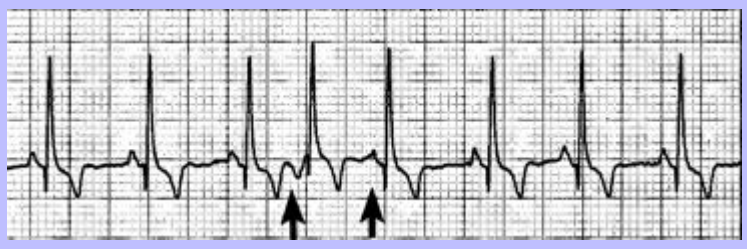

Figure 202-27 Schematic representations of normal sinus rhythm (NSR) and premature complexes. *NSR:* The heart rate remains constant, and the interval from P to P or from R to R does not change. *Resetting:* A premature atrial complex (PAC; beat 3) resets the sinus rhythm so that the period from the beginning of the premature P waves to the next normal P wave is equal to exactly one P-P interval. *Resetting with pause:* The PAC (beat 3) is followed by a pause greater than one P-P interval but less than two P-P intervals. Both resetting and resetting with pause are examples of noncompensatory pauses (the rhythm of the *SA* node is affected by the premature beat, which alters the SA node's ability to provide a normally-timed, “compensatory” beat after the premature beat). *Compensatory pause:* The premature ventricular complex (PVC, beat 3) is followed by a compensatory pause; that is, the period from the normal P wave in the beat preceding the PVC to the normal P wave of the beat after the PVC is equivalent to exactly two P-P intervals. The sinus P wave occurs on time, but it is not conducted through the atrioventricular (AV) node to the ventricles, which are in a refractory state due to the PVC. *Interpolation:* A PVC (beat 3) occurs between two normal sinus complexes without disrupting normal rhythm. Because of concealed conduction into the AV node, interpolated PVCs commonly delay AV nodal transmission of the next beat, which manifests as prolongation of the PR interval for the heartbeat that follows the interpolated PVC (see also Figure 202-32). This characteristic is useful for differentiating interpolated PVCs from motion artifact.

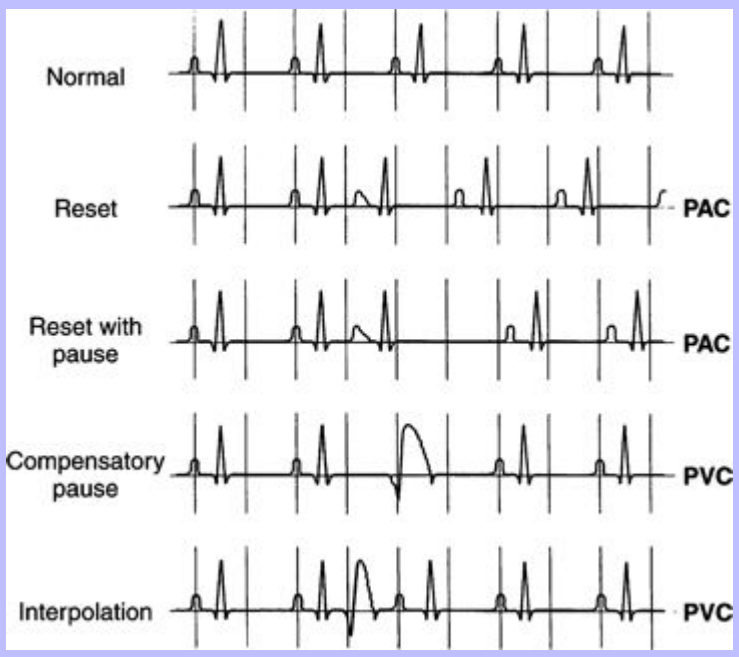

Figure 202-28 Supraventricular tachycardia. A burst of premature (rapid) QRS complexes is seen in the middle of the tracing. The QRS complexes are of the same shape as sinus QRS complexes. No clinical signs were present in this older Golden retriever dog, either at admission or during follow-up, and an echocardiogram was unremarkable. Lead II, 25 mm/sec, 1 cm = 1 mV.

202.6.3.2.3 Atrial flutter

Atrial flutter is characterized by a rapid and regular series of atrial depolarizations, without a rest phase between atrial depolarizations (see Figure 202-19). Identification of this arrhythmia is therefore based on the occurrence of (1) rapid, rhythmic waves of atrial electrical activity referred to as *flutter (F) waves*, usually occurring at a very high rate (often > 300/min); (2) absence of a return to baseline of the F waves (giving a "saw tooth" baseline appearance); (3) QRS complexes of a supraventricular appearance; and (4) a variable, irregularly irregular R-R interval. Atrial flutter is different from other atrial tachycardias in that no return to the isoelectric baseline occurs after each atrial depolarization in atrial flutter. This diagnosis may be very challenging when each flutter wave is transmitted through the AV node to the

ventricles. Such 1:1 conduction leaves the F waves buried in the preceding QRS complexes, which complicates the diagnosis (see Figure 202-19). Atrial flutter occurs as a result of a macro re-entrant circuit within one atrium—an abnormal, self-perpetuating cyclical electrical loop in the atrium in which an endless circle of electrical conduction can be initiated through atrial stretch, for example. Termination of atrial flutter can occur spontaneously, but treatment is necessary when a persistently high ventricular rate occurs. Treatment most commonly aims to control ventricular rate (see Atrial Fibrillation, following). Permanent abolition of atrial flutter is achieved with radiofrequency catheter-based interruption of the flutter circuit (see Radiofrequency Ablation, following).[59]

202.6.3.2.4

Atrial fibrillation

AFib is a common and important arrhythmia. It represents 14% of all canine arrhythmias, including a 50% incidence in cases of dilated cardiomyopathy in dogs, and it can bring on clinically overt hemodynamic changes requiring specific treatment.[64] A prevalence of AFib in up to 2% of the human population is estimated,[59,65,66] but a similar statistic is not available in veterinary medicine. AFib is characterized by complete electrical disorganization at the atrial level, leading to a chaotic, rapid series of atrial depolarizations (400 to 1200 per minute) (Figure 202-29). In AFib, the AV node acts as a "gatekeeper" for this chaotic electrical activity, allowing only those electrical depolarizations with optimal intensity, timing, and orientation to pass through to the ventricles and thus controlling the ventricular rate to some extent.

The three ECG characteristics of AFib are (1) supraventricular-appearing QRS complexes (narrow, upright, and of only slightly variable amplitude in lead II, unless ventricular aberrancy/BBBs are concurrent); (2) an irregularly irregular rhythm, with ventricular rates that may be low, normal, or most commonly without treatment, high; and (3) no visible P waves (replaced by a fine undulation of the isoelectric line, termed *f waves*). The absence of organized atrial depolarizations can have hemodynamic, and therefore clinical, consequences during physical activity or in patients with advanced stages of structural heart disease. During diastole, active filling is associated with the P wave (i.e., atrial contraction), which can account for up to 30% of total ventricular filling. Its absence therefore can reduce ventricular volume to suboptimal levels, producing overt clinical signs during exertion. Furthermore, the rapid overall ventricular rate, as well as the premature occurrence of some individual QRS complexes, bring about poor diastolic filling. For these reasons, some contractions may be ineffective intermittenly and one or more ausculted heartbeat, may be without a corresponding palpable arterial pulse (i.e., pulse deficit). AFib is one of the few arrhythmias that may be suspected from the moment of auscultation and palpation during the physical examination, based on the chaotic irregularity of the cardiac rhythm on auscultation and palpation of the chest, together with pulse deficits. Polymorphic VT and frequent PVCs, however, should be included in the differential diagnosis of this physical exam finding (see following). Counterintuitively, high vagal tone (e.g., from concurrent gastrointestinal [GI] disease) predisposes to AFib, because parasympathetic stimulation of atrial myocytes accelerates their repolarization in a heterogeneous fashion, which increases the likelihood of the initiation of arrhythmia.

1055 1059

Table • 202-1 Drugs Used for the Treatment of Cardiac Arrhythmias

GENERIC NAME	TRADE NAME	ADMINISTRATION ROUTE	COMMON INDICATIONS	DOSE	COMMENTS
Adenosine	Adenocard	IV	Terminates acute paroxysmal supraventricular tachycardia	1.5–3.0 mg/dose; repeat in 1 min to maximum of 6–12 mg	Side effects: sinus arrest, sinus bradycardia (SB), and atrioventricular (AV) block; often ineffective in dogs and cats
Amiodarone	Cordarone	Oral	Recurrent ventricular fibrillation; recurrent hemodynamically unstable or malignant ventricular tachycardia (VT); atrial fibrillation (AFib)	4.5 mg/lb bid PO × 1 week, then 2.2–3.8 mg/lb PO sid; if IV, give in graded dose to 5 mg/lb; in sick dogs dose is unknown; serum levels is 1–2 µg/mL	Side effects include proarrhythmia, Coombs' positive test result, pulmonary fibrosis, hypothyroidism, liver necrosis, photosensitivity, and gastrointestinal (GI) toxicity
Atenolol	Tenormin	Oral	Same as propranolol	0.15–0.5 mg/lb bid in the dog; 0.5–1.4 mg/lb sid to bid in the cat	Weakness, depression, hypotension, bradycardia, inappetence
Atropine			1. Test responsiveness of sinus node	0.01–0.03 mg/lb IV	1. Do not use in states of heart failure
Tablets		Oral	2. Hyperactive carotid sinus reflex (SA arrest)		2. Do not administer when bronchial tree secretions a problem
Injectable		IV, IM, SQ	3. AV block (second and third degree)		

Digoxin	Lanoxin		1. Supraventricular premature contractions and tachyarrhythmias 2. Right heart failure 3. Pump dysfunction	0.22 mg/m2 bid PO as maintenance dose; doubledose initially first 24 h forrapid effect; lower dose in large (>30 lb) and giant breeds of dogs	1. Digitalize cautiously 2. Monitor with ECG3. All doses approximate and must be titrated based on patient response
Tablets	Cardoxin	Oral			
Elixir		Oral			
Injectable		IV		0.0312 mg per cat eod PO in cats—not for use in restrictive disease states	4. Side effects: malaise, anorexia, vomiting, diarrhea
Diltiazem	Cardizem (not sustained-release form)	Oral IV	Supraventricular tachyarrhythmias; feline hypertrophic cardiomyopathy used orally and chronically	0.2–0.7 mg/lb q8h PO in dogs 0.7 mg/lb q8h PO in cats IV: 0.02–0.03 mg/lb; repeat every 2 min to effect—max dose 2 mg/lb IV	Side effects include bradycardia, hypoten-sion, collapse, and severe weakness; if SUT is physiologic response to systemic problem, correct the problem first (or risk of cardiac arrest)
Esmolol	Brevibloc	IV	Supraventricular tachycardia	0.025–0.1 mg/lb/min (25–100 µg/lb/min) 0.05–0.22 mg/lb IV Effects occur within 2 min	Short-term IV agent; used to control ventricular rate while agents are given for long-term effects; used for AFib, atrial flutter, supraventricular tachycardia; side effect is rapid, severe hypotension; do not use in congestive heart failure (CHF) -compromised patient

Isoproterenol Injectable	Isuprel Injectable	IM, IV, SC	1. Advanced second-degree and third-degree heart block 2. SA arrest 3. SB (?)	For bradyarrhythmias: one 1-ml vial (0.2 mg) in 250 D5W IV to increase heart rate, use to effect (0.5–1 mL/min) 0.1–0.2 mg SQ or IM q4h for heart block (variable efficacy by these routes)	May be used on temporary basis parentally until conduction improves or pacemaker is implanted
Lidocaine 2% without epinephrine	Xylocaine	IV only	Ventricular tachyarrhythmias causing hemodynamic disturbances or malignant arrhythmias; do not use for occasional VPC or hemodynamically stable multiform beats	1. 1–2 mg/lb IV slow bolus over 2 min or until arrhythmia controlled 2. 1 mg/lb IV slowly, then 10–40 µ/lb/min continuous infusion or 1 mg up to 4 times over 5 minutes to effect 3. For cats, 0.25–0.5 mg/lbIV bolus, then 5–20 µ/lb/min (0.005–0.02 mg/lb/min) CRI	1. Reserve for serious arrhythmias 2. Toxicity includes convulsions and respiratory arrest 3. Single IV dose lasts 15–20 min only 4. Excretion is hepatic
Metoprolol	Lopressor Toprol XL	Oral	Hypertension, beta-blockade	0.2–0.5 mg/lb sid or divided in multiple doses bid-tid depending on product used	Used for hypertension, beta-blockade, CHF arrhythmias (both supraventricular and ventricular)
Mexiletine	Mexitil	Oral	Ventricular tachyarrhythmias	2–5 mg/lb q8-12h (dogs)	Few side effects; may be used with digoxin and class I and II antiarrhythmic agents; hepatic excretion

Phenytoin	Dilantin		1. Some ventricular tachyarrhythmias	7–14 mg/lb q8h orally 2.24–4.5 mg/lb IV	Infrequently used as an antiarrhythmic drug; hepatic excretion
Capsules		Oral	2. May be useful in treating arrhythmiascaused by digitalis overdose		
Injectable		IV			
Procainamide	Pronestyl		1. Ventricular premature contractions	1.3–10 mg/lb q2-6h (to 8hsustained release form)	1. IV effect is brief, and oral maintenance dose must be given q4h
Capsules	Pronestyl-SR		2. VT	2. Dogs: 1–10 mg/lb IV over 30 min, then infuse 10–20 µg/lb/min (0.01–0.02 mg/lb/min) CRI	2. Oral forms available in sustained release tablets may not be absorbed
Tablets	Procan SR	Oral		3. Cats: 0.5–1.0 mg/lb IV bolus, then 5–10 µg/lb/min CRI	3. Hepatic excretion
	Injectable	IV			
Propafenone	Rhythmol	Oral	(a) Supraventricular tachyarrhythmias	Unknown; begin in medium-to large-size dogs with 75–125 mg orally tid	May be proarrhythmic with structural heart disease; do not use if Q-T is prolonged
		IV (?)	(b) Accessory conduction arrhythmias		
			(c) VT		
Propranolol	Inderal		1. Supraventricular tachyarrhythmias	Oral: general 0.2–0.5 mg/lb q8h: 2.5–20 mg q8-12h small dogs; 10–40 mg q8-12h medium and large dogs; 40–80 mg q8-12h large and giant dogs; 2.5 mg q12-24h cats; 0.1–0.5 mg IV no more frequently than q1-3 min to 5 mg maximum; administer until rate slows or toxicity occurs Cats: 0.1-0.5 mg IV boluses, 2.5–5 mg/cat PO sid-bid	1. Use with caution: as a negative inotropic agent, it may induce CHF
Tablets		Oral	2. To slow ventricular rate in atrial fibrillation or to distinguish the latter from VT		2. Excessive dose causes reduction in cardiac rate and prolongation of PR and QT intervals
Injectable		IV	3. Arrhythmias of digitalis intoxication		
			4. Pre-excitation syndromes		
			5. Some ventricular arrhythmias, when other agents fail		

1. Quinidine sulfate (tablets)	Quinidinesulfate	Oral	1. Ventricular premature contractions 2. VT	3–10 mg/lb (of base) IM or PO q6-8h; may be given q2h until loading dose controls arrhythmia or induces toxicity	1. Do not use in presence of CHF unless this is being treated simultaneously
2. Gluconate (long-acting tablets)		Oral	Sustained release forms given 8.8–12h PO		2. Toxicity results in increased heart rate and prolongation of the PR, QRS, and QT intervals
3. Gluconate (injection)		IM		3–10 mg/lb (of base) q2-4h IM, PO; sustained-release forms: 4–10 mg/lb PO q8h	3. Often effective in lower doses when used with procainamide, mexiletine, or a beta-blocking agent 4. Hepatic excretion 5. IV use may cause hypotension 6. Injectable product is not used IV—only IM (epaxial) 7. Competitive with digoxin; do not use together
Sotalol	Betapace	Oral	Class II and III for ventricular arrhythmias	Canine: 0.44–2.8 mg/lb bid-tid Feline: 10–20 mg/cat bid	GI disturbances; hepatotoxicity; decreased HR; P-R prolongation
Tocainide	Tonocard	Oral	Ventricular tachyarrhythmias	7–11 mg/lb q8-12h (dogs)	May need to use with other class Ia antiarrhythmic agents for better effect; hepatic excretion

Verapamil	Isoptin	Oral IV	Supraventricular tachycardia	Oral: 0.2–1.0 mg/lb bid-tid IV: 0.01 mg/lb IV to maximum of 0.07 mg/lb	Side effects: weakness, collapse, bradycardia; contraindicated in shock, heart block, sick sinus syndrome (SSS), CHF, VT

Figure 202-29 Atrial fibrillation (AFib). The irregularity of the rhythm is less apparent when the ventricular rate is fast, as when this dog with dilated cardiomyopathy and congestive heart failure (CHF) was first evaluated (*left panel,* ventricular rate = 280/min). Diuretics, digoxin, and eventually beta-blocking therapy led to good rate control and a clearer electrocardiogram (ECG) diagnosis (*right panel,* ventricular rate = 135/min). Lead II, 25 mm/sec, 1 cm = 1 mV.

A major diagnostic impostor on ECG is the combination of AFib and BBB (Figure 202-30), which produces wide QRS complexes and therefore can appear to mimic VT, but without P waves to conclusively indicate AV association (BBB) or dissociation (VT). In such a situation, a vagal maneuver can be performed, and its effect on the AV node could reduce the ventricular rate with AFib + right bundle branch block (RBBB) but not with VT. In addition, sustained, monomorphic VT is generally characterized by regular R-R intervals, whereas AFib with BBB is not.

Table • 202-2 Comparison of Ectopic Beats of Supraventricular or Ventricular Origin

FEATURE	SUPRAVENTRICULAR	VENTRICULAR
Wide, bizarre QRS complexes	Very rare	Common
QRS complex shape	Same as sinus QRS	>10% different from sinus QRS
P wave for every QRS	Yes; often of different shape	No; Ps occur regularly throughout tracing, but independently of QRSs
T wave	Same as sinus T wave	Different from sinus T wave
Postextrasystolic pause (see Figure 202-27)	Usually noncompensatory	Usually compensatory
QRS fusion beats as hallmark	No	Yes
Positive response to vagal maneuver	Possible	Virtually never

Figure 202-30 Atrial fibrillation (AFib) with right bundle branch block (RBBB). This impostor for ventricular arrhythmia is distinctive in its irregular R-R interval and its response to vagal maneuvers. Lead II, 25 mm/sec, 1 cm = 1 mV.

AFib in dogs most often is caused by primary, underlying cardiac disease. However, AFib may also occur in individuals with structurally normal hearts (e.g., anesthesia, hypothyroidism, rapid, large-volume pericardiocentesis, GI disease, volume overload causing atrial stretch) if those hearts contain sufficient atrial myocardial mass to permit fibrillation (i.e., medium to large breed dogs).[67] In giant breed dogs, particularly the Irish wolfhound, AFib commonly occurs in otherwise healthy dogs with grossly normal atria (i.e., lone AFib).[67,68] It remains to be determined whether those patients with AFib and structurally normal hearts that progress to dilated cardiomyopathy do so because of their arrhythmia, or whether, conversely, AFib is only the arrhythmic prelude to a disease that later causes dilation and systolic dysfunction.

In cats, AFib occurs uncommonly and is virtually always associated with structural heart disease causing atrial enlargement.[69] Most cats have clinical signs suggesting heart failure (e.g., dyspnea) or thromboembolism at the time of diagnosis of AFib, but 20% to 25% of cases of AFib in cats are discovered incidentally (e.g., during a routine annual examination) and as such, this arrhythmia may be an early manifestation of heart disease in some cats. AFib does not clearly influence survival negatively in cats compared with the prognosis associated with the underlying heart diseases proper. In a subgroup of 24 cats with AFib and known survival statistics, 21% lived between 6 and 12 months after the diagnosis of AFib and 33% survived 1 year or more.[69]

1059

1060

AFib usually is a persistent, permanent arrhythmia. It does occur paroxysmally in the dog[70] and very rarely so in the cat. Paroxysmal AFib usually is of short duration and in most cases progresses to persistent AFib because of severe underlying cardiac disease (usually atrial enlargement).

In most cases of AFib, two goals of treatment exist: (1) managing the underlying heart disease and (2) maximizing cardiac output by controlling (slowing) the rate of conduction through the AV node if needed (see Figures 202-29 and 202-31). The approach of letting the atria fibrillate and concentrating on ventricular rate control, rather than attempting to convert the AFib to sinus rhythm, was recently supported by the results of a prospective study of 4000 human AFib patients. It was found that converting the AFib back to sinus rhythm brought no significant benefit in terms of survival, and that conversion carried a higher risk of adverse effects.[71] As a rule, beta-blockers, calcium channel blockers, or both are given in low initial doses and up-titrated to effect, typically over a period of days to a few weeks, based on heart rate. Subsequently, even once an acceptable range of heart rates has been reached, periodic drug dose adjustments (e.g., re-evaluation every 3 to 6 months, sooner if problems occur) are usually necessary to maintain good rate control.

In small animal medicine, the ideal ventricular rate varies for each patient depending on many factors, including stage of CHF and body weight. One substantiated guideline suggests a target ventricular rate for dogs with AFib weighing 20 to 25 kg of approximately 130 to 145 bpm.[72] A recent study compared ventricular rates in canine AFib obtained on careful physical examination by trained persons including cardiologists to the rate obtained simultaneously by ECG. The level of accuracy ranged from 64% to as low as 12% for veterinary students and some veterinarians.[73] Follow-up monitoring of ventricular rate control relies on repeated ECGs rather than physical exams alone. (Antiarrhythmic drugs to consider: digoxin; class II or class IV agents; combination therapy is often most successful and produces fewer adverse effects than high doses of a single drug.)

202.6.3.3 Disturbances of Ventricular Excitability

Disturbances of ventricular excitability are important because they involve the main element in the cardiac pump, and may therefore have very severe hemodynamic and clinical repercussions. However, it must be recognized that ventricular arrhythmias have very diverse mechanisms and causes (especially noncardiac), such that severity, treatment, and prognosis depend on more than ECG findings alone.

202.6.3.4 Ventricular Ectopy: Premature Ventricular Complexes, Accelerated Idioventricular Rhythm, and Ventricular Tachycardia

202.6.3.4.1 Ventricular extrasystoles or premature ventricular complexes

Ventricular extrasystoles (synonyms: premature ventricular contractions, beats, or depolarizations [PVC; VPB, VPC, VPD, ventricular ectopy]) are premature depolarizations generated by an ectopic focus located in the ventricular tissue.[1,2,23,45,74] These arrhythmias are the most common of all rhythm disturbances.[64] Their identification often is simplified by the wide QRS complexes they generate, which have a different morphology (shape) than normal sinus QRS complexes. Most ventricular extrasystoles have a wide, often bizarre-appearing QRS complex (>0.07 second in dogs), without an associated P wave, and a different (often very large) associated T wave (Figures 202-32 and 202-33). Single PVCs are usually followed by a compensatory pause (see Figures 202-27 and 202-33) but may be interpolated instead (see Figures 202-27 and 202-32). Multiples of two PVCs are referred to as *a pair*; 1:1 alternation between sinus beats and PVCs is referred to as *bigeminy;* and three or more PVCs in a row constitutes

ventricular tachycardia (VT; see following). *Trigeminy* describes a repeating pattern of either 2:1 PVCs: sinus beat, or 2:1 sinus beats: PVC.

For purposes of identifying an underlying cause and for accurate therapy, it is important to differentiate ventricular extrasystoles from PACs (see Table 202-1). It is also essential to differentiate ventricular extrasystoles from the other major causes of widened QRS complexes: (1) morphologic changes due to cardiomegaly and axis shift (see Figure 202-8); (2) intraventricular conduction disturbances within the bundle branches (see Figures 202-44 and 202-45); (3) abrupt motion or other artifact (see Figure 202-23); and (4) the wide but nonpre-mature QRS complexes of ventricular escape beats (see Figure 202-42, *a*). These four causes for wide QRSs are not ventricular arrhythmias, do not involve a pathologic focus in the ventricle, are not associated with a disproportionately high occurrence of VT/VF, and therefore are not treated with anti-arrhythmic drugs.

Causes of ventricular extrasystoles include virtually any cardiac or systemic disorder,[75] with the most common of these including such primary cardiac diseases as cardiomyopathy,[55,56,76] valvular heart disease, congenital heart disease, and endocarditis[77] and such systemic problems as hypokalemia, anemia, hypoxia, blunt trauma,[78] gastric dilatation-volvulus,[79,80] abdominal masses (commonly splenic or hepatic)[81–83] intoxication, and acidosis. Normal dogs will commonly have up to 24 PVCs daily as recorded on Holter studies.[22,23] In cats, ventricular extrasystoles seem to be associated predominantly with cardiomyopathy rather than extracardiac causes. The most challenging aspect of managing ventricular extrasystoles remains the evaluation of their severity and the assessment of the need for treatment (see Ventricular Tachycardia and treatment discussions, following). Evaluation of causes and whether to treat ventricular ectopy are discussed under Ventricular Tachycardia, following.

Two specific diseases of dogs are almost exclusively arrhythmogenic, producing PVCs and VT, and often overt clinical manifestations of acute arrhythmia (malaise, syncope, Stokes-Adams seizures, or sudden death) as the chief abnormality. Familial ventricular arrhythmia of Boxer dogs (Boxer cardiomyopathy, arrhythmogenic RV cardiomyopathy and dysplasia) causes ventricular extrasystoles and VT.[84,85] Initially no thoracic radiographic or echocardiographic changes are seen, although individuals with disease that is more advanced may have dilated cardiomyopathy (see Chapter 203, Canine Myocardial Diseases). No sex predilection has been found, and it is suspected that the syndrome is inherited as an autosomal dominant trait (no carriers).[45] The causative lesion is a degeneration of myocytes in the outflow tract region of the RV, as supported by histopathologic studies[84] and the typical, left BBB-like appearance of the PVCs indicating their RV origin.[74] In many cases the ventricular arrhythmia is an incidental finding in Boxer dogs that otherwise appear normal. These occult, latent cases are predisposed to developing clinical signs later in life, having offspring with the disease, or both. Also commonly, familial ventricular arrhythmia of Boxers produces overt clinical signs that are the patient's chief complaint. Overt arrhythmic manifestations range from aborted syncope (episodes of stumbling or “drunken” appearance) to true syncope, sudden cardiac death, or both.[46,84] These events may be triggered in some cases by intense sympathetic activity, including excitement and physical exertion, and thus are managed by avoiding circumstances that trigger such behavior. Since its original description,[84] the disease seems to coexist less commonly with grossly dilated ventricles, poor contractility, or both, whereas overt manifestations due to severe ventricular extrasystoles are now a common problem in the breed. This change may simply reflect increased awareness of the problem and early screening. Clinical confirmation of the diagnosis begins with identification of the signalment and chief complaints as described previously and ultimately rests on the demonstration of ventricular

1060 1062

extrasystoles on ECG in the absence of any other inciting cause (diagnosis of exclusion). Frequently, serial Holter monitoring is necessary to evaluate potential breeding individuals, because affected dogs may have only a few PVCs per hour. The presence of PVC pairs, or of VT, strongly supports the diagnosis.[24,85] Treatment involves management of arrhythmias (see Ventricular Tachycardia, following) and prevention of transmission of the disease through screening and not breeding affected individuals.

Figure 202-31 Therapeutic approach to atrial fibrillation (AFib).

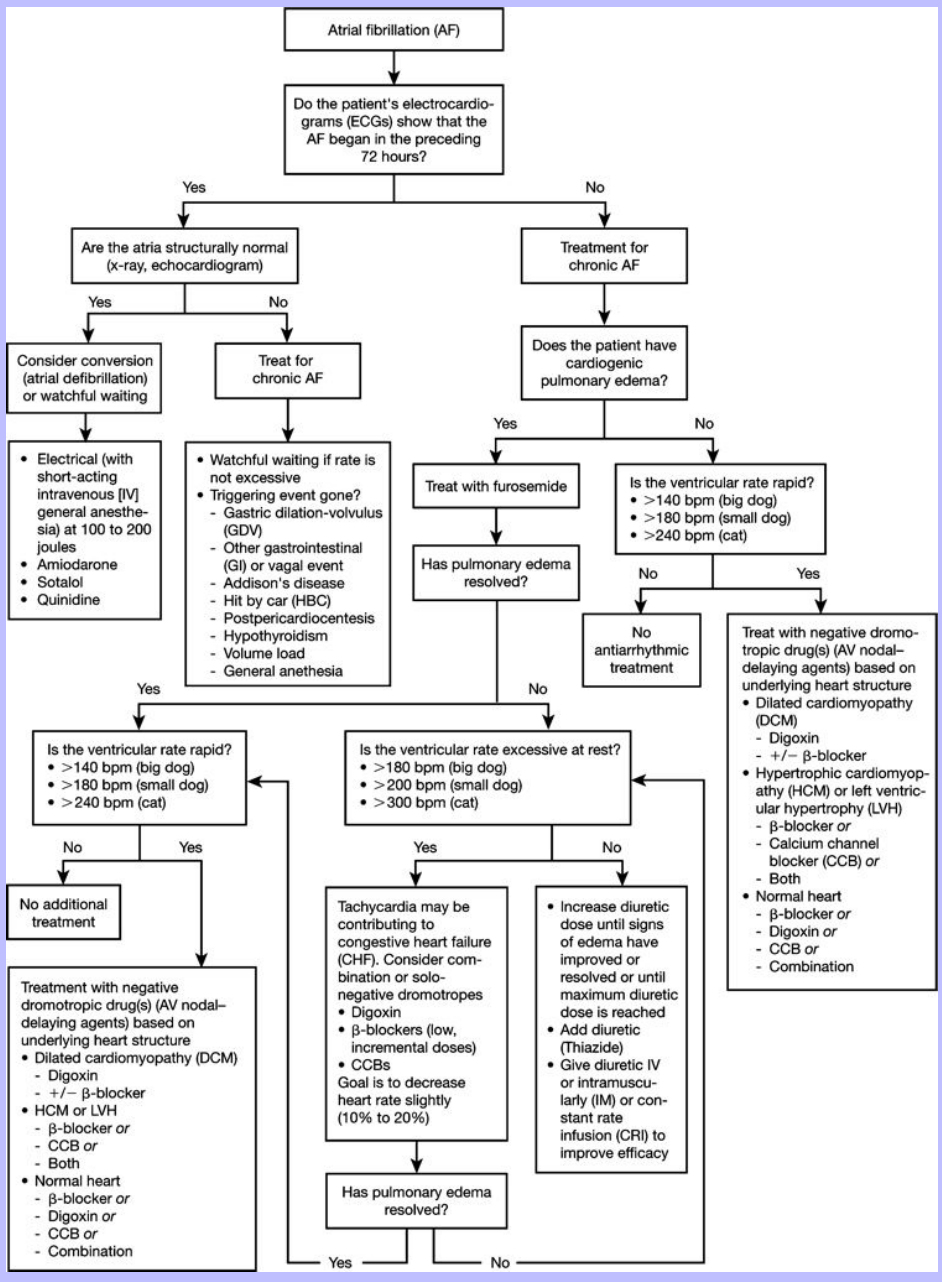

Figure 202-32 Premature ventricular complex (PVC). The classic, wide and bizarre appearance of a prematurely occurring heartbeat is seen. These PVCs are interpolated between normal QRS complexes (see also Figure 202-27). Lead II, 50 mm/sec, 1 cm = 1 mV.

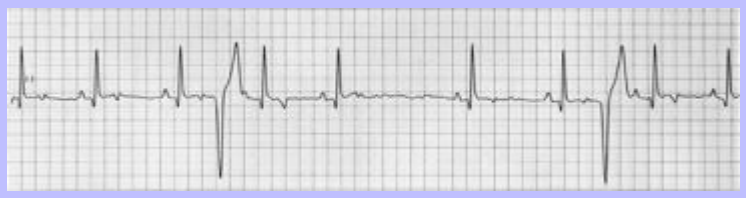


Inherited sudden cardiac death of German shepherd dogs may similarly exist in a latent state or may produce overt clinical signs.[86,87] The disease occurs rarely but is international in distribution and has affected several generations.[87] The predominant abnormality is paroxysmal, rapid VT. Dogs with this disease often develop clinical signs early in life, and these include both syncope and a high prevalence of sudden death. Therefore the disease causes clinical manifestations mainly in puppies or young adult dogs (mean age: approximately 1 year; age range: 4 to 30 months). As a rule the arrhythmia does not coexist with structural cardiac changes, such that thoracic radiographs and echocardiograms generally are normal. A myocardial repolarization defect appears to be the cause of the arrhythmia.[88] Although treatments that limit bradycardia (e.g., vagolytic drugs, ventricular pacing) reduce the occurrence of arrhythmia, no definitive treatment exists for the disorder at this time.

202.6.3.4.2

Accelerated idioventricular rhythm

Accelerated idioventricular rhythm (AIVRs) has been identified as a specific subset of ventricular tachycardia (VT) for the last 30 years (and was given the clear but oxymoronic name *slow VT* at first). AIVRs have the same ECG characteristics as VT, except rate. AV dissociation, wide and bizarre QRS complexes, and the possibility of capture beats and fusion beats are seen. In medium-sized dogs, the rate of AIVRs is between 70 and 160 bpm, which places it between idioventricular (i.e., escape) rhythms (<70 bpm) and true VT in terms of rate. The causes of AIVRs are similar to those of ventricular extrasystoles, but the lower ventricular rate is less compromising of diastolic ventricular filling time; as a result, AIVRs generally are well-tolerated.[89] Treatment therefore is directed at the underlying cause; antiarrhythmic medications are not considered unless management of the underlying cause is ineffective at abolishing the arrhythmia and the rate increases to the point that the criteria for VT are met (Figure 202-34).

Figure 202-33 Three premature ventricular complexes (PVCs). This cat with hypertrophic cardiomyopathy developed PVCs both of the classic wide and bizarre appearance *(arrows)* and of a more subtly different morphology *(arrowhead)*. In all cases, PVCs are premature, not associated with a P wave, different in morphology from sinus QRS complexes, and have a T wave that is different from sinus T waves. Lead II, 50 mm/sec, 1 cm = 1 mV.

202.6.3.4.3

Ventricular tachycardia

VT is a series of three or more ventricular extrasystoles occurring at a high rate (Figures 202-35 and 202-36). It may be continuous (sustained) or intermittent (paroxysmal). Causes are the same as those listed for ventricular premature complexes (see previous discussion). Clinical manifestations are frequent (weakness, syncope, Stokes-Adams-type seizures) but their occurrence depends directly on the hemodynamic consequences of the rhythm (see Clinical Impact of Rhythm Disturbances). An increasingly rapid tachycardia, for example, will cross a threshold of ventricular rate beyond which a greater number of beats will not translate into greater cardiac output. This "point of diminishing returns," which is highly individual and varies according to the variables described previously, exists because diastolic filling time is most compromised at high heart rates. Thus very rapid VT, like any other very rapid tachycardia, can produce overt clinical signs of reduced cardiac output. At a lesser extreme, Doppler echocardiography has shown that VT may be asymptomatic because VT has been demonstrated in conjunction with an adequate cardiac output. This situation is particularly true in cases of VT at slower rates (approaching AIVR; see previous discussion).

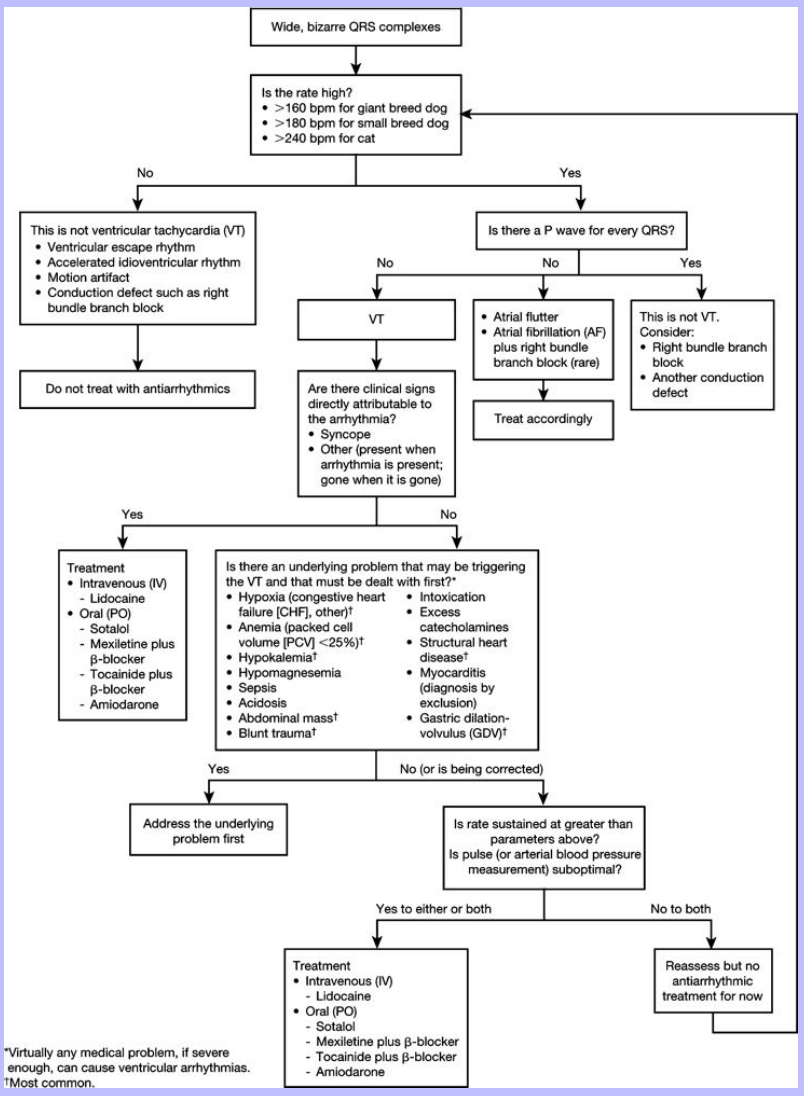
The identification of VT is easier when it is paroxysmal. The typical appearance is one or several series of QRS complexes that are widened (>0.07 second in the dog), do not resemble the sinus QRS complexes, are associated with giant T waves, are not linked to P waves, and may include capture beats (sinus P-QRS complexes after the paroxysm of VT) and fusion beats (QRS complexes with a morphology that is intermediate, between sinus QRS complexes and ectopic QRS complexes) (see Figure 202-35). Capture beats and fusion beats are pathognomonic for VT. In VT, P waves are present (the atria depolarize, but the impulse is blocked at [or just after] the AV node because the more rapid rhythm [VT] dominates the ventricles) but are often masked by QRS complexes. Thus the presence of P waves at regular intervals but not fixedly associated with QRS complexes is consistent with VT (see Figure 202-36). The ECG diagnosis can become more challenging when VT is continuous, particularly if it is of septal or RV origin and thus produces QRS complexes that are fairly narrow and that may resemble supraventricular complexes. Wide QRS complexes caused by other factors (see previous discussion of ventricular extrasystoles) must not be mistaken for VT.

The goals of treatment of VT are, in order: (1) to accurately identify the arrhythmia, (2) to eliminate or palliate predisposing factors that may be responsible for the arrhythmia, (3) to control the rhythm and rate so as to optimize cardiac output, and (4) to avoid detrimental side effects of antiarrhythmic treatment (see Figure 202-34). The desire to suppress VT to reduce the risk of progression to lethal arrhythmias is not sound. Although it is known that ventricular arrhythmias can degenerate into increasingly unstable rhythms, no drug has ever been shown to delay this progression (see Therapy of Arrhythmias, following). Prophylactic treatment of asymptomatic ventricular arrhythmias is detrimental in human medicine and therefore is not recommended in human or veterinary medicine. (Antiarrhythmics drugs to consider for VT: none or class I, II, or III antiarrhythmics.)

1062

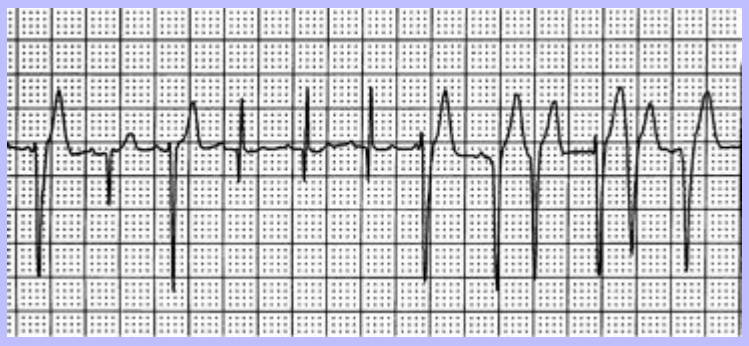
1063

Figure 202-34 Approach to patients with a rhythm consisting entirely of wide, bizarre QRS complexes.



1063

Figure 202-35 Ventricular ectopy in a dog. Premature ventricular complexes (PVCs) (first and third beats) and ventricular tachycardia (VT) (from seventh beat to end of tracing). This tracing presents many hallmark findings of ventricular ectopy. A *fusion beat* (beat 2) is an electrical hybrid formed by the collision of a PVC and a sinus beat. The reader should note its characteristically normal PR interval and QRS morphology that is intermediate between a PVC and a sinus beat. A *capture beat* is the term given to the sinus beat that resumes normal sinus rhythm (NSR) after ventricular ectopy (beat 4). In this case the sinus rhythm lasts for only three beats. The next-to-last beat occurs very prematurely and thus demonstrates the R-on-T phenomenon. Lead II, 25 mm/sec, 1 cm = 1 mV.



202.6.3.4.4 Ventricular flutter

Ventricular flutter is a rapid and prefibrillatory stage of VT. The ECG appearance of this rhythm is a tight, tall sinusoidal wave in which it is impossible to separate QRS complexes and T waves and in which neither capture nor fusion beats are seen. This intermediate stage between VT and VF is rare, brief, and precedes cardiac arrest. It must be differentiated from motion artifact. Artifact masquerading as ventricular flutter still shows evidence of coordinated ventricular activity (normal QRS complexes within the “flutter” impostors) on close inspection (see Figure 202-11). Ventricular flutter is considered a severe ventricular arrhythmia and warrants immediate correction of predisposing causes, intravenous antiarrhythmic treatment, and possibly electrical defibrillation.

202.6.3.4.5 Ventricular fibrillation

VF is a disorganized, chaotic pattern of ventricular depolarizations involving complete desynchronization of ventricular electrical activity. Hemodynamically, it produces circulatory collapse and arrest. Therefore it is a preagonal state leading to death within minutes. Indeed, the cardiac rhythms

that are defined as producing cardiac arrest include VF, asystole, and pulseless electrical activity (pulseless VT, electromechanical dissociation [EMD]).[90] The ECG appearance of VF consists of erratic, patternless waves of variable morphology, amplitude, and frequency (Figure 202-37). The underlying cause is generally a severe disorder, such as myocardial trauma, anoxia, severe electrolyte disturbance, and advanced states of shock. If VF is suspected on ECG, artifact must immediately be ruled out; poor electrical connection between the patient and the ECG leads can mimic VF. Rapid confirmation of VF consists of (1) applying isopropyl alcohol to the skin-ECG lead interface to improve conductivity; (2) assessing that the arrhythmia is present in multiple leads, not just lead II; and (3) noting that the patient is unconscious, because VF is inconsistent with adequate cerebral perfusion. VF is often preceded, and therefore heralded, by ventricular extrasystoles (possibly demonstrating the R on T phenomenon), then sustained VT, then ventricular flutter.[2] When the rhythm has reached VF, treatment (cardiopulmonary resuscitation), though often unrewarding, must be instituted immediately and generally involves electrical defibrillation if available. (Antiarrhythmic treatments to consider: electrical defibrillation, precordial thump, KCl and $CaCl_2$, Class III).

Figure 202-36 Ventricular tachycardia (VT) in a dog. With ventricular arrhythmias, the sinus node and atria continue to function, as evidenced by P waves *(dots)*. Atrial activity occurs regularly but independently of the QRS complexes (AV dissociation). Lead II, 25 mm/sec, 1 cm = 1 mV.

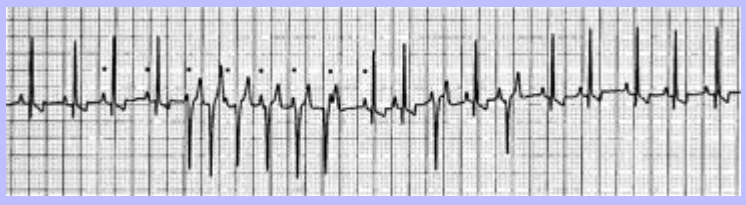


Figure 202-37 Ventricular fibrillation (VF) in a dog. An important differential diagnosis is technical error (poor electrical connection between patient and ECG machine). Lead I, 25 mm/sec, 1 cm = 1 mV.

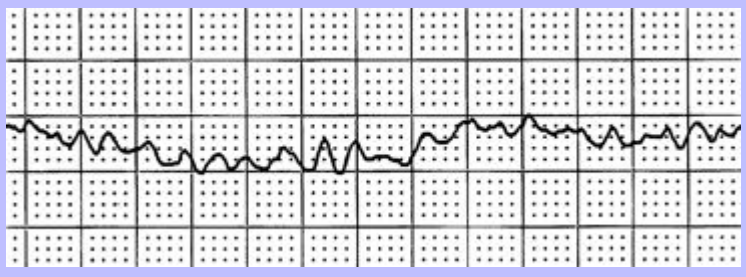

202.6.3.4.6 Torsade de pointes

TdP is a ventricular arrhythmia that arises from prolongation of the QT interval.[91,92] The rotation of the peaks of the QRS complexes on the horizontal axis of the ECG is due to the ever-changing geometry of the re-entry circuit, which oscillates within the ventricles. The diagnosis of TdP is based on the following criteria: (1) the rhythm immediately prior to onset of TdP is slow, and the QT interval is prolonged (>0.25 second in the dog); (2) the onset of TdP involves an R on T ventricular extrasystole (e.g., depolarization [R wave] occurs during the vulnerable part of the T wave); (3) the ensuing rapid (>180 bpm) ventricular rhythm has QRS complexes that are more regular than in VF but that are continuously changing in amplitude and polarity (Figure 202-38). The total duration of a self-resolving paroxysm of TdP is usually very brief (5 to 10 seconds), but it may persist for longer; in those instances it often evolves lethally into VF. TdP is not commonly recognized in the dog but may be caused by any disorder that prolongs the QT interval:[92] congenital long QT syndrome (Dalmatian), hypokalemia, hypocalcemia, and overdose or toxicity due to antiarrhythmic drugs, particularly class 1A antiarrhythmics such as quinidine. The treatment is highly specific and requires discontinuation of all antiarrhythmic drugs and institution of intravenous magnesium sulfate (10 to 30 mg/lb slow intravenous administration).[92]

1064

1065

202.6.3.4.7 Ventricular parasystole

Ventricular parasystole ("one heart beats as two") is a complex arrhythmia that results from the concurrent and independent activity of two pacemakers, one being a normal supraventricular pacemaker and the other existing in a protected site in a ventricle.[93] By definition, parasystole has (1) a ventricular focus with independent, abnormal automaticity and that has a rate that is greater than an escape focus and (2) a unidirectional (entry) block that shields this focus from sinus depolarizations. Parasystole is most often benign, does not warrant antiarrhythmic treatment, and regardless is usually refractory to antiarrhythmic therapy.

202.6.4 Disorders of Conduction

Disorders arising from faulty intracardiac electrical conduction are simply referred to as *blocks*. Blocks are grouped according to anatomic and functional criteria. Anatomic criteria separate them depending on their level of physical location: SA blocks, AV blocks, BBBs, and fascicular blocks.

Functional criteria characterize blocks according to their degree of severity. First-degree block produces a delay in conduction; second-degree block causes complete but intermittent block; and third-degree block causes complete, sustained block.

202.6.4.1 Atrioventricular Block

AV blocks are defined as delays or stoppages of conduction between the atria and the ventricles (specifically, between the upper part of the AV node and the His bundle prior to its trifurcation). First-degree AV block simply is a delay in AV conduction. Conduction through the AV node is slower than normal, but every impulse crosses the node successfully (Figure 202-39). It may be permanent or transient and may arise from a structural lesion or simply be functional. The ECG diagnosis is based on normal, sinus-appearing QRS complexes and a prolonged PR interval. The clinical manifestations are nil; first-degree AV block is an ECG finding only and does not warrant treatment. Its importance is at best diagnostic, drawing the clinician's attention to possible causes of delayed conduction, which include AV nodal damage in the major forms of heart disease and iatrogenic problems including excessive administration of such cardiac glycosides as digitalis or other antiarrhythmic therapy. Most commonly it is normal and is due only to high vagal tone. First-degree AV block does not progress to second-or third-degree AV block except in cases of drug toxicity.

Second-degree AV blocks involve the complete (but transient) interruption of AV conduction. Therefore a P wave exists for every QRS complex, but a QRS complex does not exist for every P wave. Two important subtypes of second-degree AV block exist. The first, Mobitz type I second-degree AV block, is characterized by a progressive lengthening of the PR interval until ultimately a P wave is blocked (P wave without QRS complex), known as the *Wenckebach phenomenon*. Anatomically, Mobitz type I second-degree AV block originates high in the AV node and is said to carry a good prognosis because it is closely related to first-degree AV block, and virtually never causes clinical signs (Figure 202-40). The second, Mobitz type II second-degree AV block, by contrast, demonstrates perfectly regular PR intervals for all QRS complexes, but one or more P wave or waves is or are blocked (Figure 202-41). Mobitz type II second-degree AV block arises from the AV bundle and is said to carry a more guarded to poor prognosis because it more closely resembles third-degree AV block; however, objective evidence to support this extrapolation from human cardiology in veterinary patients is lacking. In *simple* Mobitz type II second-degree AV block, more conducted P waves occur than blocked P waves, whereas in *advanced* Mobitz type II second-degree AV block (as in Figure 202-41), more blocked P waves occur than conducted P waves. The presence or absence of clinical signs appears to be related to the overall ventricular rate. Therefore simple Mobitz type II second-degree AV blocks rarely produce clinical manifestations such as exercise intolerance, whereas the more advanced Mobitz type II second-degree AV blocks commonly produce clinical signs that are similar to third-degree AV block: weakness, lethargy, syncope, and Stokes-Adams seizures (true convulsions caused by critical, arrhythmia-induced cerebral hypoperfusion) even with minimal exertion.

Figure 202-39 First-degree AV block. The interval between each P wave and the following QRS complex is markedly prolonged in this extreme example (PR interval = 0.18 second). Lead II, 50 mm/sec, 1 cm = 1 mV.

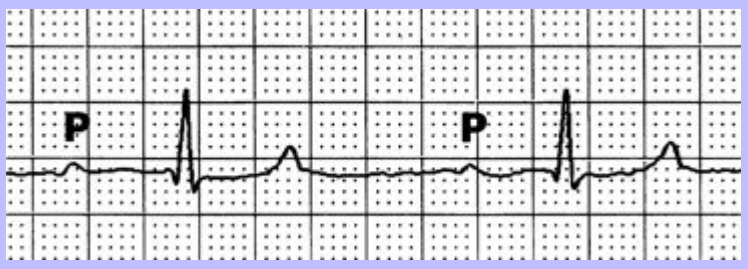

Figure 202-40 Second-degree AV block, Mobitz type I (Wenckebach phenomenon). Gradual prolongation of the PR interval occurs until a P wave is completely blocked *(arrow)*. Lead II, 25 mm/sec, 1 cm = 1 mV.

Third-degree AV block is a complete and sustained interruption of AV conduction. The ventricles depolarize according to a slow, regular, autonomic rhythm, called an *escape rhythm* (junctional or ventricular; see following) (Figure 202-42). It is essential to recognize the lifesaving *salvage* function of a ventricular escape rhythm, because it prevents asystole. Therefore even though ventricular escape QRS complexes are wide and bizarre, ventricular antiarrhythmic therapy is absolutely contraindicated.

In third-degree AV block, communication between the atria and ventricles is nonexistent (complete AV dissociation). Therefore the ECG diagnosis is based on the complete absence of P wave conduction (P waves without QRS complexes; no consistent PR interval) and on slow ventricular QRS complexes, which are usually of a uniform, but wide, bizarre morphology (shape) and that usually occur with near-perfect regularity. Third-degree AV blocks typically produce marked exercise intolerance, weakness, and syncope. 1065
Even so, it is possible to encounter older animals, not very active by nature, who have "asymptomatic" 1066
third-degree AV blocks, or individuals (especially cats) with third-degree AV block and a rapid escape rhythm in which the block is an incidental finding (see Figure 202-42).[1,3] The asymptomatic situation also is likely in cases of *isorhythmic AV dissociation*, a situation in which third-degree AV block occurs but the atrial rate and ventricular rate are nearly identical (see Figure 202-42).

Figure 202-41 Second-degree AV block, Mobitz type II. P waves are blocked without a gradual lengthening of the preceding P-R interval, in contrast to Mobitz type I second-degree AV block. For most of the tracing, only every third atrial impulse crosses the AV node and activates the ventricles, as evidenced by the fixed P-R interval for every third P wave (3:1 block). Lead II, 25 mm/sec, 1 cm = 1 mV.

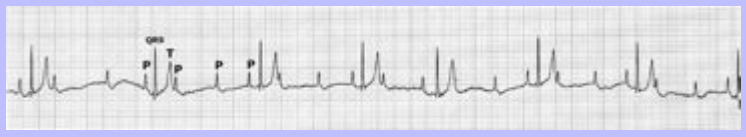

Figure 202-42 Third-degree AV block. No connection occurs between P waves and QRS complexes. Lead II, 25 mm/sec, 1 cm = 1 mV. In the upper panel, the escape rhythm is clearly ventricular because the QRS complexes are wide and bizarre in lead II and are slow to occur (rate = 55/min). This cat had clinical signs caused by the arrhythmia (lethargy) and required implantation of a pacemaker. In the lower panel, the escape rhythm is likely junctional (supraventricular), because the QRS complexes are narrow and upright in lead II, and they occur at a near-normal (near-sinus) rate (150/minute). That is, AV block is present in the proximal part of the AV nodal-His complex, and the escape rhythm originates in the distal part. This arrhythmia was an incidental finding in an otherwise normal cat.

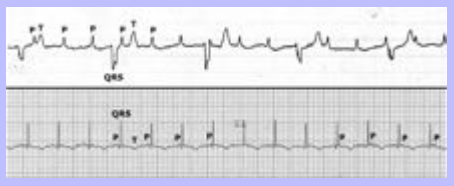

The causes of AV blocks are diverse. First-degree AV and Mobitz type I second-degree AV blocks often are functional (high vagal tone in healthy individuals, negative dromotropic effects of digitalis, antiarrhythmics, or alpha 2-stimulating anesthetics). Less commonly, cardiac disease with atrial dilation and AV nodal lesions may be present. Mobitz type II second-degree AV block and third-degree AV block are sometimes functional (hyperkalemia, digitalis toxicity, alpha 2-stimulating anesthetics), but are commonly associated with a structural lesion, be it inflammatory (endocarditis, Lyme myocarditis,

traumatic myocarditis) or degenerative (physical disruption arising from cardiomyopathy, endocardiosis, or fibrosis).[94,95] Treatment is therefore aimed at the underlying cause when possible. In clinically overt, advanced, Mobitz type II second-degree AV blocks or third-degree AV blocks, response to parasympatholytic or sympathomimetic drugs tends to be fairly disappointing and potentially dangerous. Pacemaker implantation is a better choice (Figure 202-43).

Figure 202-43 Normal pacemaker function. Electrical activity generated by pacemakers appears as spikes on the electrocardiogram (ECG) *(arrowheads)*. The spikes are larger for unipolar pacemakers (left panel) than for bipolar pacemakers (right panel). No atrial activity was present in the dog in the left panel. No association exists between atrial activity (P waves) and paced activity in the right panel because the pacemaker activates only the ventricles (VVI mode). Lead II, 25 mm/sec, 1 cm = 1 mV.

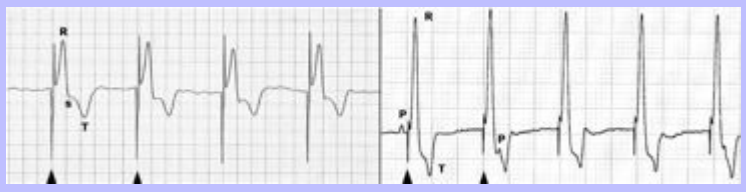

Figure 202-44 Left bundle branch block (LBBB) in a dog. The QRS complexes are very wide (0.10 second, *small double arrow*) but of otherwise normal configuration. Normal sinus rhythm. Simultaneous leads I, II, and III, 50 mm/sec, 1 cm = 1 mV.

202.6.4.2 Bundle Branch Blocks

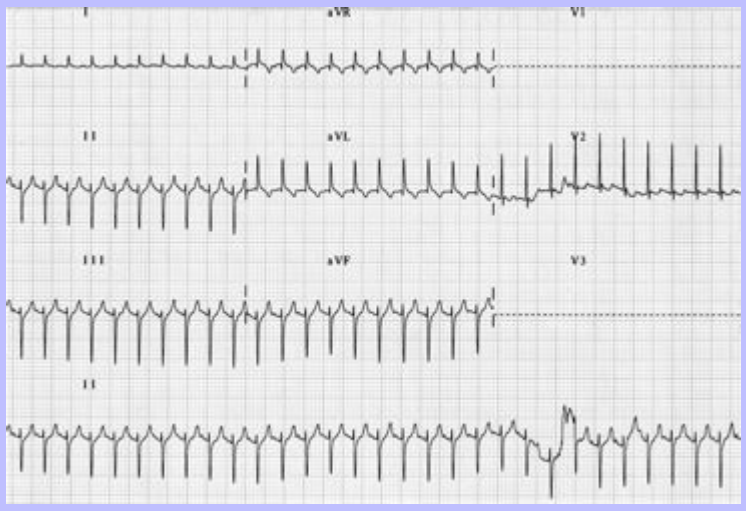
BBBs are slowings or interruptions of conduction involving one or more of the ventricular branches of the His bundle. Blocks may be functional (transient interruptions due to the depolarizations occurring during the refractory period) or structural (permanent interruptions due to a physical disturbance). The ECG diagnosis of BBBs is based on the abnormal shape of the QRS complexes, which become widened due to the desynchronization of the two ventricles. The duration of the QRS complexes is greater than 0.07 second in dogs with BBB, and the polarity is positive in lead II for left BBBs and negative in lead II for RBB blocks (Figure 202-44 and 202-45). If BBBs occur during sinus rhythm, the ECG diagnosis is straightforward, because other than the very abnormal appearance of the QRS complexes, the P-QRS-T sequence throughout the ECG is normal: a P wave occurs before each QRS and the PR interval is fixed and normal. If the block occurs concurrently with a nonsinus rhythm, such as AFib, however, establishing a diagnosis in BBB can be much more challenging (see Figure 202-30). A BBB together with AFib mimics ventricular extrasystoles or VT, which may misdirect therapeutic decisions, (see previous discussion of atrial fibrillation). Cats with heart disease (especially cardiomyopathy) are classically described as being prone to developing block in a subdivision of the LBB known as the *left anterior fascicle* (or LAF).[5] LAF block produces a tall R wave in leads I and aVL, and a deep S wave in leads II, III, and aVF, and therefore a left-axis deviation (see Figure 202-6; Figure 202-46).[12]

1066

1067

Figure 202-45 Intermittent right bundle branch block (RBBB) in a dog. Each QRS complex is preceded by a P wave. This important finding indicates that this is a supraventricular rhythm and not a ventricular arrhythmia. The cyclical increasing-decreasing heart rate, constant PR interval, and similar appearance of all P waves indicate that this rhythm is respiratory sinus arrhythmia (RSA). The wide, bizarre QRS complexes occur when the sinus rhythm is slightly faster (shorter R-R intervals), indicating a rate-dependent form of intraventricular conduction disturbance. The wide, bizarre appearance of QRS complexes in this lead II tracing indicates that this disturbance is a block of the RBB. RBB block generally is a normal or inconsequential finding in dogs and has no hemodynamic repercussions in the patient. The main significance of RBB block lies in how easily it can be mistaken for a ventricular arrhythmia. Lead II, 25 mm/sec, 1 cm = 1 mV.

Figure 202-46 Left anterior fascicular (LAF) block. Prominent S waves occur in leads II, III, and aVF, indicating a leftward mean electrical axis (MEA) deviation (−75 degrees). Motion artifact is noted in the last quarter of the rhythm strip *(lower-right corner)*. This adult cat had moderate left ventricular (LV) hypertrophy echocardiographically, as suspected from the large (deep) QRS complexes. Seven-lead electrocardiogram (ECG) and simultaneous rhythm strip; 25 mm/sec, 1 cm = 1 mV.



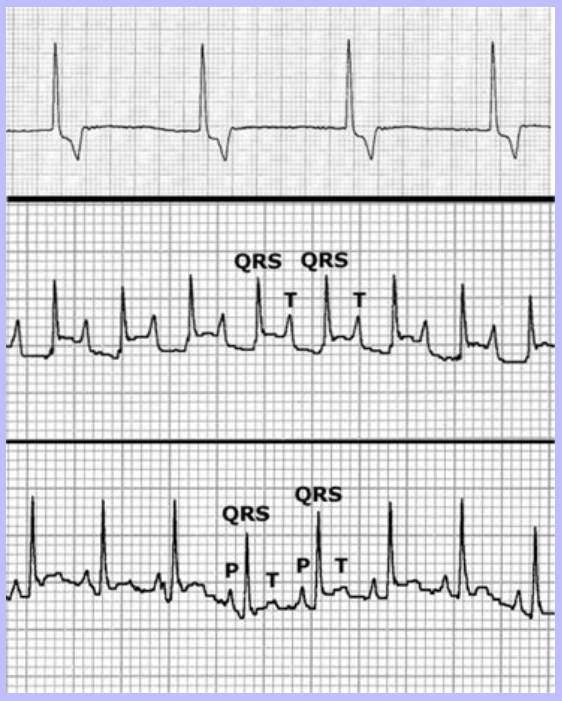
The causes of BBB are many, because they may be due to a variety of pathologic changes including hypertrophy (as in feline hypertrophic cardiomyopathy), dilation (as seen in dilated cardiomyopathy), and inflammation (endocarditis, traumatic myocarditis). In the dog, RBB block is often a completely normal, unnecessarily worrisome ECG finding (see Figures 202-30, 202-45). Clinical manifestations of BBBs alone generally do not occur.[11,12] These disturbances therefore do not warrant specific treatment beyond that of their underlying cause. The importance of recognizing BBB lies in the fact that they could be the first indicators of underlying cardiac disease, which itself warrants further diagnosis and treatment, and that they can be misinterpreted as ventricular arrhythmias.

202.6.4.3 Atrial Standstill (Silent Atrium)

This rhythm disturbance does not truly fall into the category of blocks. It is an arrhythmia characterized by the total absence of atrial depolarization (Figure 202-47). A sinus impulse may nevertheless be properly formed and conducted to the AV node if the internodal pathways remain functional. In this situation, common with hyperkalemia, the rhythm is referred to as *sinoventricular*. Otherwise, if no sinus impulse arises and the atria are electrically silent, then a junctional or ventricular escape rhythm must emerge to avoid asystole. The three differential diagnoses for atrial standstill are (1) moderate to marked hyperkalemia ($K^+ > 7.5$ mEq/L), (2) atrial myopathy, and (3) ECG artifact (P waves too small, or

isoelectric, preventing them from being seen properly on a chosen ECG lead). Perhaps the most easily identified initial change of moderate hyperkalemia on ECG is disappearance of the P waves; this change follows mild tenting of the T waves (often imperceptible) and precedes ventricular flutter and cardiac arrest. Alternatively, atrial standstill may occur due to marked atrial stretch,[96] as occurs particularly in cats with various forms of cardiomyopathy, or atrial parenchymal hypoplasia, as is seen in association with a dystrophic form of neuromyopathy, particularly in the Springer spaniel. Either way, the ECG appearance is therefore of a regular rhythm, usually with QRS complexes that are of a supraventricular appearance, and with a normal rate but without detectable P waves in any lead on the ECG. Differentiating between the two main causes of this rhythm using the ECG alone is difficult, and immediate measurement of serum electrolytes is warranted.

Figure 202-47 Atrial standstill. In the upper panel, a primary atrial myopathy was responsible for the lack of atrial activity seen in this dog's tracing. Serum [K^+] = 4.3 mEq/L (within normal limits). Lead II, 25 mm/sec, 1 cm = 1 mV. In the middle and lower panels, presence (middle) and absence (lower) of atrial standstill in a cat with urinary obstruction before and after correction of severe hyperkalemia, respectively. The reader should note the rapid ventricular rate in the middle panel (220/min) despite an elevated serum [K^+] (8.4 mEq/L). In contrast to dogs, severely hyperkalemic cats often are tachycardic. Lead II, 25 mm/sec, 1 cm = 0.5 mV.



202.6.4.4 Electromechanical Dissociation

EMD is not, strictly speaking, an abnormality of cardiac rhythm. *EMD* refers to the absence of conversion of an electrical rhythm into a mechanical force of contractility.[97,98] The ECG therefore may show virtually any rhythm, and the diagnosis rests on the combination of a hemodynamically collapsed patient with an ECG that shows any rhythm but asystole. The pulse is usually barely perceptible or absent, the patient typically is unconscious, and EMD most commonly is a prearrest or terminal condition (Figure 202-48). Treatment requires correction of underlying causes if possible and then is aimed at increasing circulation to improve myocardial perfusion. Because EMD generally indicates profound myocardial hypoxia, the prognosis is poor even with treatment.

1067

1068

Figure 202-48 Electromechanical dissociation (EMD). By definition, pulselessness was present during this ECG. Lead II, 25 mm/sec, 1 cm = 1 mV.

202.6.5 Complex Disorders Involving Abnormalities of Both Excitability and Conduction

Of the multiple rhythm disturbances described previously, many can occur jointly on the same ECG tracing, producing mixed disturbances of excitability and of conduction. This next section will discuss examples of disturbances of excitability and of conduction that produce specific clinical syndromes.

202.6.5.1 Pre-Excitation Syndromes

In pre-excitation, the normal impulse originating from the SA node is split at the end of atrial depolarization, with part of the impulse traveling normally through the AV node and another part of the impulse traveling simultaneously through an abnormal shaft of rapidly conductive fibers that links the atria and the ventricles, (also called an *accessory pathway* or *bypass tract*) thus bypassing the AV node. The result is partial, premature, immediate activation of the ventricles through the bypass tract, without the benefit of a pause in the AV node; hence the term *pre-excitation*. With one major exception (see following), the effect of this abnormal pattern of activation is minimal, because only a part of the atrial contribution to ventricular filling is lost. The ECG demonstrates that the normal delay through the AV node was pre-empted by conduction through the bypass tract (i.e., no segment separates the P wave from the QRS complex) and that conduction through the bypass tract caused asynchronous activation of the ventricles (the bypass tract and the normal AV nodal conduction ultimately each activate their share of the ventricles), resulting in a notched QRS complex. The size and location of the QRS complex's notch, the *delta wave*, depends on the distance that separates the bypass tract and the AV node in the individual's heart (i.e., on the amount of myocardium that the His bundle and the bypass tract can each depolarize before the impulses collide with each other; Figure 202-49).

Under usual circumstances, pre-excitation is an incidental, clinically silent finding. However, in individuals with pre-excitation, a premature atrial depolarization may initiate a type of re-entry cycle that can produce extreme tachycardias. Although bypass tracts conduct impulses rapidly, their refractory period typically is longer than that of the AV node. Therefore the timing of a premature supraventricular depolarization may fail to conduct through the bypass tract but be able to conduct through the AV node, depolarizing the ventricles normally. As the impulse completes the depolarization of the ventricles, the bypass tract has repolarized and is able to conduct. Bypass tracts can often conduct impulses in either direction, such that the ventricular impulse conducts retrograde through the bypass tract to the atria, initiating an endless loop of conduction. This type of self-perpetuating circuit is a type of *macrore-entry circuit*, and it may produce a potentially very rapid and clinically overt (apparent discomfort, exercise intolerance, lethargy, syncope) tachycardia called *orthodromic* [the impulse travels in a normal direction through the AV node] *AV re-entrant tachycardia*, or the *Wolff-Parkinson-White* (WPW) syndrome.[59,63,99] Dogs with this syndrome may have unrelenting heart rates above 300 bpm. Initial treatment can involve vagal maneuvers that, through slowing of AV conduction (i.e., negative dromotropic action), break the cycle of re-entry. Amiodarone or procainamide may be used in the management of such tachyarrhythmias in dogs. Conversely, digoxin is contraindicated because it decreases the refractory period of the bypass tract. Many drug therapies or combinations thereof have been used to reduce the occurrence of WPW episodes in pets with *symptomatic* re-entrant tachycardias caused by pre-excitation. Frequently in these cases, no drug therapy is entirely successful, and the clearest and most successful form of treatment involves referral to a specialized center for intracardiac catheter-based radiofrequency interruption (ablation) of the re-entrant pathway, which permanently abolishes pre-excitation and all future risk of recurrence of the WPW syndrome.[63,100]

Figure 202-49 Pre-excitation. The P-R interval is the same as the duration of the P wave (i.e., no P-R segment is seen). This finding indicates pre-excitation of the ventricles through an accessory bypass tract. The asynchronous activation of the ventricles is demonstrated through the presence of a subtle notch in the QRS complex, the delta wave *(arrow)*. Lead I, 25 mm/sec, 1 cm = 1 mV.

202.6.5.2 Sick Sinus Syndrome

SSS (bradycardia-tachycardia syndrome, sinus node dysfunction) involves a complex disturbance of the cardiac conductive tissues, producing simultaneous defects in sinus activity (SB and sinus arrest), AV conduction disturbances (first-degree and second-degree AV blocks) and disturbances in supraventricular and ventricular excitability (Figure 202-50). Therefore the disturbance is not a problem involving only the SA node, as the name *SSS* suggests, but rather is an illness that affects cardiac tissue at all levels.

The cause of SSS is unknown. Some human beings with SSS have autoantibodies directed at SA nodal tissue or at cholinergic receptors,[101,102] but these mechanisms have not been described in dogs with SSS. Certain epidemiologic features stand out from cases reported in the veterinary literature. The disease is recognized almost exclusively in dogs, and the stereotypical breed predilection for female miniature Schnauzers is far from exclusive, many other breeds, notably Cocker spaniels,[103,104] West Highland white terriers,[103,105] and mixed breed dogs represent an ever-increasing proportion of patients with this disorder. The spectrum of disease described as SSS likely regroups more than one distinct disorder that future research will categorize into separate entities.

The age of onset typically is mid to late adulthood (6 to 10 years), and the association with chronic mitral valvular disease is common but not obligatory. Histopathologically, nodal tissue fibrosis is seen, associated with vascular disturbances (microcoronary arteritis). The ECG diagnosis often requires repeated and sufficiently long (2 to 3 minute) tracings, to convincingly demonstrate some or all of the aspects of SSS: SB (often with first-or second-degree AV block), prolonged sinus pauses with variable escape beats and bursts of supraventricular tachycardia or ventricular extrasystoles at various rates (see Figure 202-50). In some cases only SB occurs. Because these features occur intermittently, the diagnosis often is only made by obtaining an ECG during an episode of syncope, stumbling, or ataxia (near syncope), which are the most common overt clinical manifestations of this arrhythmia. Ambulatory ECG, especially cardiac event recording, is ideally suited for establishing the diagnosis of SSS when the in-hospital ECG is unhelpful (see Ambulatory Electrocardiography). Such technology has identified that episodes occur during bradycardia rather than tachycardia. Vagolytic drugs may acutely improve the situation by reducing the impact of bradycardia episodes and pauses, but definitive treatment when episodes are recurrent generally requires the implantation of a pacemaker (see following). Digitalis glycosides are usually contraindicated, including in the CHF patient, because of the risk of furthering AV block and thus decreasing ventricular rate. If CHF is present, diuretics (e.g., furosemide) and angiotensin-converting enzyme (ACE) inhibitors are typically used, with or without spironolactone. Correction of bradycardia through pacemaker implantation occasionally improves cardiac output sufficiently to eliminate CHF and allow the gradual reduction, and possibly discontinuation, of diuretics.

Figure 202-50 Sick sinus syndrome (SSS). Second-degree AV block followed by an extremely long sinus pause, an escape beat, sinus bradycardia or a supraventricular escape rhythm, and one premature ventricular complex, are seen. Lead II, 25 mm/sec, 1 cm = 1 mV.

202.7 THERAPY OF ARRHYTHMIAS (Table 202-1)

First and foremost, any underlying or predisposing factors involved in the precipitation of arrhythmias need to be identified and resolved when possible (see Figure 202-34). For example, attempting to treat VT with antiarrhythmic drugs when a patient is hypokalemic is counterproductive and probably dangerous. Hypokalemia can both make ventricular arrhythmias more likely to occur and, through effects on myocardial sodium channels, hypokalemia makes the arrhythmia refractory to the more commonly used intravenous antiarrhythmics including lidocaine.

Overall, a practical approach to choosing antiarrhythmic therapy incorporates known clinical efficacy, adverse drug reactions, pharmacokinetic effects, and results of administration. Substantial changes in the approach to antiarrhythmic therapy have evolved since the publication of the 1991 Cardiac Arrhythmia Suppression Trial (CAST) in human beings with myocardial infarction. In this multigroup, placebo-controlled, double-blinded study, researchers unexpectedly found an increased rather than decreased risk of death when certain type IC antiarrhythmic agents were administered. Although ambient ventricular arrhythmias are still regarded as a risk factor for adverse cardiovascular events, these arrhythmias are increasingly perceived as *messengers* of myocardial disturbance rather than primary problems needing to be quelled. Accordingly, the rush to treat asymptomatic ventricular arrhythmias has been markedly reduced.[106,107] By contrast, the general approach to the treatment of supraventricular tachyarrhythmias, whether latent or responsible for clinical signs, has remained the same or become more aggressive in small animal medicine (Figure 202-51).[63,100]

The decision to treat ventricular arrhythmias in veterinary medicine should be based on the functional effects of the rhythm, not the frequency ("more than *x* PVCs/min") or morphologic complexity (monomorphic versus polymorphic) of the abnormal beats.[89,106] Expressions of the functional effects of arrhythmias that can be assessed clinically include the presence of clinical signs (e.g., lethargy, syncope, Stokes-Adams seizures) and perfusion during the arrhythmia (pulse quality, mentation, and if available, short-term trends in blood pressure parameters).

Ventricular tachyarrhythmias may be progressive and can compromise cardiac output. However, even complex ventricular arrhythmias, when they are asymptomatic, do not necessarily represent a target for attempting to reduce the risk of sudden death.[107] In human medicine, from which the overwhelming majority of veterinary clinical cardiac arrhythmia information is extrapolated, "rendering treatment to suppress a risk factor because of the temptation to equate causality with association between the risk factor and a putative clinical outcome has never been more misguided than with nonsustained ventricular tachycardia."[107]

"When to treat?" probably remains the single most important and unresolved question in veterinary cardiology. The veterinary experience may or may not be substantively different from the human. Therapy based on human medical recommendations may be inappropriate considering the principal differences in causes of disease between the species (e.g., coronary versus noncoronary heart diseases). Clinicians do not know what happens to dogs or cats with arrhythmias of differing causes, nor are we generally able to compare arrhythmias of different causes regarding outcome or specific drug therapies. Survival and efficacy studies for complex arrhythmias in veterinary medicine are few, and, with one exception, none has been double-blinded or controlled. The exception is a prospective study of 49 Boxer dogs with familial ventricular arrhythmia *(Boxer cardiomyopathy)* that were randomized to receive one of four antiarrhythmic medication strategies. Results of the study showed that some antiarrhythmics were better than others for reducing the occurrence of arrhythmia, but none of the four significantly decreased the extent of clinical manifestations of the arrhythmias (syncope).[46] Otherwise,

experience-based generalizations may be made, including the observation that dogs with mitral endocardiosis are not likely to die suddenly of arrhythmic causes, whereas cardiomyopathic Doberman pinschers and dogs with advanced subaortic stenosis have a greater risk of sudden death when they reach a stage of disease associated with ventricular ectopy. When overt clinical signs such as syncope or aborted syncope are present, it is difficult to argue with therapeutic efforts to contain the arrhythmia. When clinical signs are absent, however, it is relevant to compare the potential side effects of therapy, including proarrhythmia, to the potential and difficult-to-prove benefit of a stabilized or normalized rhythm. Proarrhythmic effects of cardiac drugs aside, Calvert[108] has shown the adverse effects of routine anesthesia and surgery in Doberman pinschers with occult cardiomyopathy, thereby reminding the clinician to consider the dangers of medical procedures that may exacerbate uncontrolled arrhythmias.

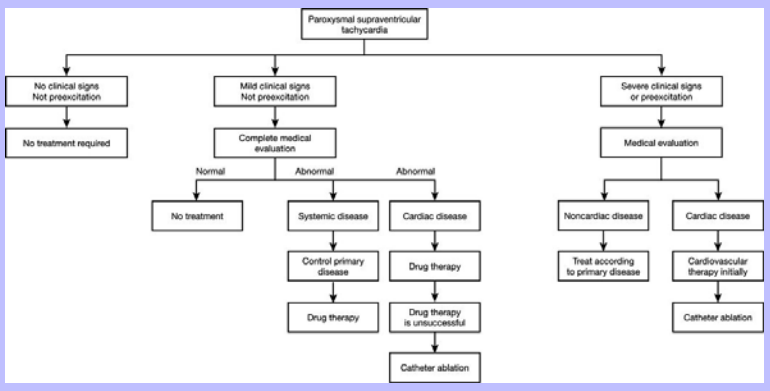
202.7.1 Classification Systems for Antiarrhythmic Agents

Antiarrhythmic drugs have traditionally been classified into one of four groups according to their predominant effect on the action potential. Dissatisfaction with the shortcomings of the Vaughn-Williams (V-W) classification scheme for antiarrhythmic drugs resulted in the creation of a competing classification system[109] correlating antiarrhythmic drugs with the mechanism of the arrhythmia and vulnerable parameters, as well as actions of the drug.[110] The scheme, known as the *Sicilian gambit* (SG), is based on the actions of drugs on arrhythmogenic mechanisms and was another attempt to provide a rational basis for therapy. Regrettably, although academically reasonable, it has not improved the clinical approach to arrhythmia therapy in human or veterinary medicine.

Limitations of the traditional V-W system include its incomplete classification, crossover within the system among specific drugs, and its discussion principally of blocking mechanisms, whereas activation of channels, receptors, or both are downplayed. Antiarrhythmic agents may be effective in a number of ways: slowing tachycardias, terminating arrhythmias, making them tolerable, or preventing their initiation.[109] The V-W classification is based only on the electrophysiologic drug effects of isolated, normal cardiac tissue (except for class II agents), which is different from the diseased state. The classification excludes compounds such as digitalis, adenosine, and alpha-adrenergic-blocking agents. The V-W classification system assumes that we know more than we really do. Not all drugs within a class have the same physiologic or clinical effects. The danger in using only the V-W scheme is that most drugs have more than one mode of action, and all the drugs within a category clearly are not always the same.

1069 1071

Figure 202-51 Approach to management of supraventricular arrhythmias.



Antiarrhythmic therapy for the practicing veterinarian with access to ECG monitoring, ambulatory ECG (available at most referral veterinary centers or via on-line rental [see previous discussion]), and echocardiography (available at many referral facilities) is described later in this chapter. Electrophysiologic testing and terminology, although desirable, are (with few exceptions) not practiced. Therefore the discussion of these techniques is limited to what is required to make knowledgeable medical decisions in practice. Only commonly used drugs or those likely to be useful in canine or feline heart disease are discussed. New drugs are identified, as are new uses for older drugs.

202.8 CLASS I ANTIARRHYTHMICS (Table 202-1)

Class I drugs selectively block the fast sodium channels, decreasing sodium influx during phase zero of depolarization. A reduced slope of phase zero is the manifestation of decreased conduction velocity. Slowed conduction velocity can interrupt a reentrant pattern.[3] These drugs work best in cells dependent on the fast sodium channel for their action potential, such as normal and ischemic Purkinje cells and ventricular myocardial cells. Within this class are three subgroups, distinguished by their electrophysiologic and antiarrhythmic differences. Most of the compounds within this class fail to perform adequately in the presence of hypokalemia.

202.8.1 Class IA Drugs

Class IA antiarrhythmic drugs are intermediate sodium channel blockers that markedly depress phase zero action potential, depress conduction of electrical impulses through the heart, and slow cardiac repolarization by lengthening the effective refractory period.[3] By depressing the conduction velocity and prolonging the refractory period, arrhythmias dependent on re-entry may be interrupted. Drugs in this class include quinidine (prototype IA drug), procainamide, and disopyramide (Table 202-1). Quinidine decreases the rate of spontaneous depolarization in pacemaker fibers, prolongs anterograde refractoriness accessory pathways, and can suppress or trigger delayed afterdepolarizations. Quinidine may prolong the PR interval, widen the QRS complex, and lengthen the QT interval, and it was originally indicated for the control of supraventricular and ventricular arrhythmias. Today it and the other class IA drugs have very limited usefulness in clinical antiarrhythmic therapy of small animals. Proarrhythmic and other side effects make quinidine an agent that is now rarely used.

Procainamide has cardiac effects similar to those of quinidine. However, its propensity for inducing hypotension with intravenous use or increasing ventricular rates from enhanced AV conduction is less than that of quinidine. Procainamide specifically has been demonstrated to prolong the effective refractory period and slow conduction in the accessory pathway of dogs with orthodromic AV reciprocating tachycardia.[111]

Procainamide is metabolized by the liver and eliminated by the kidneys. The sustained release formulations may be poorly absorbed and even eliminated as intact tablets in the feces of dogs. Procainamide may be used in conjunction with other class I agents and beta-blockers for refractory arrhythmias. Oral administration of the drug at higher than usually recommended doses to achieve trough serum concentrations of 10 to 12 μg/mL were successful in controlling some supraventricular tachyarrhythmias.[111,112] Side effects are infrequent and include anorexia, nausea, vomiting, fever, proarrhythmia, and agranulocytosis. In a four-way trial of antiarrhythmic drugs in boxer dogs with ventricular arrhythmias, procainamide (10 to 12 mg/lb orally, three times a day) successfully reduced the frequency of ventricular ectopy. However, the frequency of syncope was unaffected, and there were substantial side effects.[46]

202.8.2 Class IB Drugs

Class IB agents block fast sodium channels, which decreases the slope of phase zero, depresses automaticity, and increases the threshold for VF. These drugs have an affinity for binding with inactivated sodium channels, thereby acting selectively on diseased or ischemic tissue. Minimal effects are seen on the sinus node, AV node, and atrial muscle or on inotropy. Lidocaine, phenytoin, tocainide, and mexiletine are examples of drugs in this class (Table 202-1).

Lidocaine is used for acute control of life-threatening ventricular arrhythmias. In usual doses it is not likely to affect myocardial contractility, systemic arterial blood pressure, the QRS complex, or AV conduction time,[3] although extremely high doses have been shown to decrease ventricular contractility. Lidocaine suppresses automaticity and conduction velocity and prolongs refractoriness in ischemic cardiac cells.

Lidocaine is most effective when used intravenously, owing to first-pass hepatic metabolism. It is less than 10% protein bound. Hepatic disease, chloramphenicol, propranolol, halothane, cimetidine, and norepinephrine may all delay hepatic metabolism of lidocaine. Hepatic microenzyme inducers enhance degradation.

Lidocaine intoxication results in ataxia, mental depression, and seizures. These signs usually subside within minutes after lidocaine infusion is discontinued. Diazepam or a short-acting barbiturate may be necessary to control seizures. Lidocaine may be administered by slow (2 to 5 minute) intravenous loading bolus (1 to 2 mg/lb) followed by a continuous rate infusion (CRI) of 10 to 30 µg/lb/min in dogs. Alternatively, after the initial bolus, an additional amount can be given at half the dose every 10 minutes to maintain the rhythm. Caution is recommended when using lidocaine in cats because of historical reports of bradyarrhythmias and sudden death. Lower bolus doses of 0.25 to 0.5 mg/lb slowly followed by 5 to 10 µg/lb/min CRI are recommended for cats. Intramuscular lidocaine is less efficacious and is rarely used.

Tocainide and mexiletine are structurally analogous to lidocaine but have oral bioavailability. Response to lidocaine may not be a predictor of response to these oral agents, however.

Tocainide is orally absorbed and undergoes hepatic metabolism and renal excretion. It may be used after lidocaine or as initial treatment in a hemodynamically stable patient. At 6.8 to 11.4 mg/lb orally every 8 hours, peak levels were reached in cardiomyopathic Doberman pinscher dogs after 2 hours and began to diminish by 8 hours. Fifteen of 23 (70%) dogs experienced a 90% diminution of VT, and there was a 70% reduction of all PVCs in 80% of the cardiomyopathic dogs. Although there was no relationship between dose and serum concentration, dogs without signs of toxicity had serum levels under 11 mg/L and all those with toxic signs exceeded 14 mg/L.[113] Side effects observed within 8 days are weakness, head tremor, ataxia, and head bobbing. Long-term side effects, including corneal dystrophy, corneal edema, and renal failure, were observed in more than 50% of dogs.[113,114]

Mexiletine is absorbed orally and undergoes less than 10% first-pass hepatic elimination. It is 70% protein bound. The drug is eliminated by renal excretion, and its half-life varies depending on urine pH. Side effects are infrequent in the dog but can include nausea, inappetence, and tremor.[115] Sinus bradycardia, ataxia, dizziness, and thrombocytopenia are other potential problems. No data exist regarding its use in cats. In a group of Boxers with familial arrhythmia, mexiletine was given jointly with the beta-blocker atenolol as one of four forms of therapy being tested. This antiarrhythmic therapy reduced the frequency and “grade” of ventricular arrhythmia, and there was a reduction in peak heart rate. However, the frequency of syncope was not reduced with this form of treatment or with any other in the study.[46] Mexiletine is only available in the

oral formulation in North America. Both mexiletine and tocainide appear to have synergistic properties when combined with class IA or class II agents.[46]

202.8.3 Class IC Drugs

Class IC drugs are blockers of slow sodium channels and are strong depressants of phase zero and conduction velocity. They exert a minimal effect on refractoriness or action potential duration. They are indicated for supraventricular and some ventricular arrhythmias and arrhythmias involving accessory pathways. They are notorious in humans for their proarrhythmic tendencies when given in patients with coronary artery disease. They depress contractility, cardiac output, and systemic blood pressure. These drugs are contraindicated in the presence of AV block, BBB, and myocardial depression. Flecainide and propafenone are class IC agents.

Flecainide is indicated for paroxysmal supraventricular tachycardia (SVT) and paroxysmal AFib but not for chronic AFib or in patients with ventricular dysfunction, ventricular hypertrophy, ischemic heart disease, or valvular heart disease. It has not been studied in clinical small animal medicine. This drug may induce or aggravate congestive heart failure.

Propafenone has local anesthetic effects and a direct stabilizing action on myocardial tissue, as well as weak beta-adrenergic–blocking activity. It prolongs A-V nodal conduction (A-H and H-V) and has negative inotropic action. It is effective against many SVT and accessory pathway arrhythmias but has not performed as well as had been hoped in the context of treating ventricular arrhythmias.[116] In structurally normal hearts, proarrhythmia is unlikely in humans. Propafenone is only available in the oral form in North America.

202.9 CLASS II ANTIARRHYTHMICS

Class II antiarrhythmics (beta-blockers) decrease or nullify the electrophysiologic and arrhythmogenic effects of beta-adrenergic sympathetic stimulation.[117–119] The magnitude of the beta-blockade effect is dependent on the prevailing level of sympathetic tone. Sympathetic stimulation increases the likelihood of slow calcium channels opening and increases the rate of pacemaker discharge. Overall, beta-blockers depress the slope of phase 4 depolarization and minimally raise the threshold for activation in sinus and AV nodal cells, thereby suppressing automaticity. The effect of beta-blockers on normal cell refractoriness and conduction is modest, and it is unlikely that they influence cardiac repolarization. As a result of the negative inotropic (contractility), chronotropic (rate), and dromotropic (AV node clearance time) effects, cardiac output is reduced and myocardial oxygen requirements and LV work are decreased in normal tissue. In the past several years the beneficial effects of beta-blockers have become increasingly recognized in the setting of severe myocardial disease, where initiation of treatment at extremely low doses and careful up-titration appear to provide a long-term cardioprotective effect.

Beta-blockade is indicated for supraventricular tachycardias, including atrial flutter, AFib, and pre-excitation tachyarrhythmias. It is more effective in controlling the ventricular rate response to AFib when combined with digitalis. Beta-blockade should be helpful in ventricular arrhythmias induced by sympathetic stimulation.[120] It may be used in combination with a class I agent for refractory ventricular tachyarrhythmias in the dog[46] or alone as the primary agent in the cat. Beta-blockade traditionally has been useful in the treatment of systemic hypertension, obstructive heart disease,[121] thyrotoxicosis, and digitalis toxicity. Elimination of propranolol paradoxically is longer in hyperthyroid cats than in euthyroid cats. Additional roles in the management of pheochromocytoma, theobromine intoxication (see Figure 202-25), dilated cardiomyopathy, and portal hypertension are possible.[119]

Contraindications include AV block and SSS (unless a functional artificial pacemaker is in place). Many beta-blockers are not cardioselective (i.e., they exert their effects on both $beta_1$ and $beta_2$ receptors), resulting in bronchial smooth muscle constriction. Nonselective beta-blockers are contraindicated in patients with dynamic bronchial disease. Beta-blockers, especially nonselective types, may interfere with the compensatory response to hypoglycemia and exercise.[119]

Since the publication of the last edition of this textbook, a number of clinical studies involving thousands of human patients have been conducted, and they have demonstrated conclusively that when properly initiated and titrated, some specific beta-blockers are of benefit in patients being treated for CHF (see Chapter 199).[117,122–125] Of specific interest in CHF, carvedilol has both beta-adrenergic and $alpha_1$-blocking activity, which provides additional vasodilation. These effects appear to be unrelated to the drug's antiarrhythmic action. However, other beta-blockers that do not also possess $alpha_1$-blocking properties are also similarly effective in treating heart failure patients.[124] When administered correctly, beta-blocking drugs improve long-term myocardial function through a number of mechanisms.[117,118,125,126] Because of the potential for adverse effects from excess beta-blockade, the dose rate must be individually titrated.[127] Side effects of beta-blockade therapy include lethargy, fatigue, depression, anorexia, vomiting, and diarrhea. Adverse reactions might include hypotension, onset or recurrence of CHF, AV block, bronchospasm, or hypoglycemia. Myocardial depression may be addressed with carefully titrated isoproterenol or dobutamine infusions, and sinus bradycardia with atropine or glycopyrrolate administration, but prevention of these effects through slow, meticulous up-titration and regular monitoring is the preferred course. After chronic oral use, drug withdrawal should be gradual to prevent acute arrhythmia induction or systemic hypertension.

When a beta-blocker is given to patients with CHF, they must be euvolemic. That is, patients receiving beta-blockers under any circumstance should not have pulmonary edema or other form of critical fluid retention. The slight decrease in heart rate and ventricular contractility that may occur with even small doses of these agents may mean the difference between survival and decompensation in a patient with fulminant pulmonary edema, for example. Other contraindications for beta-blockers include systemic hypotension and peripheral vascular disease.

Cardioselective ($beta_1$-blocking) agents exert their primary effect on cardiac $beta_1$ receptors, especially at lower doses. This property is helpful in patients with asthma, chronic bronchial disease, hypoglycemia, peripheral vascular disease, or thrombosis. Atenolol, esmolol, and metoprolol are examples of $beta_1$-selective blockers. Other beta-blockers possess mild intrinsic sympathomimetic activity (ISA) that provides some protection for patients with underlying myocardial failure or those dependent on high sympathetic tone to maintain cardiac output.

1072

As with all beta-blockers, dose must be titrated individually. Published doses are target doses, and initiation of therapy often begins at one eighth, one quarter, or one half of these doses, with the lowest fraction used when the myocardium is most dyskinetic (hypocontractile).[127] For example, in healthy dogs, acute carvedilol doses of 1.5 mg/kg orally, twice a day are tolerated and effective at preventing STach.[128] However, in dogs with experimentally induced mitral regurgitation, a target dose of 0.4 mg/kg once daily of carvedilol should be reached via initiating the drug at a dose of 0.2 mg/kg or less, because a small but significant, acute decrease in systemic blood pressure is seen with the 0.4 mg/kg dose.[127] In general with beta-blockers, careful up-titration from small initial doses is the rule, especially with a history of CHF. Retitration is also required when switching

1073

to sustained release formulations. Intravenous therapy is reserved for acute arrhythmias, especially anesthetic-or pre-excitation related supraventricular tachycardias (see Class IV Antiarrhythmics, following).

Propranolol was the standard beta-blocker used in veterinary medicine for years, and it remains the drug against which newer agents are compared. It blocks both $beta_1$ and $beta_2$ receptors. It is well absorbed orally, experiences large and variable first-pass hepatic and portal elimination, and has variable plasma protein binding. The half-life is 3 to 6 hours in dogs, but effects may persist long enough to require only twice-daily dosing after prolonged use. Lethargy in cats is a prominent side effect. Beta-blocking agents with longer durations of action are often used in place of propranolol.

Atenolol is a $beta_1$-selective agent with the advantage of requiring once or twice daily dosing in cats. In nine normal cats, atenolol reduced heart rates for 12 hours or more; β-blockade was not evident at 24 hours using an oral dose of 1.4 mg/lb.[129] A practical approach for determining whether once daily or twice daily atenolol dosing is best for a particular cat consists of initiating the medication to be given once daily in the evening. A daytime recheck visit is scheduled for 7 to 14 days after initiation of treatment, and if an exam room heart rate is superior to the desired maximum with beta-blockade (e.g., maximum 180 bpm in a chronic heart failure patient; maximum 160/min in a compensated patient never having been in heart failure), then the dose is increased to twice a day. In a four-way drug study involving boxer dogs with familial arrhythmia, atenolol alone at 0.17 to 0.27 mg/lb did not change the frequency or "grade" of ventricular ectopy or the heart rate, and there was no reduction in the frequency of syncope.[46] When atenolol was combined with mexiletine, results were slightly more positive (see previous discussion).

Another longer-acting drug, metoprolol, is effective in dogs requiring beta-blockade and in those with CHF associated with MVD or DCM. Studies of induced CHF in dogs indicate efficacy of a sustained release human formulation for the dog, and suggest a possible beneficial increase in ejection fraction when beta-blocking agents are added.[130]

Esmolol is an ultrashort-acting (9 minutes), rapid onset (2 minutes), cardioselective beta-blocker. It has been used as a trial agent (initial dose of 0.05 mg/lb intravenously; may increase to dose of 0.22 mg/lb [0.5 mg/kg] given intravenously over 1 minute) to transiently block AV nodal conduction in supraventricular arrhythmias[63] and at a similar dose over a period of 6 minutes to reduce LV outflow tract gradients in cats with obstructive hypertrophic cardiomyopathy.[131] It may also be given at the lower dose to temporarily slow a supraventricular tachycardia, which can assist in identifying its ECG features for an accurate diagnosis or may terminate the arrhythmia.

202.10 CLASS III ANTIARRHYTHMICS

Class III drugs specifically prolong the action potential duration and the refractory period, principally by inhibiting the repolarizing potassium channel (I_K). This class of drugs reduces the myocardium's ability to generate a new action potential before repolarizing, and thus these drugs slow or terminate tachycardia. These effects are most pronounced at higher heart rates. These drugs lengthen the action potential duration in a tachycardia,[132] but they should have few effects at normal heart rates. They are noted for increasing the threshold for AFib and VF. Each drug in this class also frequently displays properties of other antiarrhythmic classes. This drug group includes amiodarone, sotalol, bretylium, ibutilide, and dofetilide (Table 202-1). Only the first three agents are used in small animal medicine, and bretylium is expected soon to be unavailable because of the exhaustion of the world supply of bretylium.[90]

Amiodarone is one of the drugs of choice for many supraventricular and malignant ventricular tachyarrhythmias in humans. It exhibits properties of all four classes of antiarrhythmic agents and thus is considered a "broad-spectrum" antiarrhythmic. Unlike many antiarrhythmics, amiodarone has not been linked to increased mortality in large clinical trials in human cardiology, and it is second only to automated internal defibrillators in terms of beneficial outcomes in human patients with severe ventricular arrhythmia.[116] It may be useful in dogs with LV systolic dysfunction and to offer rate control, as well as for converting acute AFib to sinus rhythm. Amiodarone relaxes vascular smooth muscle, resulting in a decreased afterload that also may be beneficial. Amiodarone increases serum digoxin levels so that the dose of digoxin should be halved. Quinidine and procainamide levels are also elevated.[133] Side effects reported in humans include liver damage, photosensitization, thyroid derangements, ocular lesions, and irreversible pulmonary fibrosis. In dogs, neutropenia and hepatopathy have been reported with amiodarone treatment,[134] as have anorexia, GI disturbances, hepatopathy, and positive Coombs' testing.[135] These signs resolved with discontinuation of treatment. Anecdotal reports of acute hypersensitivity, hyper-or hypothyroidism, likewise have surfaced but are not conclusively attributable to the drug. In an experimental study, normal dogs given amiodarone 12 mg/lb orally, twice a day for 3.5 weeks, followed by 12 to 14 mg/lb orally, once a day as maintenance, had serum amiodarone concentrations considered to be therapeutic (1 to 2.5 μg/mL) within 4 days, but these levels only reached a steady state after 11 weeks of treatment.[37] However, several anecdotal reports have surfaced indicating that adverse effects occur at this dose and that a lower dose may be preferable, such as 4.5 mg/lb orally, twice a day for 1 week and 2.2 to 3.8 mg/lb orally, once a day subsequently for maintenance.[136] No clinical reports exist in veterinary medicine that address hemodynamic or electrophysiologic effects that could indicate proarrhythmia—a major concern in humans with the long QT syndrome. Despite the clear benefits of amiodarone in human cardiology, acceptance in veterinary medicine is compromised by these descriptions of adverse effects and the lack of reports indicating a benefit of amiodarone therapy over other antiarrhythmic agents. Amiodarone use has not been described in cats.

Sotalol provides both class III (higher dose) and class II (l-isomer, lower dose) effects. It is not a negative inotrope and thus does not decrease LV contractility. It induces systolic and diastolic hypotension and is considered to have ~30% beta-blocking potency compared with propranolol. It is considered to be protective against proarrhythmia, particularly life-threatening ventricular arrhythmias. Currently, only *dl*-sotalol, which combines the class III and class II effects, is used (*d*-sotalol caused increased mortality in human clinical trials and is not advocated).

In the first reported veterinary study using sotalol, three classes of Boxer dogs with familial ventricular arrhythmia were identified: asymptomatic, syncopal, and CHF. Slowing of the heart rate and first-degree AV block were the only side effects observed, although proarrhythmic effects have been suspected in other cardiomyopathic dogs with sotalol. The dose of sotalol administered to these dogs was 0.44 to 2.8 mg/lb/day twice a day orally, titrated to effect. The heart failure dogs received less medication, up to 104 mg/day average versus the syncopal group at 183 mg/day. Syncopal signs were diminished on sotalol therapy, and dogs with markedly diminished shortening fraction did not appear to exhibit untoward drug effects.[139] In a second study comparing four types of treatment for familial ventricular arrhythmia of Boxers, sotalol 0.68 mg/lb to 1.6 mg/lb orally twice a day significantly reduced the number of PVCs, arrhythmia grade, and maximum and minimum heart rates. However, there was no significant change in the occurrence of syncope for sotalol or for any of the other three treatments studied.[46] Sotalol has been effectively administered to cats with severe ventricular arrhythmias at 10 to 20 mg orally every 8 to 12 hours.[138] It is thought that class II effects are predominant at lower doses and class III effects are predominant only at higher doses (>160 mg in humans).

Sotalol's good oral absorption is reduced when given with food. Steady state is reached within 2 to 3 days. It is indicated for life-threatening ventricular arrhythmias, may be used with caution in CHF, and should not be abruptly discontinued. Sotalol is used cautiously with other drugs that decrease blood pressure, as well as other antiarrhythmics, specifically those that prolong the Q-T interval. The authors of this chapter have observed prolongation of the P-R interval with sotalol treatment in dogs, as has been reported anecdotally. No overt problems or progression occurred, and it was not necessary to discontinue the drug concurrent with this finding.

202.11 CLASS IV ANTIARRHYTHMICS

Class IV drugs, known as the *calcium channel blockers*, selectively inhibit slow inward calcium current channels (L-type) during the action potential. Calcium channel blockers interrupt arrhythmias resulting from abnormal automaticity and triggered mechanisms and inhibit re-entry. They slow the sinus rate and, more profoundly, AV conduction by blocking the inward calcium current carried by the L-(and probably T-) type channels.[140] By decreasing sarcoplasmic reticulum release of Ca^{++}, they also decrease the force of contraction. Decreasing the amount of calcium into the myocyte may help to decrease myocardial protein synthesis and thus attenuate the pathologic process of hypertrophy. They have indications for the control of most supraventricular tachycardias. Contraindications include SB, AV block, myocardial failure, SSS, and digoxin toxicity. Calcium channel blockers are classified as either dihydropyridines, which do not affect conduction and act principally on the vasculature (e.g., nifedipine, amlodipine), or nondihydropyridines, which have SA and AV nodal (but minimum vascular) effects (e.g., verapamil, diltiazem) (see Table 202-1).

Verapamil has potent negative inotropic effects, offers moderate rate control, and has minimal peripheral vascular effects. In dogs it may slow the sinus rate, increase AV conduction time, or decrease the ventricular response. In acute supraventricular tachycardias, it is given in 0.01 mg/lb intravenously in increments to a maximum of 0.07 mg/lb. Acute hypotension, AV block, collapse, or hypocalcemia may result from overly zealous up-titration. Judicious calcium chloride administration may correct iatrogenic disturbances.

Diltiazem's effective antiarrhythmic properties, combined with minimal inotropic depressive actions, have caused it to be used widely in cats with hypertrophic cardiomyopathy. Its frequency-dependent channel blockade in the AV node makes it effective in slowing supraventricular arrhythmias as has been shown in experimental dogs.[141] It is usually used in combination with digoxin to effectively slow the ventricular rate in AFib, except if LV thickening is present. Comparison studies in dogs between diltiazem and beta-blockade, with or without digoxin, are not available. Diltiazem-induced vasodilation may create a reduction in afterload that is of chronic benefit to the patient with systolic heart failure.[140] Regular (not sustained release) diltiazem has been administered to cats with hypertrophic cardiomyopathy in a nonplacebo-controlled study. Over 6 months there was a reduction in LV and septal wall thickness and a reduction in LA size.[142] The dose of diltiazem for dogs and cats is 0.2 to 0.7 mg/lb three times a day. However, because three-times-daily dosing of a lifelong drug can be extremely challenging for many cat owners, sustained release formulations of diltiazem (e.g., Dilacor®, Cardizem-CD®), which carry the advantage of once daily administration, have been used extensively. Evidence has shown that cats receiving 4.4 mg/lb oral sustained release diltiazem CD have plasma concentrations of the drug that are similar to cats receiving 0.44 mg/lb regular diltiazem orally, three times a day.[143] However, sustained release diltiazem is hampered by its apparently lower efficacy at preventing STach when compared with the beta-blocker atenolol, as well as a significant occurrence of reversible but severe adverse effects including anorexia, vomiting, lethargy, and evidence of hepatopathy in a substantial proportion of treated cats in one large prospective, placebo-controlled study.[144] For these reasons, sustained release diltiazem is used cautiously or not at all in cats with hypertrophic cardiomyopathy.

For intravenous treatment of supraventricular tachycardias, diltiazem has been recommended at 0.2 to 0.44 mg/lb[141] or 0.12 mg/lb over 2 minutes and repeating until conversion or a maximal dose of 2.2 mg/lb has been reached. These high doses are reserved for patients with tachycardia and a structurally normal heart. Patients with a structurally compromised heart (e.g., cardiomyopathy) should be given one-sixth to one-quarter of the starting dose (i.e., 0.02 to 0.03 mg/lb) initially, and then the dose should be titrated upwards to effect. If the tachycardia is a physiologic response to a systemic problem (e.g., hypovolemia, CHF), it is essential to treat the underlying problem first. Administration of intravenous drugs to suppress an appropriate physiologic tachycardic response can be fatal. Intravenous rate-suppressing drugs such as the calcium channel blockers are given when, despite treating systemic problems that could trigger high heart rates (e.g., CHF), an extreme tachycardia persists and is felt to compromise cardiac output. An example is a dog with dyspnea and weakness caused by dilated cardiomyopathy, cardiogenic pulmonary edema, and AFib with a ventricular rate of 310 bpm. If vigorous diuretic treatment, oxygen therapy, thoracentesis (if necessary), calming, and possibly mild sedation do not reduce the ventricular rate, the tachycardia itself may be compromising cardiac output and intravenous calcium channel–blocking (or beta-blocking) treatment meant to acutely and *slightly* lower the ventricular rate (e.g., to 260 bpm initally) should be considered. Continuous ECG and blood pressure monitoring are essential with all IV calcium channel–blocking agents.

Amlodipine and nifedipine are potent vasodilators that produce a marked decline in arterial blood pressure through calcium channel blockade. They have minimal effect on AV nodal tissue and are not used as antiarrhythmic agents. Instead they are used for treating systemic hypertension (see Chapter 130).

202.11.1 Digitalis Glycosides

Digitalis glycosides (digoxin) have multiple effects on cardiac muscle and conductive tissues. Their predominant antiarrhythmic properties result from neuroendocrine and baroreceptor effects and parasympathomimetic action on the SA and AV nodes and atrial muscle.[145] AV nodal conduction is slowed, AV nodal refractoriness is increased, and vagal tone to ventricular muscle is increased. Digitalis glycosides 1074
are the only antiarrhythmic agents that produce a positive inotropic effect, although this effect may be limited 1075
in degree and real benefit. Their primary indications for use are treatment of supraventricular tachycardias, which they accomplish by slowing the ventricular rate response. Often a second agent in combination, such as a beta-blocker or calcium channel blocker, is needed to attain adequate rate control. Combination therapy of this sort is particularly beneficial because both products are then administered at lower doses and thus are less likely to induce toxic reactions. A recent, intriguing finding is an endogenous cardiac glycoside deficiency that appears to exist in some dogs with naturally occurring CHF and AFib.[146]

They are contraindicated in pre-excitation, because they may speed conduction through the accessory pathway and thus promote VF. Caution should be exercised with the use of digoxin in the face of existing ventricular arrhythmias. Dosing and pharmacokinetics are discussed in Chapter 199.

Digitalis intoxication is a serious, potentially life-threatening event. GI signs may be the first symptoms observed. Myocardial poisoning may take one of several forms, all of which culminate in cardiac arrhythmias. Increased sympathetic tone may result in increased automaticity. Slowed conduction and altered refractoriness may precipitate re-entry. Increased intracellular calcium levels predispose the cell to delayed after depolarizations. Any of these changes can be the source of arrhythmogenesis. Electrocardiographically, VT, supraventricular tachycardia, junctional escape complexes, SA arrest, Wenckebach or other forms of AV block, and tachycardias with aberrant conduction may be seen. The cornerstone of treatment is to stop the drug immediately and completely. Supportive fluid and electrolyte therapy should be provided as necessary.

Hypokalemia exacerbates digitalis intoxication. Specific treatment for VTs may be needed. Lidocaine and beta-blockers may be considered, as well as many other drugs, depending on the predominant arrhythmia. Atropine may help patients that are symptomatic from bradyarrhythmias. Acute ingestion may be treated with cholestyramine or activated charcoal to reduce absorption. Soluble, intravenously administered digitalis neutralizing antibodies (Fab fragments) bind serum digitalis molecules and are the treatment of choice for life-threatening digitalis (or oleander) poisoning,[147] although high cost limits the use of this treatment. After resolution of clinical signs of intoxication and a minimum of 48 hours without receiving a dose, the digoxin may be restarted at half the dose.

One must be aware of numerous potential drug interactions when using digitalis glycosides. Kaolin-pectin, metoclopramide, neomycin, antacids, and bran decrease oral absorption, and quinidine and verapamil may increase serum digoxin levels substantially. Decreased excretion may result with captopril, verapamil, and spironolactone,[3] although newer protocols incorporating spironolactone therapy in the standardized treatment of CHF have not demonstrated this interaction to be a problem.

202.11.2 Adenosine, Edrophonium, Phenylephrine

Adenosine is an endogenous nucleoside occurring in all cells of the body. Therapeutically, when given intravenously, it slows AV nodal conduction and restores sinus rhythm in patients with paroxysmal supraventricular tachycardia. Adenosine is indicated as the drug of choice in human patients with acute paroxysmal supraventricular tachycardia, including those caused by the WPW syndrome (see previous discussion). Suggested total doses for a human adult are 1.5 to 3.0 mg initially, repeated to a maximum of 6 to 12 mg.[120] In dogs, doses corresponding to two or more times this amount on a body weight basis have been ineffective in abolishing supraventricular tachycardias,[63] and adenosine is considered much less effective in veterinary patients. In small animal medicine, adenosine's lack of a convincing advantage over intravenous diltiazem or esmolol and its high cost make it a second-or third-line treatment agent.

Edrophonium is an anticholinesterase agent with both nicotinic and muscarinic side effects. This drug classically has been used for the diagnosis of myasthenia gravis (MG) and may be useful to treat SVT acutely. The dose is 0.05 mg/lb intravenously. Side effects include vomiting and muscular twitching.[3,120]

Phenylephrine, an alpha-adrenergic agonist, slows AV nodal conduction and induces vasoconstriction and hypertension. A baroreceptor-mediated reflex is thought to be the mode of slowing SVT. It is given at 0.002 to 0.004 mg/lb intravenously.[120]

202.11.3 Radiofrequency Ablation

In human medicine, cardiac catheter-based electrophysiologic testing followed by radiofrequency ablation of re-entrant circuits has become the treatment of choice for intra-atrial re-entry (e.g., atrial flutter) and AV reciprocating tachycardias such as WPW. This type of treatment can permanently interrupt the pathways and terminate the arrhythmia. Radiofrequency ablation thus offers the possibility of a permanent cure for certain arrhythmias including WPW and atrial flutter.

The high rate of success, low morbidity and mortality, and cost-effectiveness of this technique have resulted in an entirely new subspecialty of human medicine dedicated to the study and treatment of specific electrophysiologic dysfunctions of the heart. In veterinary medicine, radiofrequency ablation has received limited attention.[100,111,148] In addition to eliminating the subsequent need for antiarrhythmic medications,

radiofrequency ablation of arrhythmia pathways prevents, and can even reverse and eliminate, structural changes such as ventricular dilation caused by a persistent arrhythmia *(tachycardiomyopathy)*.[100] Although radiofrequency ablation therapy has clear indications and applications in small animal medicine, the cost, need for specialized equipment, required skills, and limited demand restrict its use to a small number of highly specialized cardiac institutions at this time.

202.11.4 Pacemaker Therapy

Implantable cardiac pacemakers were first placed in human beings in 1958.[149] During the intervening period there has been a revolution in the understanding and treatment of bradyarrhythmias, as well as pacemaker and electrode technology.[149] Whereas over one-half million pacemakers are now placed annually by physicians, only several thousand have been implanted clinically in dogs and cats during the past four decades.[95] Internal cardioverter-defibrillator-pacemaker implants increasingly are the treatment of choice for ventricular arrhythmias in humans.[116] Their clinical use in dogs previously has met with problems, and such treatment remains under development.[150]

In small animal medicine, pacemakers are used predominantly for bradyarrhythmia therapy, including sinus node dysfunction (SSS), AV block, and atrial standstill.[103,104,151,152] In human beings, implantable electrical devices are used for pacing and cardioversion, defibrillation, and specific forms of heart failure.[149]

Costs, availability of pacemaker generators and pacing leads, the age and debilitated state of some candidate dogs or cats, and concerns regarding complications, aftercare, and general philosophy continue to restrict the availability of this technique to a limited number of patients. Whereas the human literature is replete with articles and current recommendations, such as dual-chamber versus single-chamber ventricular pacing, the balance of this section identifies current veterinary techniques and experiences with pacemaker implantation in North America. Although veterinary pacemaker techniques are not up to those used in humans, current treatment options for animals are discussed.

1075

1076

Reported methodology, problems, side effects, and expectations are addressed in three large cases series totaling some 300 dogs[3,103,104] and reports of fewer than 10 cats.[3,94,153] Pacemakers were originally implanted transdiaphragmatically using epicardial leads,[95] but now most are implanted in the dog transvenously through the jugular vein and attached internally to the RV wall. This is accomplished either with a “tined” lead or a lead that is screwed into the ventricular endocardium and myocardium.[151,152] In cats such adverse reactions to transvenous leads as chylothorax have been observed anecdotally and in at least one report.[94] The trend today is to implant epicardial leads in cats requiring pacemaker treatment. The permanent pacemaker generator is usually buried in a subcutaneous pocket of the neck, lateral thorax under the cutaneous trunci muscle,[104] or cranial abdomen and is connected to the pacing lead through a subcutaneous tunnel. Anesthesia has used a balanced formula avoiding barbiturates,[151] and temporary pacing during the initial part of pacemaker implantation is recommended. Traditionally, temporary pacing was achieved transvenously,[151] but a recent evaluation of transthoracic pacing, a function found in many modern defibrillators in veterinary intensive care units, has demonstrated that this completely noninvasive form of temporary cardiac pacing is effective and safe in canine patients.[154]

Pacemakers are usually identified via a three-letter code.[3,149,152] The first letters identify the chamber or chambers paced, sensed, and the response to sensing. Whereas the DDD mode is the preferred pacemaker for

most humans, the VVI mode is used most often in dogs and cats. It is essential to ensure that the pacemaker generator's polarity and the pacing lead polarity are compatible. Unipolar generators may be used with any pacing lead that fits, but bipolar generators must only be used with bipolar pacing leads.[151] The pacemaker's program, the fit between generator and pacing lead, and the length of the lead must all be confirmed prior to beginning implantation.

Most veterinary cardiologists and internists secure their pacemakers from private sources, morgues, or from the ACVIM Cardiology Specialty group. With limited equipment availability, especially pacing lead wires, clinicians must be gracious about the gifts they receive. New pacemakers and wires individually would otherwise cost tens of thousands of dollars for each unit.

Perhaps a perfect pacemaker candidate does not exist. Patients are often older, and the pacemaker does not provide a cardiac panacea. Nevertheless, some stratification of prognosis is possible. Some dogs requiring a pacemaker are in CHF when the need for a pacemaker is identified. These dogs generally experience a marked improvement in, or resolution of, heart failure with pacing, but overall still have a prognosis that is less favorable than dogs without CHF. In one study the 1-year mortality rate after pacemaker implantation was 60% if there was pre-existing CHF and 25% if there was not.[103] Evidence of renal failure (azotemia with isosthenuria) or opportunistic infection (e.g. pneumonia) has resolved with pacing, and such findings at the time of initial diagnosis should not be considered absolute contraindications to pacemaker implantation.

New developments in cardiac pacing include the single-lead AV mode of pacing and alternate sites of generator and lead placement. Using a specific type of single RV pacing lead, it is possible to pace both the atria (through a nexus in the lead that transmits impulses at the level of the RA) and the ventricles (at the distal tip of the lead). This approach offers several advantages, including the use of only one pacing lead to activate both the atria and the ventricles, and preservation of AV synchrony, resulting in superior hemodynamics.[155] In terms of placement of the pacing lead and generator, two reports address the high complication rate (10% overall[103] and up to 35% in large breed dogs[156]) of lead dislodgement. An alternative approach uses thoracotomy and passage of the pacing lead through the costocervical vein instead of the external jugular vein. This approach was successful, with none of six large dogs undergoing pacemaker implantation in this manner sustaining dislodgement of the lead.[156] A drawback is the need for concurrent thoracotomy and fluoroscopic guidance. A second approach consists of routine transvenous jugular implantation but with placement of the generator under the cutaneous trunci muscle instead of between muscles of the lateral neck. This modification was associated with a complication rate of only 6.7% in terms of lead dislodgement.[104]

Overall, pacemaker implantation is an effective form of cardiac therapy in dogs. Prolonged survival routinely is documented, reported complications continue to be addressed via refinements of technique, and in the largest retrospective study of dogs with pacemakers, 80% of owners described a high degree of satisfaction with the procedure.[103]
